ELLANGOWAN COLLIERY.

ONE OF THE MOST EXTENSIVE COAL MINES IN THE WORLD.

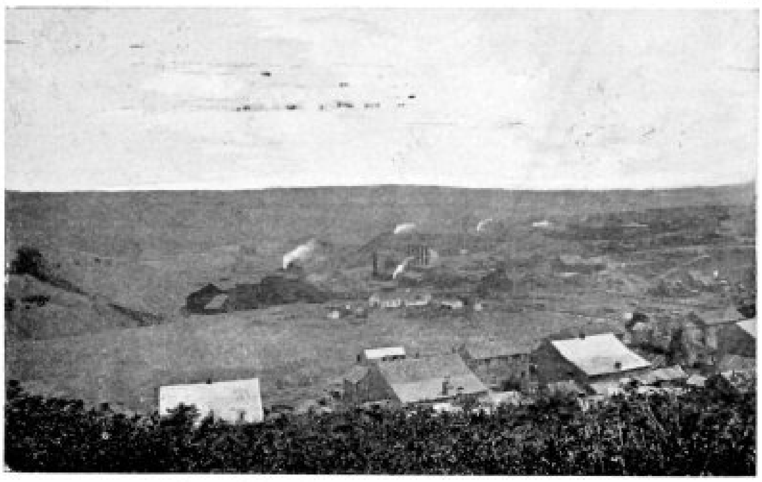
A Description of The Seams Worked, The Methods of Working and the Surface Improvements.

(By Geo. B. Hadesty, Mining Engineer.)

One of the oldest, largest and most productive collieries owned and operated by the Philadelphia and Reading Coal and Iron Company is Ellangowan. It is situated in the Western Middle anthracite coal field of Pennsylvania, in Schuylkill county, on a line between the towns of Mahanoy City and Shenandoah and about midway between them. The workings are principally on the south dip, in what is classified as the Ellangowan Basin, (which is shown in Figure 1,) and they are so extensive that they approach Shenandoah City and Knickerbocker collieries, on the north, North Mahanoy and Suffolk collieries on the east, Suffolk and Maple Hill collieries on the south, and West Shenandoah, Turkey Run, and Cambridge collieries on the west.

Ellangowan colliery was first opened about 1860, under the name of Maple Dale, by Mr. James Lannigan, and to this day is called "Lannigans" by many of the working people.

Its workings at that time, and on up to about 1870 consisted of drifts, all above water level. About 1870 the lands on which the colliery is situated became by purchase the property of the Philadelphia and Reading Coal and Iron Company, and about 1873 they began operating the colliery.



GENERAL VIEW OF ELLANGOWAN VALLEY, LOOKING SOUTH.

During 1871 and 1872 a shaft with two (2) hoisting compartments, each 7 ft. by 12 ft., and one water compartment 5½ ft. by 12 ft., was sunk a depth of 335 ft. cutting the Holmes vein, 15 ft. thick, the Four Foot vein, 5 feet thick, the top split of Mammoth vein, 18 ft. thick and the middle split of Mammoth vein 12 ft. thick. Gangways were immediately opened in the middle split of the Mammoth vein, and driven east and west and tunnels started from them north and south, to the underlying and overlying veins. Since that time if any colliery in the Schuylkill region was in operation, Ellangowan was also, except in case of serious accidents, which have been very few during the thirty-five years that the colliery has been in operation. The most serious accident, financially, was the total destruction of the breaker by fire, on January 5th, 1878, fortunately however no person was injured.

The sinking of the shaft was commenced in what was termed at that time a novel way, but just such ideas have undoubtedly lead to the present improved rock drilling apparatus. A strong horizontal frame was constructed of 18 inch square timber over the head of the shaft, on which heavy iron girders, with slots, were bolted. The drilling machines were fastened to these girders by clamps, and holes for blasting drilled to any desired depth. When one hole had been drilled the necessary depth, the machine was moved along the girders to the point desired for the next hole, and in a short space of time was again ready for operating. There were three of these iron girders and twice as many drilling machines, so that the work could be executed as fast as desired or possible. At the point where the shaft was sunk, the wash and other soft measures contiguous thereto, continued to a depth of 30 ft. below the surface line. To prevent too heavy a strain on the shaft timbers proper, and make as secure a job as possible, 12 inch round timbers were placed skin to skin outside of the space required for the regular shaft timbers, to a depth of 35 ft. Inside of these round timbers the shaft timbers proper, 12 inches square, were placed skin to skin, to a depth of 30 feet; below this point they were set at 3 feet from center to center and continued at that distance to the bottom of the shaft, except in places where more soft measures were met, when the timber was again set skin to skin.

The plan of shaft timbers near surface is shown in Figure 2. On the shaft level, the tunnels driven north cut the bottom split of the Mammoth vein, the Skidmore, Seven Foot and Buck Mountain veins, and the tunnels driven south cut the top split of the Mammoth vein, the Four Foot, Holmes, Primrose and Orchard veins.

A plane 100 yds. long was driven from the Shaft Level east top split gangway, and on the level thus opened, tunnels were driven north to the underlying veins.

Owing to the extreme lift from the shaft level to the water level, in the veins above the top split, and the fact that it would require several planes or counter shutes to work it, a single track slope, 12 foot spread, 8 foot collar and 8 feet off of rail, was sunk from the surface, in the Holmes vein, to the shaft level, a distance of three hundred and forty-one (341) yards. From this slope three lifts were turned, east and west, and where the lifts were of such a length that the coal could not be worked advantageously, counter gangways were driven about midway between the lifts. On the second lift of the slope, tunnels were driven south to the Primrose and Orchard veins.

From these tunnels, on different levels, two gangways

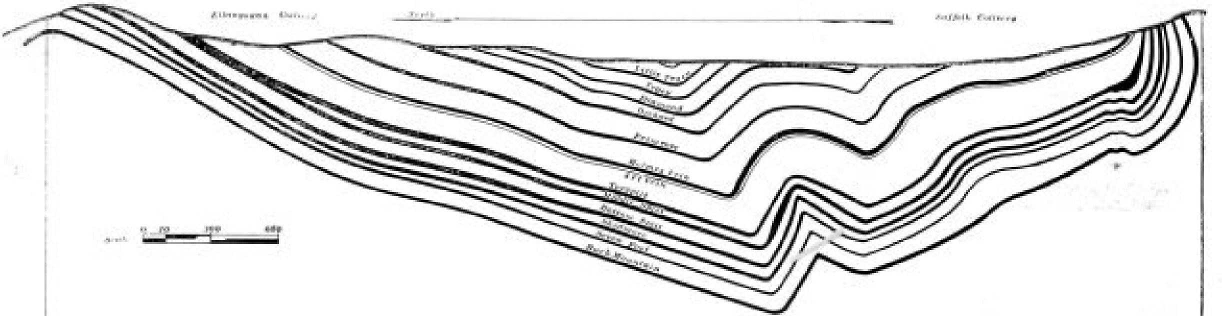


FIG. 1.—CROSS SECTION THROUGH ELLANGOWAN BASIN.

were opened in each vein, one east and the other west so that the colliery was a mammoth one from the time the company took charge and began shipping.

Some idea of the magnitude of the operations can be formed when we consider:

1st. The veins worked cover a surface area, separately of 32,000,000 square feet, or nearly 600 acres.

2d. The extreme run east and west is nearly 3 miles.

3rd. The aggregate thickness of the different veins worked is one hundred and twenty-five (125) feet. This

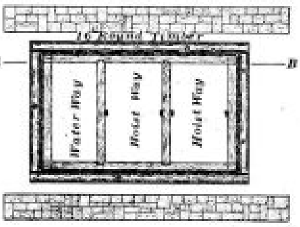

FIG. 2.

is not counting the same vein on different levels, but all the veins on one level.

4th. There are over thirty (30) miles of gangways, through which coal is passing every day that the colliery is in operation.

5th. There are 1390 yards of tunnels through rock and slate, connecting the different veins on the various levels.

6th. There are over 900 men and boys, employed in and about the colliery.

7th. Coal is being mined in 41 different gangways.

8th. Eight hundred and eighty wagons of coal (of 2½ tons each) have been dumped into the breaker in one day of ten hours.

There are few collieries where such a diversity in the methods of mining is necessary. While our section shows a comparatively even and regular pitch (which is the case on the line of shaft where section is taken), yet in the large territory covered by the workings there are possibly as many changes in the character and pitch of the veins as there are veins.

In order to fully demonstrate the different methods, we have thought it well to take them separately, and by plans, sections and brief remarks, make them so plain that their advantages for the particular pitches and veins in which they are used can be readily observed.

Fig. 3 shows one method which was used where the dip of the vein was about 20 degrees. An ordinary shute 3 yards wide was driven from the gangway to the first or "stump" heading, where it was widened out to the width desired for the breast. In veins where there is little refuse and no explosive gases they have no gob, and the sheet iron, which is necessary on this pitch, was continued up the center of the breast, and the coal from the face and sides easily diverted to it. The plan, however, shows a gob, as it can be more readily understood how the breast would be worked without the gob.

The first heading is usually 8 or 10 yards from the high side of the gangway, is driven with the gangway and used as a return airway to the first working breast

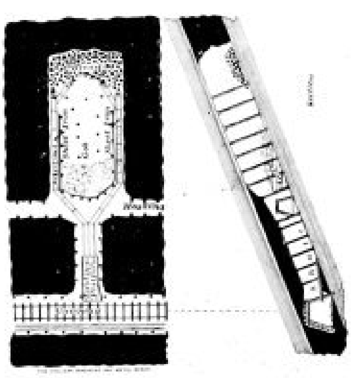

FIG. 3.

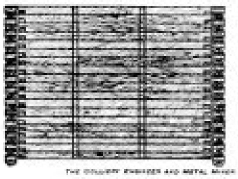
(counting from the face of gangway), where the air is turned and passes up the breast to the heading nearest the face. Through this it passes to the next breast outside, and so on until it reaches the main return airway. These headings, which are about 6 ft. wide by 5 ft. high, are driven every 15 or twenty yards above the first heading, and when a new one is completed, the next below is bratticed so as to insure a free circulation of air at the face of breast.

Fig. 4 shows another method, which, owing to the light pitch on the levels now working, is used considerably. This method is considered necessary where the pitch is too heavy to run the mine wagons directly into the breast, and too light to carry the coal on sheet iron shutes. It is termed amongst anthracite miners a buggy breast.

The shute is opened in about the same manner as described in the preceding method, but when they are ready to open or start working the breast, it is necessary to construct a running shute from the gangway to a point available for a dump. From here a narrow-gauge track is laid, usually in the center of the breast, and extended as the driving of the breast progresses. The space on either side of the buggy track is used as a depository for any refuse which can be readily removed from the coal. There are quite a number of breasts at this colliery in which the pitch of the vein is regular for 30 or 40 yards, when it suddenly increases so much that another shute has to be constructed and a second buggy used on the light pitch which comes in above; in fact, there are some breasts at this colliery in which three buggies are necessary before the coal reaches the mine wagon on the gangway.

Section through A B



The ventilation of these breasts is accomplished in the same manner as that described in the preceding method.

Figure 5 shows a "wagon breast," or a breast in which the regular mine wagon is run directly into the point of work: this method is used very little at present but was necessary a few years ago in the extensive flat in the east Holmes vein working. The breast is turned from the gangway with an easy curve about 16 ft. radius, and driven about 4 yards wide to the first heading, where it is widened to the full breast width 8 or 10 yards, according to circumstances. The plan shows the wagon track thrown to the left after entering the breast proper, the reason for this is obvious, as what little dip the vein has is naturally in that direction, and being the lowest point in the breast is the best location for the track. Ventilation is procured by using the gangway as the inlet and the headings and breasts as the outlet. Doors are placed in the breast at the high side of the gangway, abandoned headings are bratticed with sail cloth or boards and in this manner an uninterrupted current of air is secured.

In Fig. 7 we have an entirely different method from any of those already described. This method was used in the shaft level Bottom Split and Top Split gangways, where the average dip of the vein was forty-five (45) degrees. It consists of a breast with two shutes, the gob in the center and headings every 15 or 20 yards. Where the amount of refuse in the vein is small and does not accumulate fast enough to keep the gob well up to the face of the breast, strong batteries are constructed near the face, 5 or 6 ft. high, at right angles to the pitch of the vein, and the refuse is thrown over the top of them to the gob below. These batteries afterwards serve as a stopping for an additional gob as the breast advances. These breasts are ventilated by the air passing up the inside shute to the face of breast, and down the outside shute to the heading nearest the face, thence through this heading to the next breast outside and so on to the main airway. It has proven a very satisfactory method of ventilation.

In the western part of the basin in the counter or upper levels, the Middle Split of the Mammoth vein and the Bottom Split of the Mammoth vein were so close to one another, that it was inexpedient to drive a gangway in both veins, and yet the slate separating the veins was so thick that it was considered impracticable to mine both splits together and prevent the slate becoming mixed with the coal, at a reasonable cost. After a consultation amongst the officials of the mining department it was decided to experiment with the method described in Fig. 6, which proved very successful and was continued.

The gangway was driven in the Bottom Split, breasts with two shutes, as described in Fig. 7, were driven

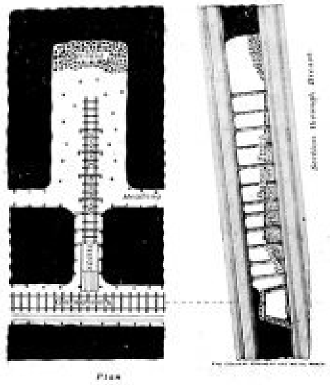


FIG. 4.

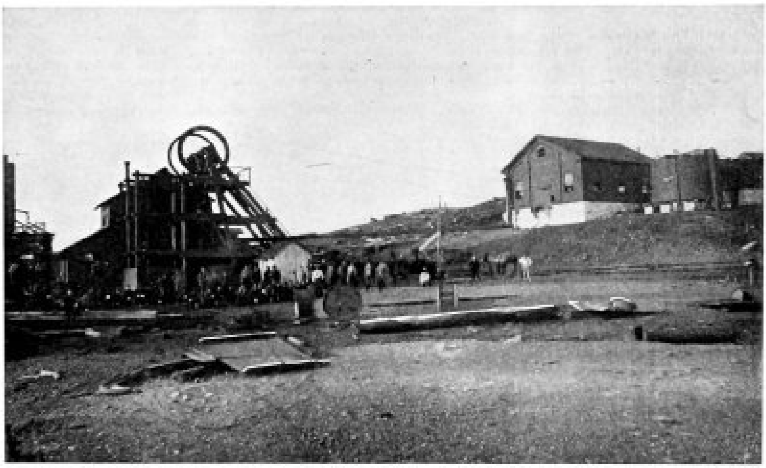
from it, and the Bottom Split coal mined in that way. On the opposite side of the gangway, midway between these two shutes, "back" shutes were driven, on a pitch of about 30 degrees, through coal and slate, to the bottom slate of the Middle Split vein; from the head of these back shutes, narrow shutes were driven on the bottom slate of the Middle Split, until they had passed the gangway and shute in the Bottom Split vein below, when full width breasts were opened, and the breast continued as described in Fig. 3. Ventilation of these double breasts was readily obtained by splitting the current of air at the face of the gangway, and allowing part to pass out through the Bottom Split working as previously described, the other part passing through the last back shute to the Middle Split breasts and on out to the return airway.

Few collieries have presented such varied experiences in the mining of anthracite coal, and it has well been said, "that an honest and faithful man who had spent the greater part of his time in the different official capacities at Ellangowan colliery was a desirable man for any coal company to have."



ELLANGOWAN COLLIERY SHAFT-HEAD FRAME.—READY FOR START, 6:30 A. M.

The following table, shows the production in tons at this colliery from 1869 to 1894.

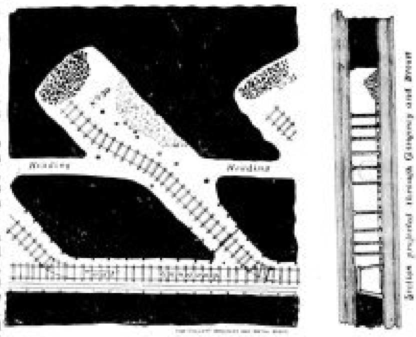


FIG. 5.

1869	Produced	29,000	Tons
1870	"	34,000	"

1893	"	319,400	"
1894	"	284,900	"

Total production 1869 to 1895 ...... 5,845,990 Tons

* January 5th, 1878, the breaker was totally destroyed by fire, and rebuilding was not completed until near the close of 1879.

The reduced shipments for the last five years are attributable to the forced suspension made necessary by the general restriction in output, in the anthracite coal trade.

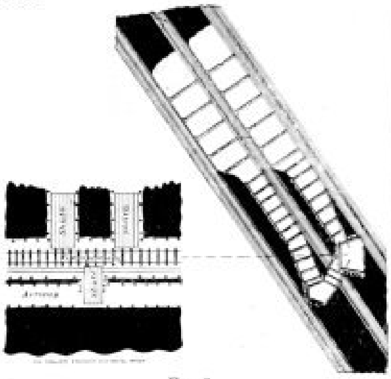

FIG. 6.

The P. & R. C. & I. Co. has stood faithfully by its agreements, not to produce more than a certain percentage of the entire output, and this colliery like all their others was reduced to one-half and three-fourths of the usual working time.

The demand for this coal is such that the colliery could readily have worked full time had they been allowed to do so.

Such an extensive operation with its numerous connections to workings on higher levels, especially in the

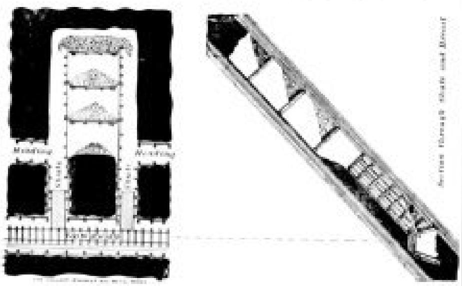

FIG. 7.

western portion, where it is connected with the famous Shenandoah City colliery strippings, naturally collects an enormous amount of water, but the officials have wisely provided for all such contingencies and have ample pumping machinery in position to handle a vast amount of water.

The apparatus consists of two (2) large bull pumps, one with steam cylinder 50 inches in diameter, water cylinder 20 inches diameter and a stroke of 120 inches, having a capacity of 1,173,600 gallons per twenty four hours; and another with steam cylinder 55 inches in diameter, water cylinder 24 inches in diameter and a stroke of 120 inches, having a capacity of 1,692,000 gallons per twenty four hours.

These bull pumps are located over and in the water compartment of the shaft. A view of the large steam cylinder and its connections is shown in Fig. 11.

There are also in place in the pump room, driven in rock at the foot of the shaft, three standard P. & R.

FIG. 8.—VIEW OF SURFACE ARRANGEMENTS FOR HOISTING ON INSIDE SLOPE. ROPES PASS OVER THE SHEAVES AND DOWN BORE-HOLES.

C. & I. Co. 9″ × 38″ pumps, with steam cylinders 18 inches diameter, water cylinders 9 inches diameter and 38 inch stroke, each pump having a capacity of 1,152,000 gallons per twenty four hours.

This gives us a combined pumping capacity of 6,321,600

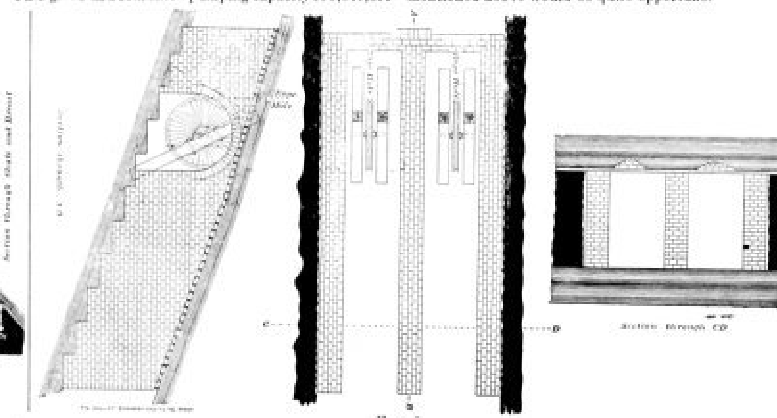

FIG. 9

gallons per twenty four hours with the pumps running at a mean speed; if forced they are easily capable of pumping 20 per cent. more per day.

In addition they have provided two iron water tanks with a capacity of 600 gallons, which in emergencies are used in the hoisting compartments of the shaft; considering that the hoisting engines are capable of hoisting one of these tanks every fifteen seconds, and allowing twenty-five seconds for filling and emptying, we have 1,296,000 gallons per twenty four hours. They have also furnished a large tank, with a capacity of 1,600 gallons for use on the slope, which can deliver on the surface 576,000 gallons of water in twenty four hours; summarising, the apparatus in position and on hand, ready for use, is capable of discharging on the surface 8,193,600 gallons of water every twenty-four hours. It may seem impossible that such an amount of water could collect in one colliery, but such is the case, and at times with all these appliances it was barely possible to handle the water as fast as it accumulated.

Right here a few remarks on the 9″ × 38″ pumps mentioned above would be quite opportune.

These pumps are used at all of the P. & R., C. & I. Co. collieries, were designed and constructed at their extensive and well equipped shops at Pottsville, Pa., and for simplicity, durability and effectiveness have few equals in their class.

They are so simple in construction that any person with a slight idea of mechanics can put them together, run them and keep them in repair, so durable that they will last as long if not longer than the most expensive pumps, and so effective that when in good condition, as regards packing, etc., they have been submerged for periods of ten days to two weeks and continued running as smooth and regular and delivered as much water as ever. When the water had been lowered enough to reach the pumps, the pistons were re-packed, a few slight repairs made and the pumps started up again.

Having now traversed the inside or mining portion of the colliery, as briefly as consistency will allow, we will now follow the coal from the shaft and slope toward and to the breaker. Once landed on the surface, the loaded mine wagons are run by gravity to the foot of the car hoist or plane, shown in Fig. 10, which has two tracks for hoisting the loaded wagons or cars, and one track for lowering the empty cars. The loaded cars are hoisted to the top of this plane, close to which the breaker tip or dump is located, dumped and then returned by gravity to the empty track of the plane, lowered and distributed to the shaft and slope.

This plane is supplied with three endless car hoist chains, one for each track, with hooks or catches at convenient distances, which take hold on the axle of the car, so that cars can be hoisted or lowered at most any time desired, as the machinery running the chains is connected to the breaker engine and is in constant motion while the breaker is in operation.

The coal having been dumped into the breaker, the preparation for market now begins, and this colliery, like nearly all the Reading operations, has the reputation of shipping some of the best prepared coal.

To follow the coal in its different courses through the breaker, we fear would become too tedious to most readers, so we will described the breaker machinery, etc., as briefly as possible.

The breaker is 130 feet long, 90 feet wide and 55 feet high from the rail at loading shutes, shown in Fig. 12; and is fitted out with all modern machinery for the prep-

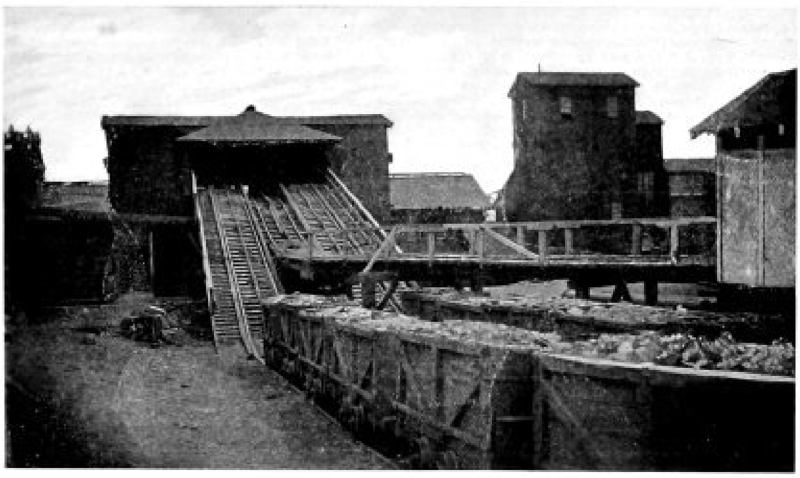

FIG. 10.—CAR HOIST ON PLANE TO BREAKER TIP.

aration of anthracite coal, some of which is: 4 sets rollers, from 22 to 36 inches in diameter and from 30 to 52 inches long, 8 screens 5 feet diameter 12 feet long, 2 screens 5 feet diameter 9 feet long, 4 screens 4 feet diameter 6 feet long, 12 wooden jigs with scrapers, etc., complete, 9 sets of coal and slate elevators, and all other necessary appliances, all of which are run by an engine with an 18 inch cylinder and 60 inch stroke.

In addition to the breaker there is a separate jig house, 53 feet long, 41 feet wide and 40 feet high, which contains 8 wooden jigs, 9 screens from 4 to 5 feet in diameter and from 6 to 13 feet long, and 2 sets of elevators 50 feet long. This machinery is run by an engine with cylinder 16 inches diameter and 34 inch stroke.

The breaker, jig house and all other colliery buildings are heated by steam, which requires nearly 3,000 ft. of gas pipe from ¾ inch to 4 inches in diameter, and 3 large heaters 30 inches diameter by 30 feet long. These heaters are used in the breaker where an extensive heating surface is necessary.

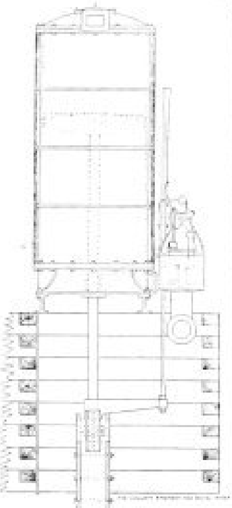

Fig. 11.

The steam generating plant consists of 8 tubular boilers 72 inches diameter by 18 feet long, capable of producing 180 horse power each, also 18 cylinder boilers 34 inches diameter by 30 feet long, which can furnish 30 horse power each, or a combined capacity of 1,980 horse power. The latter, or cylinder boilers, are gradually being replaced by the tubular boilers, which are superior in many ways, although the old cylinder boiler had its advantages, the principal one being that during the droughts, so general in the coal regions where nearly all neighboring springs are destroyed by breaches and crop falls, the acidulated water discharged from the mines could be purified cheaply to such a degree that it could be used for steam purposes in these boilers, but then there was constant danger of neglect in the proper purification of the water, and the company has undoubtedly pursued a wise and economical course in gradually replacing them with the more modern tubular boilers, which are capable of producing a greater per cent. of power per ton of fuel consumed. This change, of course, necessitates an adequate supply of pure spring water, which is furnished by the Anthracite Water Company from their reservoir on Waste House Run, a few miles north of Ellangowan. To meet the increased demand, this water company has laid during the summer of 1894, nearly 7,000 feet of 10-inch hautboy pipe, connecting their reservoir with those of the Mahanoy City water company, which owns several reservoirs, and in addition have a pumping station in the Catawissa Valley on Messer's Run and Nigger Run, which can furnish a supply almost inexhaustible.

To close this article without making mention of the improvements now in progress and the future prospects of Ellangowan, would be unjust alike to the reader and the company.

During the past year or two the slope was extended below the shaft level a distance of 110 yards, to develop a new lift, which, by the way, is Ellangowan's limit in the basin, this slope will be used as a tender slope for men, feed, timber, etc. A double track slope for hoisting coal has also been sunk to this level, which is now completed and in operation. On this new, or 5th lift, gangways are driving in the Holmes vein (14 feet thick) east and west, and a tunnel has been started from the west Holmes gangway toward the Buck Mountain vein, which it is estimated will be cut at 400 yards. The tunnel has already cut the Four Foot vein, 5 feet thick, the Top Split of the Mammoth vein, 12 feet thick, and the Middle Split of the Mammoth vein, 12 feet thick, and will cut veins aggregating 43 feet in thickness. Considering the run east and west and that the veins will yield 50 per cent., which is a low estimate for this colliery, we have 5,050,000 tons yet to be produced from this level alone. Estimating that the coal remaining unmined in the upper lifts will yield fully as much, gives us in round numbers 10,000,000 tons to be produced from the whole colliery; then taking an average production for the past five years, we find that Ellangowan colliery will have coal enough to continue operation 25 years more, or a total of 60 years since it was first opened.

In our estimate for the new lift, we have not considered any veins above the Holmes as they are reserved for Maple Hill colliery on the south.

A word in regard to this new slope: When it was decided to open the new lift it was first proposed to extend the present slope, with a double track, then widen the entire length above the shaft level and have a double track slope from the surface to the new lift and take the coal to the surface through this slope.

This plan, however, has so many disadvantages that it was finally abandoned and the single track slope extended, and provision made for a double track underground slope from the shaft level to the new lift. After selecting the most available location, a narrow shute was driven on line of the proposed slope from the new lift to the shaft level. After this the slope was started from the shaft level, and this chute was used to convey the coal excavated for the necessary width of the slope, to the gangway below, so that no engines were required in the sinking of the slope. The timber was lowered from the shaft level as needed by an ordinary hand crane and hemp rope.

For various reasons it was deemed advisable to place the engines for this slope on the surface, and bore holes 8 inches in diameter were bored from the surface, with a regular oil well drill rig, and so accurate the surveys, that the deviation from the point desired in the mines, was scarcely noticeable.

In one hole, 4 inch oil well casing was placed and enclosed with sand and cement, this pipe was for one rope. In the other hole, 4 inch oil well casing for the other rope, 2 inch gas pipe for speaking tube, and 1½ inch gas pipe for signal wires, were placed and the whole enclosed with sand and cement. A view of the engine house and sheaves for this slope are shown in Fig. 8.

When the holes were completed, and the landing of the slope on the shaft level nearly completed, it was found that owing to the pillars in the immediate vicinity of the slope being very narrow there were indications of a "squeeze" or settling which if allowed to continue might eventually ruin the bore holes and damage the entire slope. As the heavy timber already in place gave evidence of the heavy strain it was decided to build brick and cement walls, and to use steel T rail for laggings to support the roof, this was done and so satisfactory were the results that we show in Fig. 9 how the walls were constructed.

In closing, the writer wishes to acknowledge the courtesies extended by Mr. R. C. Luther, Gen'l. Sup't., Mr. Geo. S. Clemens, Division Engineer and Mr. John H. Pollard, Assistant Engineer in charge.

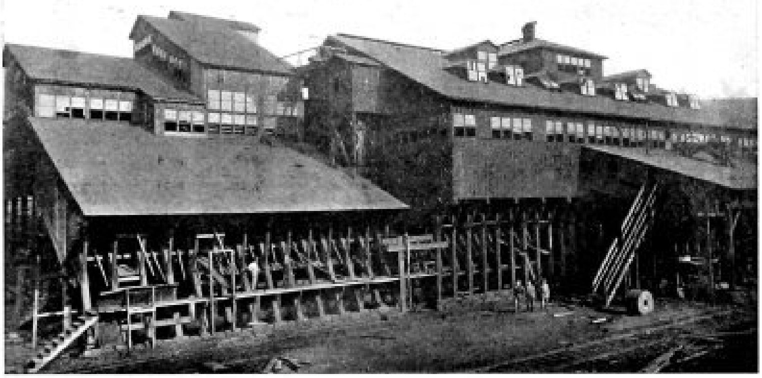

Fig. 12.—Loading Shutes at Breaker.

The Otto-Hoffman Retort Coke Ovens.

We have received from the Otto Coke and Chemical Co. of Pittsburgh, Pa., an exceedingly handsome illustrated pamphlet descriptive of the Otto-Hoffman Retort Coke Oven System, which is as much a treatise on the coking of coals of various grades and the saving of by-products as it is an advertisement of the Otto-Hoffman oven, which has met with such marked success on the continent of Europe. Every coke maker or prospective coke maker should read this work, which is sent free on application to the company's office, Lewis Block, Pittsburgh, Pa.

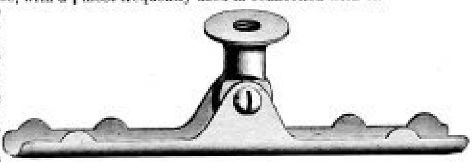
Surveying Instruments.

We have received from Messrs. F. C. Knight & Co., of 400 and 402 Locust st., Philadelphia, a copy of their latest catalogue of engineering and surveying instruments and materials. Messrs. Knight & Co. are successors to the late Edmund Draper, whose instruments won world wide renown for simplicity and efficiency. The instruments now made by this firm combine all the best features of the Draper instruments with many marked improvements. The catalogue which is a handsome publication is sent to any address, free on application.

A New Type of Mine Insulator.

The Ohio Brass Co., of Mansfield, Ohio, as will be seen by their advertising space on page III, are manufacturing and putting on the market, a new device for the suspension of trolley wires in mines.

The accompanying cuts show views of this mine insulator as well as the Jewell Trolley Sling, which is most frequently used in connection with it.



The mine insulator consists of an outer covering of either bronze metal or malleable iron, which is provided with means for attaching it directly to the roof of the mine by means of lag screws or bolts. This affords a very thorough protection for the insulating material inside of it, and effectually prevents any moisture from reaching it from the overhead drip.

This insulator is also designed in such a manner that there will be no surface leakage of the current, due to coal dust or other conducting substances settling upon it, and its construction is such that the trolley wheel in passing under the hanger cannot strike against the insulator.

This insulator was especially designed for one of the largest companies which make a specialty of installing electric railway plants in mines, and is meeting with great success.

The Jewell Trolley Sling is one of the latest designs of trolley wire ears that has been placed upon the market. The wire is simply laid in the concave lip and the projecting lugs are bent down over it, no solder being required.

The lug is swiveled in the body of the ear, so that an oscillatory motion is permitted when the trolley wheel passes over it, thus preventing the pounding effect which causes so much trouble on rigid suspension.

Both these articles are listed in the new catalogue which the Ohio Brass Co. has recently put out to the trade, and we believe that not only these articles, but very many others will be found of interest to those who are interested in this class of work.

Information Wanted.

Mr. Jos. Quigley of Westville, Picton county, Nova Scotia, one of our subscribers, is anxious to know the whereabouts of his brother John Quigley, who was last heard from in Blossburgh, Tioga county, Pa., ten years ago. If any of our readers know of his whereabouts they will confer a favor by informing Mr. Jos. Quigley at the above address.

A Unique Album.

We have received from the Link Belt Engineering Co., of Philadelphia, an album of blue prints showing the scope and variety of their designs for coal handling plants. The album contains 34 views each 8½" x 6½" on fine paper, the whole being artistically bound in white flexible covers with blue title. It is one of the handsomest and most novel publications we have ever seen.

Messrs. Abendroth & Root Manufacturing Company, makers of the Root Improved Water Tube Boiler recently received a cable order for three one hundred and thirteen horse power Root boilers to be shipped to Johannesburg, South Africa. Export trade is looking up with this company.

Written for THE COLLIERY ENGINEER AND METAL MINER.

PROSPECTING.

WHERE AND HOW TO FIND GOLD AND SILVER DEPOSITS.

Visit to the Great Leadville Gold Mine, The Ibex or Little Johnnie, and a Description of the Peculiarities of the Gold as Found.

(By Prof. Arthur Lakes, Golden, Colo.)

Leaving the town of Leadville on a sleigh, with deep snow all around us, a temperature of 17 degrees below zero, and mock suns dimly shining through the frost laden atmosphere, we drove up Stray Horse gulch with the Mosquito range on our left—a dome of snow, spotted with innumerable stumps, of what in the early days of Leadville was a thick forest of pines, just peeping above above the snowy canopy. This forest growth has long since been cut and utilized for mine timbers and for charcoal for the smelting furnaces.

On our right were steep hills and banks like sugar loaves of snow. These huge hills of debris are the crowded dumps of the older Leadville silver mine. Owing to the limited area for dumping, they have had to crib their dumps with sets of timber. After about three miles ride up the gulch, the ravine widened a little into a strip called Adelaide Park, and a little above this, a similar and more elevated strip is called Idaho Park. The so-called park is about half a mile in width, by a quarter of a mile in width.

The structure of this little strip of land is interesting and important in connection with the famous gold belt which occupies its length and breadth. It is a block of ground formed between two converging faults. The line or side of one fault is represented by the steep slope descending from the east edge of the park, down into the Big Evans gulch, and the line of the other, by the rise of Breece Hill on the west side of the park. The little valley park is dotted over with mining shafts. At the head or upper portion of the park are the shafts of the Ibex company at various distances apart. Amongst them the shaft of the far famed Little Johnnie mine. Lower down the park, the discoveries of the Ibex company at the head, have stimulated other companies to "go deep," and in several instances their shafts have found the coveted gold zone. The entire surface of the park seems to be underlaid by gold-bearing phorphyry sheets, and a gold-bearing zone.

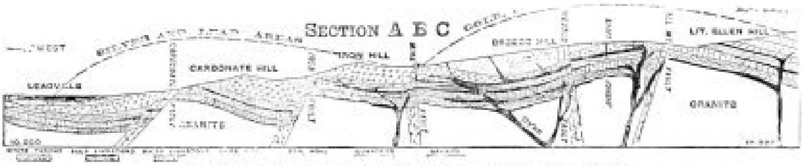
The Ibex company alone has traced its great ore body for 1,200 feet in length, by 500 feet in width. One of these porphyries is called the pyritiferous porphyry, which covers the top and lower slopes of Breece Hill overlapping the grey porphyry near the head of Idaho Park, and according to Mr. Emmons a later intrusion. A vent of it is in California gulch, and it probably extended south to Long and Derring hills, and west to Iron and Carbonate hills. The gray porphyry, through which the shaft of the Little Johnnie penetrates, appears to be between four hundred and five hundred feet in thickness, and below this again, is the ordinary white Leadville porphyry, which usually overlies or is associated with the contact silver lead deposits in the blue or Carboniferous limestone. The relation of these in the present instance, will appear in the diagram section copied from the U. S. Geological Survey Report by Mr. Emmons in Leadville, compared also with a more recent section from a different point made by Mr. A. A. Blow. In the latter the presence of younger intrusive dykes and sheets of porphyry is shown by the black lines.

To these porphyries, especially to the pyritiferous and gray porphyries, and possibly to the younger intrusive sheets, we appear to be mainly indebted for the existence of the gold belt, which lies amongst them, rather as a broad interleaved sheet, than as a narrow belt.

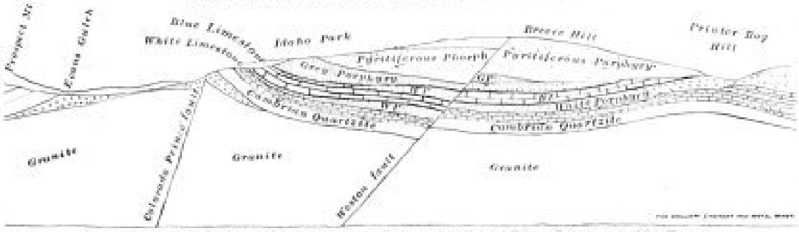
The gold ore shoot has been found locally as much as 78 feet in thickness, thinning down on either side. The ore shoot is not in an even flatshape or body, but undulates rising and falling, swelling and pinching. At the Little Johnnie mine we descended the shaft for 400 feet to the main level, where we stepped out of the "lift" and followed a tunnel through its various turnings and roundings for several hundred feet. The soft crumbling nature of the rock, together with the pressure of the hill above, require a certain amount of timbering, with upright stulls about every five feet, and lagging on the roof. The walls and roofs of these workings are all in pay ore.

DESCRIPTION OF ORE BODY.

The ore body consists of a decomposed ochreous clay, resulting perhaps from the decomposition of a porphyry highly charged originally with iron pyrites. Sometimes this reddish or yellowish clay is very stiff, and you can see the pick marks of the miners very distinctly on it; where these marks are very distinct it is a local sign of very good ore. In other places the ore body is exceedingly sandy. These sandy portions are sometimes in pockets and patches, stained with dark manganese or iron oxide; particles of quartz are numerous, and glisten like frost grains all through the ore bearing sand. This sandy material generally carries the richest ore. Sometimes in the ore body, patches of decomposed gray porphyry appear, showing their distinct spots of felspar crystals. Again, tongues of gray undecomposed porphyry come in, which some think are newer intrusive sheets intruded into the ore beds, but more probably are the original unoxidized portions of the rock. Both oxidized and unoxidized carry ore, and are shipped with the rest. In these ramifying tunnels from 7 to 8 feet in height, neither top nor bottom to the ore is shown, all is in ore of more or less value. From these levels, shafts or man-holes go up into upper levels in which large blocks of ore are stoped out. The method of timbering, whilst developing these wide thick bodies, is by series of square timber sets one upon the other. Like in a flat coal seam, after it has been excavated, the pressure from the roof is great, and in several places we saw bent or crushed timbers. As one walks along tortuous tunnels and crawls up ladders into stopes and flats, one becomes bewildered by the labyrinth. Below this upper set of excavations is a lower level, which, being wet, we did not visit, but in which we learned that some of the original undecomposed unoxidized pyrites were found, which proved to be a fairly valuable shipping ore.



SECTION THROUGH LITTLE JOHNNIE SHAFT BY MR. A. A. BLOW.



SECTION THROUGH BREECE HILL AND IDAHO PARK FROM U. S. GEOL. SURVEY BY MR. EMMONS.

Though as great a thickness as 78 feet has been found locally for the ore body, this is by no means the average thickness. In places the ore shoot dwindles down to a mere line, which may be worked and followed for some days, till it widens out into thicker bodies. They never, however, leave or lose their ore or get off its track, but follow it through all its varying thicknesses, turnings and windings. The present decomposed matter forming the bulk of the ore deposit appears to have been derived from original bodies of gold-bearing iron-pyrites, as shown in the lower level, and in the sandy or oxidized portions little square cavities are often seen, which were originally occupied by the pyrite crystals before they were oxidized out. It is a matter of some dispute at present, as to whether the ore body is a replacement of limestone at the usual Leadville "line of contact," in other words, a replacement of limestone by ore that once existed sandwiched in between two beds of porphyry, as is often observed in some of the silver lead mines of this region, or whether it is a zone of replacement and oxidation of portions of the upper gray porphyry and lower pyritiferous porphyry at about their natural line of contact. The fact that the ore body in many cases largely consists of lead carbonates, containing both silver and gold, would suggest the replacement to be that of limestone, whilst the highly siliceous character of portions of the ore body, might seem derived from a more siliceous rock, like the porphyries. Careful analysis of the ore will doubtless soon decide this point. By some, the gold belt is considered but as a distant gold-bearing prolongation of the silver-lead ore-shoots of Iron Hill, the silver-lead having by reason of a greater amount of pyritiferous and other porphyries on Breece Hill changed into a more gold-bearing product.

The ore consists of a certain amount of free gold together with bodies of carbonate of lead carrying about 50 ounces of silver to two ounces of gold, in some cases as high as eleven ounces of gold or $300 gold to the ton. So the so-called gold belt may more strictly be described as a silver-gold belt. A peculiarity of the ore is, that it contains a small per cent. of bismuth. Some of the local assayers claim that tellurides are detected in some of the gold deposits of Leadville.

The rocks containing the so-called "gold belt" dip off at a moderate angle from the the line of a great fault, and the area occupied by the present discoveries in the belt lies between two intersecting faults, the Colorado Prince fault and the Weston fault.

When the lines of these faults are met with deep under ground, despite that they represent great commotion among the rocks, and in some cases slips off several hundreds or even thousands of feet, yet contrary to what we might have expected, there is no wide gaping fissure, nor even signs of crushed broken rock. On the contrary, the sign of displacement is often only detectable by the change in the character of the rock appearing on either side of a given line, and this line is so narrow and tight, that you could not drive your knife blade into it. When this dividing line, however, is opened up, the cheeks or face of the rock on either side the fault-line are found polished as smooth as glass, by the friction of the gradual slipping movement.

At the Company's office we saw many beautiful specimens of free gold taken from this mine. One of its most striking characteristics is its peculiar flake or leaf like form. Being tarnished also with a little copper or some other mineral substance, a grey or brownish tint, like that of a dead or autumnal leaf is given to it, and a saucer full of this free gold reminds one of a plate full of grey autumn leaves chopped up a little small. These leaves or flakes issue from little cracks in the rock and stand off from it a half inch or more. At other times the rock is full of wire-gold or impregnated with specks or grains of gold. At the Carbonate Bank we saw a pile of gold bricks, some about the size of an ordinary brick, others smaller, most of them from this mine. The whole pile represented 107,000 dollars in gold. With these also were saucers full of the chopped autumnal gold leaves we have described, and marvelously beautiful masses, delicate gauze ribbons, and rosettes of crystallized gold from Breckinridge mines in the adjacent South Park, all of the bright pure yellow gold.

Despite the fact that this Leadville gold mine carries so many specimens of free gold, and despite the oxidized character of large portions of the ore, it does not appear to be a "free-milling proposition." The ore is sent to the smelter in preference to the stamp mill, as the former gives the best returns.

The soft character of the ore body, and its comparative horizontality renders its development very easy, the most important expense is that of timbering.

Nova Scotian Examination.

In our issue for June, in answering some Nova Scotian examination questions sent us by a reader, we misunderstood one question and answered it wrongly, and to make it worse, several typographical errors crept into the answer. So, to prevent our answer misleading any student, we re-publish the question and answer it correctly, giving the rule for finding the quadrant courses.

QUES. Calculate trigonometrically the bearing and distance of C from the center of the shaft in the following traverse:

No.	Angle.	Bearing.	Distance.			Remarks.
			fath.	ft.	in.	
A	0° 00′	351° 29′	10	4	8	From center of shaft.
B	90° 21′		9	3	2	
C	175° 12′		12	0	0	

From the above it is evident that the bearing from the center of the shaft to A is 351° 29′, and we will work the question out on that assumption, and assume that the graduation of the instrument is such that North is 0 or 360°, East, 90°; South, 180° and West 270°.

On page 71 of a "Treatise on Mine Surveying," by Bennett H. Brough, we find the following rule to calculate the bearing:

"To the first meridian angle add the next observed horizontal angle. If the sum exceeds 180° deduct that amount from it. If the sum is less than 180° add that amount to it. The result will be the second meridian angle, etc."

The first meridian angle is 351° 29′, or N. 8° 31′ W.

351° 29′ + 90° 21′ = 441° 50′ — 180° = 261° 50′, or S. 81° 50′ W.

261° 50′ + 175° 12′ = 437° 02′ — 180° = 257° 02′, or S. 77° 02′ W.

Sta.	Angle.	Quadrant Course.	Dist. in ft.	Nat. Cosine.	Nat. Sin.	Lat.		Dep.	
						N.	S.	E.	W.
Shaft to A	0° 00′	N. 8° 31′ W.	64.66	0.98897	0.14810	63.947			9.526
A to B	90° 21′	S. 81° 50′ W.	57.16	0.14335	0.98986		8.119		56.580
B to C	175° 12′	S. 77° 02′ W.	72.00	0.22438	0.97450		16.155		70.164
						63.947	24.274		136.320
						24.274			
						39.673			

It is shown above that station C is 39.67 ft. north and 136.22 ft. west of the center of the shaft.

Now, $\sqrt{39.67^2 + 136.32^2} = 141.98$ ft.

Now, by dividing the latitude by the departure, we find $\frac{39.673}{136.22}$, or .29124 as the natural tangent of the bearing from C to the center of the shaft. Now .29124 is the natural tangent of 16° 15′, and as C is northwest of the shaft, the bearing from C to the shaft is S. 16° 56′ E., and the distance is 141.98 ft.

Written for THE COLLIERY ENGINEER AND METAL MINER.

THE LUKE FIDLER MINE FIRE.

ITS CAUSE AND THE CONDITIONS THAT CAUSED ITS RAPID SPREAD.

A Description of the Methods Employed to Extinguish the Fire and the Difficulties Encountered in its Accomplishment.

(By Baird Halberstadt. E. M., Pottsville, Pa.)

The Luke Fidler colliery is situated about one mile east of the town of Shamokin, Pa., in the Luke Fidler basin of the Western Middle anthracite coal field.

It is operated by the Mineral Railroad and Mining Co., and together with a number of other collieries in this vicinity, is under the efficient superintendence of Mr. Morris Williams, Mining Engineer.

The operation is a large one, its shipments in 1893 amounting to 169,009 tons while employment was given to 750 men and boys.

The developments consist of a water level tunnel 2,000 feet long, cutting both dips of the Orchard and the South dips of the Primrose, Holmes, and the splits of the Mammoth coal beds.

In this basin and the Shamokin region generally the coal beds are known by numbers, beginning with the lowest bed geologically, hence the Orchard bed is called the No. 12, and the splits of the Mammoth, the Nos. 8 and 9.

Three short slopes, two of which are in rock, have been sunk from the surface. A short distance west of where the water level tunnel cuts the Holmes bed, an underground shaft (known as No. 1 Shaft) was sunk from this bed to the bottom split of the Mammoth (No. 8) bed. The top of this shaft is 150 feet below the surface. From the level of the bottom of this shaft a tunnel was driven northward some 1,100 feet to the No. 4 or Buck Mountain bed.

From the same level, two slopes were sunk on the Mammoth bed, the No. 1 Slope being 650 feet long while the No. 2 is 1,500 feet. The No. 3 Slope was sunk from water level on the Holmes (No. 10) bed for a distance of 1,000 feet.

A new shaft (see No. 2 Shaft Fig. 1) had been sunk from the surface and at the time of the breaking out of the fire, had reached a depth of 920 feet, with 45 feet yet to be sunk when it will cut the tunnel driven from the lowest gangway on the No. 8 bed.

The coal beds developed at this colliery are the Primrose (6 ft. 0 in.), Holmes (5 ft. 6 in.), Mammoth (two splits 6 ft. to 7 ft. each), Skidmore (6 ft. 6 in.) and the Buck Mountain (6 ft.). The pitch varies from 25 to 37 degrees.

The aggregate length of gangways is twenty eight (28) miles. Connections are made with the workings of the Hickory Swamp and Lancaster collieries, also with the abandoned workings of the Old Coal Run colliery.

The main fan, a 16 ft. centrifugal ventilator was situated at the mouth of the rock slope *A* which is 150 feet in length (see Fig. 1.)

The intake was from the water level tunnel and Coal Run workings. The air travelled down the inside shaft, split at the bottom, passed down the Nos. 1 and 2 slopes, thence east and west along the gangways to the faces, returned through headings and breasts to a tunnel driven to the No. 8 bed, thence by an air bridge to the air compartment in the shaft which was connected to the rock slope.

The underground shaft was divided into three compartments, two of which were used for hoisting, the third was subdivided. Through one of these sub-divisions passed the steam and column pipes to the pumps below, the other formed the return airway. The air compartment was securely bratticed off from the others with 2 inch plank which in turn were covered with floor boards.

As might be expected, the heat thrown off by the steam pipes made the brattice extremely dry: and to guard against fire, the regulations of the colliery required that in all examinations, a closed lamp or lantern should be used.

On the evening of the 8th of October last, a carpenter was ordered to examine this air box and close up such cracks and crevices as might be found. In direct violation of the rule laid down, he used a naked light, though he had a lantern with him. Passing his lamp close to a crevice, the flame from it was drawn into the air compartment and in a few moments the flames from a fierce fire reached the top, and in less than 30 minutes reached and destroyed the fan at the mouth of the rock slope and consequently the entire artificial ventilation.

The engines used in hoisting from the No. 1 Shaft were formerly underground, and to accommodate them, a room (an old breast originally) had been excavated, making a space 45 ft. x 30 ft. and 20 ft. in height. The excessive heat thrown off by the steam pipes had caused considerable scaling from the top, and to retain this, heavy cribbing had been erected. This, together with the heavy timbering on the turnouts, became easy prey to the flames.

At the foot of this shaft there were two turnouts, one 160 feet, the other 250 feet long, both in the No. 8 or bottom split bed. The slate between the Nos. 8 and 9 beds at this point, was but 10 feet thick, and as this had given away, cribbing to the height of 20 feet was necessitated over the gangway timbers on the turnouts.

As the timbers and plank, in the shaft burned away, the fire having started about midway, they fell to the bottom, setting fire to the timbering about it and extending quickly to the cribbing over the turnouts just referred to. If it be difficult to imagine, how much more so is it to describe fittingly, the spectacle presented to the gaze of the heroic miners, led by Supt. Williams, Inspector Brennan and Foremen Herr, Golden and Kohlbraker, when they advanced with pipe and hose to battle against it.

Picture to yourself if you can, a shaft of this size, the mouth of it 150 feet below the surface, heavily timbered, with these long and heavily cribbed up turnouts above and below, the whole a roaring and intensely fierce mass of fire, with flames shooting in all directions, while dense volumes of smoke, seemingly rolling and unrolling themselves, assumed fantastic shapes.

No pen can fully portray the awfulness of the scene. It can be likened only to a veritable Inferno. When the fire broke out some sixty men and boys were at work in various parts of the mine, and to rescue them alive was the first care of the officials.

Volunteers were called for and a number sufficient to form three relief parties responded.

One party descended the new shaft, another gained the interior through the old Coal Run workings, while a third passed down the timber shaft and slope, high up on the hillside, north of the colliery. So successful were these parties that all but two men were reached; two others found were directed how to escape, but, leaving the relief party still pushing forward, they evidently became bewildered and lost their way, as they never reached the surface.

To the first alarm the city firemen responded and rendered valuable aid in saving from destruction the buildings in the vicinity of the mouth of the rock slope, out of which the flames were shooting 50 feet into the air.

Upon the removal of the underground shaft engines, some time previously, they were replaced by engines on the surface, and rope holes (8 in.) were drilled through the intervening space. Down through these holes all the water it was possible to obtain was run.

While the relief parties were still searching, two 3-inch lines of gas pipe were run down the new shaft to the No. 1 inside slope and up this to as near the bottom of the shaft as possible.

These lines completed, the water was turned onto the fire, but, powerful as these streams were, they seemed to have but little effect, except to make it seemingly burn more fiercely, due, no doubt, to the fresh current of air carried in by the water.

An advance was made, but as the party proceeded, the smoke from the fire beyond came in on their rear, over and down from the cribbing, completely enveloping them, making the place utterly untenable and compelling a retreat.

The shaft and slopes formerly downcasts had now, owing to the intense heat, become upcasts, and through the latter came quantities of fire-damp (CH_4) which had gathered, since the stoppage of the fan, in the workings below. The only outlet for this gas was through the area now in flames. Two terrific explosions occurred, the concussion from which was so great that it was felt at points 1½ miles distant. So great became the volumes of smoke that notwithstanding the full current of air was forced against it, the gangways in the Hickory Swamp colliery soon became filled with smoke, and it was not until a battery had been erected, that this could be overcome.

The chances of a successful battle by the direct system of fighting, if they ever existed, had now entirely passed away.

There remained but one thing to do—flood the entire workings to save not only this, but other valuable collieries from destruction. Four human beings alive or dead remained imprisoned in the mine. Are they dead or are they wandering about in a bewildered condition, that was the question to be decided. If there remains the slightest possibility of their being alive, flooding can not be done. The relatives of the imprisoned ones, clinging to the hope that they might yet be alive, opposed flooding which meant sure death, had it not already come.

A consultation was held at which were present State Mine Inspectors Brennan, Stein, and Maguire, Superintendents Morris Williams and George T. Morgan and the writer. The case was fully discussed and every point was carefully weighed.

The condition of the mine when the last party of rescuers were driven back plainly demonstrated the impossibility of the imprisoned men being still alive. At the very outset Superintendent Williams stated in most unmistakable terms that he would sacrifice the entire colliery rather than flood it, if the *slightest* hope of rescue of the men alive or dead, remained. While the fire burned, the recovery even of their dead bodies was an impossibility. The conclusion arrived at was, that as every known means had been used to recover the men, and that as all hope was gone, there remained nothing to do but to save the colliery if possible. To this, all present assented.

Preparations were at once made to accomplish the desired end. Every known opening through which air could reach the fire was tightly battened down with plank and clay. It was decided to fill up the underground shaft with culm run in with water through the rope holes from the surface. A track was laid to the culm bank, pipes were run from the pump, and the house built over the sheaves together with the sheave wheels, were removed.

Four days after the fire broke out, October 12th, slushing began and was completed ten days later—to accomplish this there were dumped 2311 cars of culm weighing 4622 tons.

To drown out the colliery, the waters of Coal Run were run in through the Coal Run colliery. Two 8″ pumps, one duplex the other single, pumped in water from the creek south of the breaker, while all water that could be spared was furnished by the Shamokin Water Co.

Upon the completion of slushing the shaft, the battery in the tunnel was removed, and a force fan erected to permit an examination of the workings above waterlevel.

This examination revealed fire still burning, and it was then decided to flood these workings to a height of one hundred and twenty-five (125) feet above water level.

To do this the construction of two dams was necessary, one in the water level tunnel, the second in the new or No. 2 Shaft.

The dam in the tunnel (Fig. 3) was built at a point about 50 feet inside the No. 11 bed (see Fig. 2) of brick laid in Portland cement and was 5 feet thick. Deep notches were cut into the rock on the top, bottom and both sides of the tunnel as shown. Built into the dam were two pipes 8 inches and 22 inches in diameter respectively. The diameter of the larger pipe was reduced, at the outer side, by fittings and valve to 10 inches. Through this pipe it was possible for a man to to pass through the dam, to make examinations after the water had been drawn off, making it unnecessary to break through the dam, itself. The utility of this plan is obvious.

The dam in the shaft (Fig. 4.) was constructed at a point 200 feet below the surface to prevent the escape of water through the workings on the No. 11 bed, to which there was a water level outlet some distance west.

At the point noted, the planking on the outer side of the buntons was removed both above and below for 4 feet and placed on the inner side as shown. The intervening space was rammed with concrete to prevent the escape of water from the sides.

The lower face or bottom was laid with 3 inch plank, next 1 inch flooring laid in the opposite direction tightly joined, upon this came a second tier of 3 inch plank, then the whole was overlaid with 10 inch timber, these were braced with 10 inch timbers as shown. It will be observed upon inspecting the drawing, that two pipes are

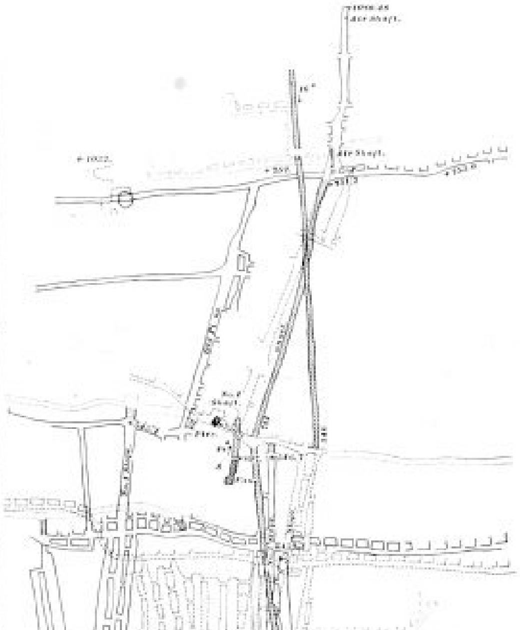


FIG. 1.—LUKE FIDLER COLLIERY, SCENE OF FIRE, OCT. 8, 1894.
DOTTED LINES SHOW WORKINGS IN NO. 8 VEIN.
SOLID LINES SHOW WORKINGS IN NO. 9 VEIN.
BROKEN LINES SHOW WORKINGS IN NO. 10 VEIN.

run through the dam. The object of these and their uses are as follows:

The smaller or 8 inch pipe extended from a point 6 feet below the dam upward to the water level where it was blanked, it was tapped with a number of holes as shown; these holes permitted the escape of air from below and prevented its compression, they also allowed the escape of a certain amount of water when it rose to these heights, and which falling upon the dam from above, assisted, by its weight, in resisting the upward pressure now exerted against it.

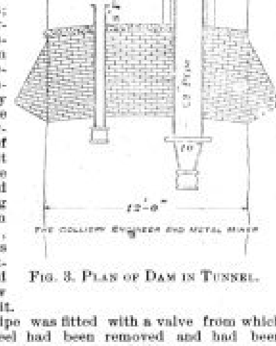

FIG. 3. PLAN OF DAM IN TUNNEL.

The 10 inch pipe was fitted with a valve from which the handle wheel had been removed and had been replaced by a pulley wheel; around this was run a rope which passed up to the surface and with which the valve could be opened or closed. Stable refuse was, as the water rose, introduced through the 10 inch pipe; this floating upon the rising water effectually closed any crack or chink if any existed in the dam.

By continuing the pipes to six feet below the dam there was less danger of their becoming clogged with floating debris, as might have been the case had they been set flush with the bottom. The upward pressure sustained by this dam approximated 1000 tons. Three months time was required to fill the workings to the desired height with water.

After a sufficient lapse of time, the water at and above water level was drawn off through the pipes in the tunnel dam. An examination was then made of these workings and not a spark of fire remained.

To remove the water from the workings below, pumps, the capacity of which was 7,000,000 gallons per diem were set to work, and in the new shaft two iron tanks with a capacity of 2,000 gallons each were placed in the hoisting ways, the valve on the 10-inch pipe was opened by means of the rope, permitting the escape of the confined water below. With these tanks 3,000,000 gallons per diem were raised and discharged. (A detailed description of these tanks, etc., will appear in a later number).

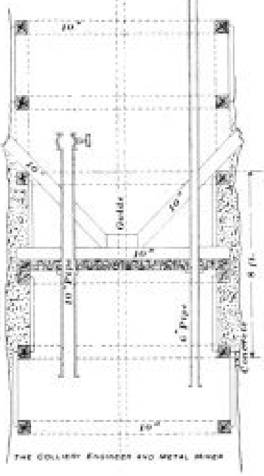

FIG. 4.—ELEVATION DAM IN SHAFT.

When the water in the shaft had been lowered to a depth which made the tanks ineffectual on account of the dam, the pumps lowered the water further, when the dam was removed, and hoisting with the tanks was resumed.

At the present rate of discharge, the mine will be free of water by August 1st. Assuming this to be so, the time required to remove the water will approximate six months.

The entire supervision of the work of subduing this, one of the fiercest mine fires the region has seen, fell entirely upon the shoulders of Superintendent Morris Williams, and he has again demonstrated that his skill as an engineer is equalled by his skill as a practical mining man.

In conclusion I wish to acknowledge the obligation he and inspector Edward Brennan have placed me under in furnishing me with data and accompanying me over the ground since the fire, as well as for numerous other courtesies.

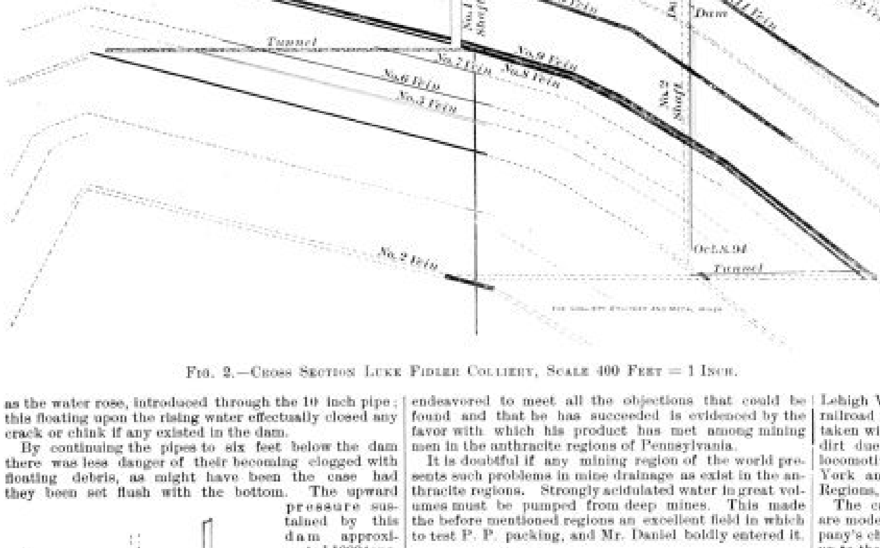

FIG. 2.—CROSS SECTION LUKE FIDLER COLLIERY, SCALE 400 FEET = 1 INCH.

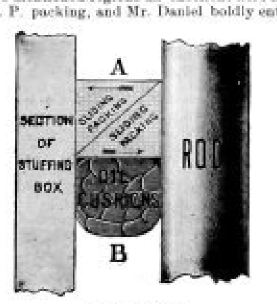
PERFECT PUMP PACKING.

Description of a Style of Packing which is Meeting With Great Success.

To say that all packings but P. P. packing have been failures in mine pumps would be untrue, but to say that they have not been unqualifiedly successful would be true. Sometimes the fault lay in the shape of the packing, and sometimes both the shape of the packing and the quality of the material used in its manufacture were to blame.

In P. P. packing, Mr. C. A. Daniel, the manufacturer, endeavored to meet all the objections that could be found and that he has succeeded is evidenced by the favor with which his product has met among mining men in the anthracite regions of Pennsylvania.

It is doubtful if any mining region of the world presents such problems in mine drainage as exist in the anthracite regions. Strongly acidulated water in great volumes must be pumped from deep mines. This made the before mentioned regions an excellent field in which to test P. P. packing, and Mr. Daniel boldly entered it.



ROD PACKING.

A glance at the above illustration shows that the packing brings into service a cushion which adapts itself to the changing position of the wedges, formed by cutting the rubber back diagonally through its section, and thus keeps up a uniform pressure. The cushion acts as a lubricant carrier.

The packing is applied by entering it, cushion first, into the stuffing box. The gland is then pushed down upon the rings and the nuts holding the gland in place are tightened with the fingers. A wrench is unnecessary, as the steam or water pressure tends to force it against the gland. This pressure slides one wedge upon the other and dilates the packing, thus adjusting it automatically. This is well shown in hoisting engines. When the engines are running forward with steam, the gland is so tightly forced on to the nuts that it cannot be moved. When they run backward without steam the gland is freely moved. In applying rings of this packing, the joints are broken, as in any other packing.

The lubricant used in the hemp cushion is of the finest grade of lubricating oil. The graphite, incorporated with the packing in its construction, has all been floated to free it from grit, and is of the finest grade. The rubber back from which the wedges are cut is a grade of canvas and rubber, which by experiment has been found to be least affected by steam, hot water, acids or alkalies. This packing has been in use for about 18 months in many of the mine pumps and other machinery throughout the anthracite region, and has been praised in every instance as something far superior to other makes.

Pumpmen, where bad water is to be handled, claim that the graphite of this packing coates the plungers of the pump with a black film that is to a large measure impervious to the action of acid water and this preserves the plunger from corrosion. The Lehigh & Wilkes-Barre Coal Co., has adopted the packing entirely and has so far given it nothing but praise. In one of their fan engines the packing gave five months and five days service and was then only removed to see what condition it was in. It was found in splendid condition. This engine has a three inch rod, badly scarred from the use of other packings. It runs day and night at a piston speed of 180 ft. per minute. For the same company, at the Hollenback mine, one of their "bull pumps" was packed with this packing. The rod in this instance weighs 7,500 lbs., and the cylinder rods are vertical instead of horizontal. Great trouble has always been experienced from condensations in the cylinder, and the squirting of water over everything near. Since packing with "P. P. P." no water leaks at all. At the D. L. & W. mines the packing has been found in their worst mine pump to give 70 times more service than the packing they were using. Mr. Townsend Poore, Master Mechanic of the company, in a letter to Mr. Storrs, claimed for it the greatest economy ever found in steam or water packings. With all others using it, the same or similar praise has been given the article. Among those using the packing as superior to all other, are the following prominent operators:

Hillside Coal & Iron Co.; (not quite through with test,) Elk Hill Coal & Iron Co.; Mt. Jessup Coal Co.; Blue Ridge Coal Co.; W. T. Smith; New York & Scranton Co.; D., L. & W. Co.; Lehigh Valley Coal Co.; J. C. Haddock; Waddell (Estate) Coal Co.; Lackawanna Iron & Steel Co.; Chamberlain Coal Co.; Simpson & Watkins; Coxe Bros. & Co.; Jeddo Tunnel Co.; Lehigh & Wilkes-Barre Coal Co.; Leisenring Coal Co.; Elliott, McClure & Co.; T. M. Righter & Co.; Midvalley Coal Co.; Columbus Colliery, (Mt. Carmel;) Newton & Old Forge Coal Co's.; Langcliffe Coal Co.; Lentz, Lily & Co.; Clear Spring Coal Co.; Stevens Coal Co.; C. M. Beauties of the Lehigh Valley.

We have received with the compliments of Mr. Chas. S. Lee, General Passenger Agent of the Lehigh Valley Railroad, a copy of a handsome album containing fifty photo-gravure illustrations of points of interest on the Lehigh Valley Railroad. The scenery along this line of railroad is unexcelled in any part of America, and this taken with the good roadbed and absence of smoke and dirt due to the exclusive use of anthracite coal on the locomotive, makes the L. V. a favorite route from New York and Philadelphia to all points in the Anthracite Regions, and to Buffalo, Niagara Falls and the West.

The car equipment is first-class. The day coaches are models of neatness and comfort, the Railroad Company's chair cars are fine, and the Pullman service fully up to that on any road in America. The dining car, run on trains Nos. 1 and 2 (between New York, Philadelphia and Buffalo) is a luxurious one. Meals are served *a la carte*, and passengers pay only for what they order. A simple, economical meal can be ordered, or the *bon vivant* can order an elaborate course dinner with wines. Each pays for what he gets and for no more. The service is first-class in every respect.

Merit Wins Success.

The Jeffrey Mfg. Co. of Columbus, Ohio, has during the past year run its full force full time, and for a number of months has had a large night force at work. Their present outlook is very good, and judging by the favor with which Jeffrey conveying machinery and Jeffrey coal mining machinery is received the shops will enjoy a continuance of this prosperity. The company is certainly an enterprising one and the officers manage the business in such a manner that the excellence of the Company's products and the promptness with which orders are filled wins new customers daily and clinches the trade of old ones.

"Facts."—"High Pressure."

The Babcock and Wilcox Company of New York, has earned a great reputation aside from that due to the excellence of the B. & W. boilers. It is due to the handsome and instructive books they publish for free distribution to steam users. Their annual publication "Steam" in several languages showed great enterprise and liberality. They have now issued two new special publications, one of which is entitled "Facts," and is really a history of water tube boiler construction. The other, entitled "High Pressure" deals with high pressure steam. Both volumes are handsomely bound, illustrated with remarkably fine engravings, and they are not only artistic in design but interesting as well.

Written for THE COLLIERY ENGINEER AND METAL MINER.

MINE SURVEYING.*

LATEST AMERICAN IDEAS AND MOST APPROVED PRACTICE.

Rewritten for the use of Mine Officials, Surveyors and Engineers, from Lectures Delivered Before the Students of Columbia School of Mines.

(By Edward B. Durham, E. M.)

CHAPTER V. (CONTINUED)

In the survey used for illustration, the total latitude and departure and elevation of the first point, as well as the azimuth of the back course, are known from previous survey. If now we add the latitude and departure of the first course to the total co-ordinates of the first station, we have the total co-ordinates of the second point, which is noted in its column opposite the second station. This is done for each station of the survey. Notice that when a *north* latitude is added to the latitude of a point *south* of the origin, it is practically subtracting it from the total latitude of that point. The directions east and west, or north and south have the same effect on the operation as the plus and minus signs in algebra. At station 71 the work closed for the day and everything was removed, so it was practically a new survey that was commenced the next day. Instead of repeating the station and the total co-ordinates of the survey of the day before, they can be dittoed down.

The only remaining thing to be found now is the elevation of the points. This must be done in a roundabout way, as the line of the survey was run between instruments, and not on or parallel to the stations. The calculations involved can be most clearly explained by taking the case in the example here given.

The elevation of station 49 was determined by the previous survey to be 737.71, and height of the instrument this time is + 5.03, as taken from the field notes. These are added together algebraically, giving 742.74 as the elevation of the instrument. The line of survey runs from instrument to instrument and in this case falls 14.54 feet which gives the elevation of instrument at 70 to be 728.20, the next line rose 4.23 feet making the elevation of instrument at 71 to be 732.43 when the work stopped and tripods were removed. The elevations of the points are found by subtracting algebraically, the heights of instruments from the elevations of the instruments. Thus the instrument at 70 is 3.64 feet below the point, if we subtract — 3.64 from 728.20 we have 731.84 which is the required elevation. This same method of procedure will continue throughout the survey, except where the tripods have been disturbed as at station 71. Here on resuming the survey on the following day, the instrument was set at a different height than on the first day, so its new elevation must be found by adding the height of instrument to the elevation of the point, as would be done in starting a new survey. If the tripods had been left standing, and had not been disturbed, there would have been no break in the line, and the calculations would have been the same as if the work had been done at one time.

The words "Back" and "Forward" are used to indicate that the first figures are those determined by the back survey while the second are those used in continuing the line forward. Station 72 was "temporary," as noted in the remarks column, and not having any point, could not have any elevation of point or height of instrument.

The trouble in carrying elevations with plummets would be, that there would occur just such breaks, as at Station 71, at *every* station, unless special precautions were taken to prevent it.

It is often convenient to know the co-ordinates of stations, while in the field, so after finishing the calculations on the sheets, they may be added to the note book opposite the stations. In the case of temporary points the elevation of the instrument will be all that is of importance. Also put a reference to the sheet, where the calculations can be found, on the page with the notes.

All the calculations connected with surveying involve angles and require the use of the trigonometrical functions, especially, the sines and cosines. These have to be looked up in tables, of which three kinds are in common use, viz:

1. Tables of natural functions, in using which the distance is multiplied by the function. Good tables of these will be found in the hand books and are most convenient for short calculations in the field.

2. Logarithmic Tables, which are an improvement over the first, in that all the arithmetical work is done by addition, thus: log. of distance + log. of function = log. of result, but it is necessary to open the book in three different places to hunt up the logarithms. Bruhn's Manual of Logarithms is one of the best and handiest for surveying. The tables given in many of the hand books are to small for rapid work.

3. The Traverse Tables, where in using it is only necessary to open the book once, and any calculation necessary is done by addition. The distances are given in lines and there are two columns headed sines and cosines, respectively. At the intersection of these with the line belonging to a given distance, will be found the product of the distance by the function of the angle given at the head of the page. The only one we know of that is suited for computing accurate surveys, is R. L. Gurden's "Traverse Table." The distances run from 1 to 100 and the angles cover every minute of the quadrant. The co-ordinates are given to four places of decimals. W. & L. E. Gurley quote, Bruhn's Manual of Logarithms at $2.50 and Gurden's Traverse Tables at $7.50.

In reducing radiating sights to horizontal and vertical distances, preliminary to plotting, the small traverse tables found in many of the text books on surveying will be found very useful and will give results as accurate as can be plotted.

PLOTTING.

For maps of small areas on a large scale, say to 1 to 300 feet, the protractor and scale can be used to plot the survey, but for extensive work, the errors are liable to accumulate and cause great inaccuracies. If the courses are laid out each time from the meridian, instead of from the last course, a greater degree of accuracy can be obtained. Although the protractor saves calculating co-ordinates, it does not furnish any check on either the instrumental work or on the plotting. The protractor will be a convenient and rapid way of plotting the radiating sights taken by the transit surveys and will be sufficiently accurate.

The plotting of the traverse of an important or extended transit survey, especially if the scale of the map is small, should be done by means of co-ordinates, using the protractor to check the angles and the scale to check the distances.

In plotting by co-ordinates the first step is to lay off the paper in carefully made squares, about two inches on a side, and so that each side will represent a whole number of hundreds of feet. The most accurate way to divide the paper is to draw a line through its center, and near the middle of it to construct a perpendicular to it on both sides, then from these as base lines, to construct with the dividers as large a rectangle as the sheet will take and sub-divide it into squares of the desired size. To erect the perpendicular, take a point on the center line where it is desired to have the lines cross, lay off with the dividers points at equal distances on both sides, then, with the line joining these two points as a base, construct isosceles triangles on both sides of the line, and, through their apices, draw a line, this will be the desired perpendicular and should cross exactly on the point first taken.

The squares look well when drawn in green or blue ink.

In plotting the stations, they may be laid off from the nearest corner, formed by the co-ordinate lines, by constructing a rectangle, with the dividers, whose dimensions are such, that the station will come at the diagonal corner of the rectangle from the corner of the square. The permanent stations are inked in, after checking the plotting, by drawing a small red circle about the point, with a bow spring compass, leaving the prick mark in the center to indicate the exact position of the station, and placing the station number near, also in red. (See Fig. 13.) The survey lines can now be drawn in red ink *between* the circles, taking care not to cut through their circumferences. Temporary points are plotted in pencil only, and after the detail taken from them, has been put on the map, they can be rubbed out.

After the survey lines have been plotted, the detail is added. Offsets are laid off from the traverse lines, and radiating sights are plotted with a protractor and scale. The points, obtained in either way, are then joined by straight lines and the map is ready to be inked in. The outline of the workings can be drawn in black.

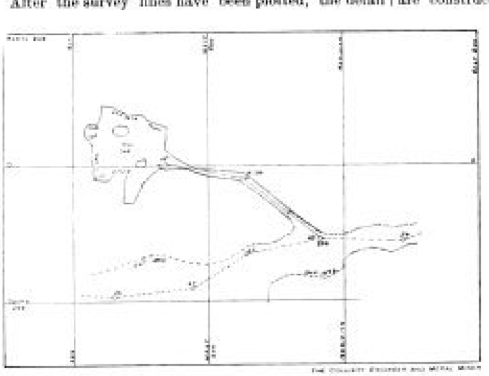

FIG. 13.—PLOT OF SURVEY.

This arrangement of colors on the map, green for the square, red for the survey lines, and black for the workings, makes a nice looking map and keeps the survey lines and construction squares in the back ground, while the outline of the workings stand out sharply. Sometimes the progress of the work from year to year, is shown by plotting the surveys made during each year in a different color, then a glance at the map will give a good idea of the area worked. Where the maps are kept up to date by frequent surveys, each one should be plotted completely and dated. Then from the plot of the original survey there will be a succession of lines showing the growth of the workings like the annual rings in trees. The area between these lines will be the area mined in the period between dates.

It is advisable to use the best, heavy, cloth mounted paper for the working maps, as they have to be handled frequently, and will soon wear out on light paper. As the paper will vary in size with the changes in the atmosphere and by wear, it is necessary that a scale should be plotted on the sheet, so that it will vary with the paper, and then new work can be plotted to the same scale as the old. Much used maps are reported as having stretched 1 to 5 feet in a 1000 feet in a few years, so in adding to old maps, care must be taken that the scale is not distorted.

A scale of 50 feet to the inch makes a very nice size for a small work, as distances can be picked off from the maps with considerable accuracy, but it would be too large for plots covering large areas.

The law in Pennsylvania requires that the working maps of the coal mines shall be 100 feet to the inch, but even this scale is found to be too large for convenience in extensive operations.

Their can be no definite rule as to the scale of the map, except that a large scale, as 50 feet to the inch, allows more accurate plotting, and more dependence can be placed on measurements taken from the map, than with smaller scales. A large scale can be used where mines are small or a large area can be readily divided so as to keep the sheets small enough to handle. A general map on a smaller scale can be made by transferring the plots of the different regions to a single sheet, by means of a pantograph.

The surface should be surveyed, and the important details in the vicinity of the workings should be plotted on the mine maps, for the mutual protection of mine and surface. Care must be exercised in mining that the ground is not so disturbed by settling as to injure the surface, or to allow water to flow into the mine. The property line must be plotted on the working map in order that ample warning may be given of the approach of the workings to the boundaries. The exact distance to the line had best be calculated, and so eliminate the errors in plotting. If a special survey is being run to determine the distance of the workings from the line, it will be convenient to use the property line as the meridian, and some point on it as the origin, then the departures of points along the face of the workings, will be their distances from the boundary. A common practice in working toward a line, is for both parties to stop mining so as to leave a wall for mutual protection. The thickness of the wall must be such that it will withstand the pressure of the overlying rocks without crumbling, and if necessary it must be able to withstand the hydrostatic pressure due to the flooding of one of the mines. The thickness of the barrier for anthracite seams can be found from the formulas given by "The Coal and Metal Miner's Pocket Book," p. 178. Width of barrier pillar = (thickness of workings × 1% of depth below drainage level) + (thickness of workings × 5). Each party should leave one half the thickness of the pillar.

Any old workings in the vicinity of the mine, must be plotted on the maps so that the excavating may not be carried too close to them, endangering the lives of the men and injuring the mine if a break is made into them, allowing gas or water to escape. In approaching abandoned workings that are liable to be dangerous, it is always advisable to drive bore holes, say 20 feet long, in advance of the excavation, as a safe guard against accident as there is no way of telling how much reliance can be placed on the old survey.

The principal plot for flat mines will be the horizontal plan and as the surveys are all referred to the horizontal, it will usually be the foundation map from which others are constructed. Elevations of points on the roof and floor should be noted frequently, in order to give some idea of the pitch of the ore body and in the case of the maps of coal mines, the dip should also be recorded accompanied by an arrow to show direction. In the latter, it is sometimes convenient to have contours of the floor, to show the formation to the best advantage. These can be drawn in from the elevations, the dips, and also by the gangways, which are usually driven on a regular grade.

Where the pitch of the ore becomes so great, that the horizontal plan is foreshortened, so that it only approximates the shape of the workings, it is customary to make a projection on an inclined plane parallel to the general direction of the deposit for the use of the mine foreman. This projection, on a reduced scale, is also used in the reports on the mine. It has the advantage of showing the workings in their true relative size, and is more intelligible to non-technical people than orthographic projections. It can be made by projecting the the distances along the strike of the ore deposit, from the horizontal plan, and using the inclined measurements recorded in the note book for the distances in the direction of the dip. The stations and traverse lines, are omitted from this plot, they being usually placed on the horizontal plan and sometimes on the vertical projection. As this incline plan or section will not be the engineer's working map, it can be projected with sufficient accuracy for its purpose. He will depend on the horizontal and vertical plans which can be made with greater accuracy.

As the pitch increases, the horizontal plan shows less and less about the mine, and the vertical projection becomes of more and more value. This is especially so when the pitch is over 45°. When the deposit becomes nearly vertical, the plan will be very small and of little use outside the engineer's office, and then the vertical longitudinal projection of the mine will be the most important guide of operations. The survey stations can be plotted by projection from the horizontal plan and by their elevations, and then the detail plotted from the survey lines by vertical offsets. Detail taken by radiating sights can be plotted as were the stations by projection and elevation.

A more accurate way, where the strike of the deposit is regular, is to take the meridian parallel to it, then the vertical projection will be in a plane parallel to the meridian and points can be located by their latitude and elevation without projecting, and radiating sights could be plotted in the same way or be projected as before.

Cross sections through a mine are often wanted, in which case they can be constructed in the same way as the vertical projection, depending also on how the data were obtained. Mr. Johnson of Longdale, Va., took cross sections through narrow chutes, in a soft hematite mine with a hanging compass.

In the case of a large mass deposit worked in floors, a general cross-section is needed to explain to others the the method of mining, and to show the arrangement of the floors and pillars. The principal working maps will be the horizontal plans of the separate floors, and each should show the pillars of the floor above, so that in leaving new pillars, they can be located so as to give the best support to the weight from above.

* Begun in March, 1895.

If there are not too many floors or levels they can all be plotted on one sheet by using a different color, or a different kind of line, for each.

This is the method used in some of the coal mines, where there are different beds, overlying each other.

If there are several floors or beds, the different lines on one map will be very confusing and it will be clearer to plot each with its own color, on a separate sheet of tracing cloth, with the meridian lines drawn on it. They can then be placed over each other in their proper relative positions for study and comparision.

This plan is often carried out much more elaborately in a glass model, by drawing the surface, and each level of the mine on a sheet of glass. These sheets are then placed in a frame at the proper distance apart so that all the beds can be seen at once in their proper relative positions. For this purpose a grade of glass known as crystal plate should be used to get the best results, as it is difficult to see through many thicknesses of ordinary glass. The plotting may be done by mixing the colors with copal picture varnish and linseed oil in proportions to flow easily and dry readily, and applying them with drawing pens and and fine brushes. A very fine model of this class was exhibited at the World's Fair, of a portion of the Copper Queen Mine of Arizona. It had horizontal plates of glass each showing the drifts of one level in its special color. These were mounted at the proper distance apart and so arranged that any of them could be slid to one side to allow the examination of those below. The nature of the rock passed through was shown by means of conventional borders to the drifts. Above the horizontal plates were arranged two sets of vertical ones, with sections through the mine plotted on them. The sections were taken both on the north and south, and on the east and west lines, at distances of 100 feet apart. The plates were suspended from overhead tracks and any or all the plates of either set of sections could be placed over the horizontal ones and be studied in connection with any of them. The sections like the horizontal plans only showed the drifts and each plate included all within 50 feet on each side of the section. The plots were all made to the scale of 50 feet to the inch.

A duplicate of this model is contained in the collection of the Mining Department of the School of Mines, Columbia College.

(TO BE CONTINUED.)

NARROW GAUGE RAILWAYS.

The Hunt System for Mining, Metallurgical and Manufacturing Establishments.

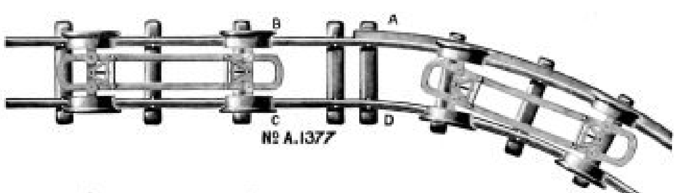
The fact that narrow gauge railways for handling and transferring coal, castings, parts of machinery and materials of all kinds in and around manufacturing establishments constitute a very important part in the economy in the operation of a plant is daily more fully appreciated, especially in a plant of considerable magnitude or where the various departments are in separate buildings. A system of cars and tracks is as much a "machine" as a lathe, a steam hammer or a loom, and should be judged in the same way. The saving in time and labor assured by its introduction, the increased dustrial establishments, is in this connection worthy of special notice.

These Industrial Railways are built by the well-known C. W. Hunt Company, 45 Broadway, New York City, who have for many years given the subject careful consideration and have acquired an enviable reputation as builders of high grade machinery of this class. In determining the gauge and the radius of the curves most suitable for an industrial railway, it is necessary to take into consideration all of the circumstances under which it is to be used.

FIG. 3.—PUSH CAR, WITH A MOVABLE CENTRE PIECE TO DUMP THE LOAD ON EITHER SIDE OF THE TRACK.

FIG. 4.—COKE CAR BUILT FOR THE TORONTO GAS COMPANY, TORONTO, CANADA.

The C. W. Hunt Company believe that if the gauge adopted by them (21½ inches measured from the outside to the outside of the heads of the rails) is not the ideal one, it comes very near to being so. In all of the railways that they have built, they have never had a user even suggest that a broader gauge would be better for any purpose.



No. A. 1377

FIGS. 1.—AND 2.—HUNT SYSTEM OF NARROW GAUGE RAILWAYS FOR MANUFACTURING ESTABLISHMENTS.

efficiencies of other machines or of the whole works at once effected, the greater protection against damage afforded material being handled or moved, and the general convenience, must be balanced against the interest on the investment and the expense of maintenance. In putting in a railway of this kind many questions arise which require careful consideration, such as: What gauge is the best for this purpose? What radius curves should be used? How heavy should the rail be? What style of cars will be best? What kind of cross ties should be used? How shall the switches and crossings be made? Can turntables be avoided? What will be the effect of grades, etc., until it looks as though one would have to abandon his regular business to decide these details. There is however no necessity of doing this, if one determines at the outset to put in a thoroughly tried and reliable system, leaving the entire matter with all vexatious details to the experience and expert judgment of the builders.

The Hunt system of narrow gauge railways for in-

In a manufacturing establishment the curves should be of so short a radius that every part of a factory can be reached directly without expensive and troublesome turntables. The Hunt Company state, "Our standard curves are 12 feet radius measured to the centre of the tracks. This radius is almost exclusively used in manufacturing establishments where cars are usually moved by hand, because cars can be used with a running gear which runs as easily on a curve of twelve feet radius as on a straight line, the axles taking a radial position with the outer wheels running on the flange, instead of on the tread, thus enabling workmen to move double the load they could with ordinary cars. It is for this reason that we build our railways with outside flanged wheels.

"These variations from ordinary railway practice make no difference whatever in the operation of the general construction, except that the curves, switches and frogs must be especially arranged to suit wheels with outside flanges."

The load which can be carried on a railway depends not upon the gauge, but upon the strength of the track, consequently, whatever strength is needed to carry a certain load can be obtained with a narrow gauge, as readily as with the standard 4 ft. 8½ in. gauge. The Hunt cars are of improved construction, and are fitted with a flexible wheel base, the axles taking a radial position on a curve, and the wheels and the curve so proportioned that there is no slipping whatever to cause friction. This departure from the old style rigid base cars is an important feature of the Hunt system and the advantage will be at once appreciated by any one who has had experience with rigid wheel base cars.

The principle on which the cars turn a curve is illustrated in Figs. 1 and 2. A cylinder rolls on a plane in a straight line without sliding friction; a cone rolls on a plane in a circle about its vertex, without sliding friction. If both of the wheels of a car running on a curve have the same diameter as the cone would have each rail, they are portions of the cone, and the wheels would run

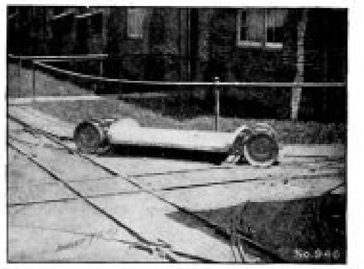


FIG. 5.—CAR FLOOR 7 IN. ABOVE THE RAILS, FOR BROWN & SHARPE MANUFACTURING CO., PROVIDENCE, R. I. THE RADIAL POSITION OF THE WHEELS ON THE CURVE IS WELL SHOWN IN THIS CUT.

around the curve without sliding friction, the axles taking a radial position. The illustration Fig. 2 clearly shows that if correctly made, there will be no sliding friction in passing the curve. In applying these principles the outer rail around the curve is made of special form so that the wheel runs on a flange instead of on the tread. The axle bearings are pivoted in the centre, between the wheels, permitting them to take a radial position, as the wheels direct.

Could the wheels be made absolutely round and exactly to the theoretical diameter, and the tracks perfectly smooth and laid to an exact circle, the cars would then pass around a curve as easily as on a straight track. It is impossible in commercial machinery to fully realize theoretical conditions, but the difference between the running gear as furnished by the C. W. Hunt Company and the ideal one is slight.

Rigid wheel base cars do not run easily around a curve because one of a pair of wheels of the same diameter, secured rigidly to the axle, must slide on the rails a distance equal to the difference in the length of the inner and the outer rail. In a car having two pairs of wheels, with the axle boxes rigidly connected to the frames, not only must this sliding take place, but it is increased by the unfavorable position in which the axles hold the wheels, as the axles cannot take a radial position, which is the one most favorable. Beside the standard cars illustrated in their latest catalogue, No. 9,504, the C. W. Hunt Company is prepared to furnish cars of special design for carrying all kinds of material, and in this system of narrow gauge railways offers apparatus embracing in its construction all the latest improvements in machinery of this class.

BOOK REVIEW.

The Modern Machinist, by John T. Usher; published by Norman W. Henley & Co., 132 Nassau St., New York. Price $2.50.

This, the latest work on machine shop practice, is written by a machinist of high standing who has had a wide range of experience both in this country and in England. The author's contributions on the subject in "*The American Machinist*" and other high grade technical publications have always been favorably received by their readers. The book contains 322 well printed pages and 257 illustrations which are strictly new, not a rehash from other works on the same subject. We notice that a large number of the cuts are perspectives, and all are well adapted to the subjects which they illustrate. Among the many subjects treated of, we notice Measuring Instruments, Vice Work, Chasing, Erecting, Lining Shafting, Planing, Shaping, Slotting, Milling, Lathe Work, etc. The book contains a copious table of contents and a good index. It should be in the hands of every person interested in the latest details pertaining to the modern machine shop.

High Grade Hoisting Machinery.

High Grade Hoisting Machinery is the title of a handsome illustrated catalogue of hoisting engines, boilers, etc., manufactured by the Pen Argyl Iron Works at Pen Argyl, Pa. The catalogue is one that will interest every mine and quarry manager. It is sent free on application to the Pen Argyl Iron Works, Pen Argyl, Pa.

This department is intended for the use of those who wish to express their views, or ask, or answer, questions on any subject relating to mining. Correspondents need not hesitate to write for supposed want of ability. If the ideas are expressed, we will cheerfully make any correction in composition that may be required. Communications should not be too lengthy, and personal reflections should be carefully avoided.

All communications should be accompanied with the proper name and address of the writer—not necessarily for publication, but as a guarantee of good faith.

The Editor is not responsible for views expressed in this Department.

☞ *Correspondence should be in as simple language, and as free of technical terms and formulæ as possible, consistent with clear solution.*

Questions on subjects not directly connected with mining will not be published.

Ventilation.

Editor Colliery Engineer and Metal Miner:

SIR:—Please insert the following question in your valuable paper.

A mine employs 400 men and boys, and 400 mules. The amount of air for each man and boy is 100 cubic per minute and for each mule 400 cubic feet per minute. The area of airway is 8 ft. sq. and 6000 ft. long, and one-third of the air is lost through friction of the mine and fan. The fan going at 85 revolutions per minute, what is the diameter of the fan?

Yours, etc.,

Ladd, Illinois. G. H.

Ventilation and Arithmetic.

Editor Colliery Engineer and Metal Miner:

SIR:—Please insert the following questions in your valuable paper for some of your readers to answer.

(1.) What would be the area of an airway to pass 50,000 cubic feet of air per minute if 20,000 cubic feet is passing through one 5′ by 4′ or 20 feet area?

(2.) What is understood by the formula $(3)^{\frac{3}{2}}$? Work out and explain.

Yours etc.,

Port Morien, July 17, 1895. A. McDONALD.

Coal Dust Explosions in Lignite Coal Mines.

Editor Colliery Engineer and Metal Miner:

SIR:—I noticed an article in the June number of THE COLLIERY ENGINEER AND METAL MINER by W. S. Carr. I have every reason to think that Mr. Carr believes in the dust theory as far as bituminous mines are concerned but he doubts the possibility of such explosions to occur in lignite mines.

The purpose of this article is to prove to Mr. Carr that such explosions do occur in lignite mines in this country. On the 9th day of October 1894 an explosion occurred in one of the leading mines of the State of Washington, whereby four men were killed. The coal worked at this colliery is lignite. No fire damp was ever found before nor after the explosion. I have never met a man yet, that is acquainted with this mine, who does not believe that this was a genuine coal dust explosion. The flame could be easily traced for a thousand feet, 700 feet in a westerly direction, and 300 feet in an easterly direction from point of ignition.

Coal dust explosions occur as often in the lignite mines as in the bituminous mines, in proportion to their number.

Another example of this class of mines is the Black Diamond Coal Co., of Mount Diablo, California. An explosion occured at this mine in 1876, when eleven men died from the effects of it. Several minor explosions occurred at this colliery and to get burned was almost a sure death. There was no fire damp found in this mine either.

Yours etc.,

Tacoma, Wn., June 27. 1895. JOSEPH JAMES.

Nova Scotian Examination.

Editor Colliery Engineer and Metal Miner:

SIR:—Referring to the June number of your valuable paper and to your solution of the question from Nova Scotia, you say: "Drawing the right angle triangle *A B C* and assuming the hypothenuse *A C* as 25 feet, and the area 100 square feet."

Now I allege the forgoing construction, from any geometrical stand point, is faulty, if not quite impossible to say the least, and I wish to submit the following as being far more correct: Lay off a line *A C*, 25 feet long, and upon it draw the right angled parallelogram *A C G F* equal to twice the area of the triangle it is desired to construct.

This figure would have a width of 8 feet = to *C G* or *A F*. Upon *A C* draw a semi-circle *A B C*, and join the points *A B* and *B C*. The triangle *A B C* being in a semi-circle is right angled; its elevation *B D* = *G C* = 8 feet, and its area is 100 square feet, which fulfils the conditions of the question.

By representing *A D* by *y* and *D C* by *z* the unknown sides to this triangle are very easily and briefly calculated.

Yours etc.,

Philipsburg, Pa., June 24, 1895. A. V. HOTT.

Removing Gas.

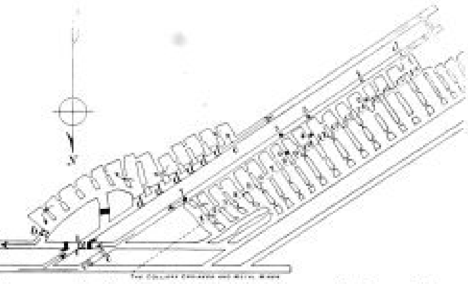
Editor Colliery Engineer and Metal Miner:

SIR:—Please insert the following in your valuable paper in answer to query given by R. R. G., in your June 1895 issue.

As shown in accompanying sketch, I would make an overcast at *a*, hung doors on places marked *d*, and at *b* would place a regulator, so that the current being split at *e*, should have a sufficient volume to diffuse the gas pent up. I would erect a door at *d* in the upper heading outside of the hole at No. 18, and would keep it open until a cross cut was made from the heading into No. 15 chamber at dot 1, when I would close the door, and open trap door at No. 18 chamber. After the gas has been removed, a cross cut should be driven from No. 15 to No. 14 at dot marked 2, and while that is in progress, a cross cut should be driven at dot 3, from heading into No. 11 chamber, and after gas has been removed, I would start a cross cut from No. 11 to No. 10 at dot 4, and while that is being driven a cross cut should be driven from heading into No. 9 chamber, at dot 5, and after gas has cleared, a cross cut should be driven from No. 9 to No. 8 chamber, at dot 6, and at the same time, a cross cut should be made from the heading into No. 1 chamber, at dot 7. After the *pent up gas* has been removed, the cross cuts, dots 1, 3 and 5, should be walled up with a strong brick wall, thus leaving but one inlet into the flooded district at No. 18. and one outlet from same at No. 1. Great care should be exercised in the selection of men for that class of work, none but well experienced men in their different callings should be permitted to work in that district.

Yours etc.,

Nanticoke, Pa. WM. H. THOMAS.



a, OVERCAST; *b*, REGULATOR; *c*, DOUBLE DOORS; *d*, SINGLE DOORS; *e*, SPLIT; ■, BRICK STOPPINGS; ● 1,2,3,4,5,6,7, PROPOSED CROSS-CUTS.

PRIZE CONTEST.

PRIZES GIVEN FOR THE BEST ANSWERS TO QUESTIONS RELATING TO MINING.

For the best answer to each of the following questions, the value of $1.00 in any of the books in our book catalogue, or six months' subscription to THE COLLIERY ENGINEER AND METAL MINER.

For the second best answer to each question, the value of 50 cents in any of the books in our book catalogue, or three months' subscription to THE COLLIERY ENGINEER AND METAL MINER.

Both prizes for answers to the same question will not be awarded to any one person.

Conditions.

First—Competitors must be subscribers to THE COLLIERY ENGINEER AND METAL MINER.

Second—The name and address in full of the contestant must be signed to each answer, and each answer must be on a separate paper.

Third—Answers must be written in ink on one side of the paper only.

Fourth—"Competition Contest" must be written on the envelope in which the answers are sent to us.

Fifth—One person may compete in all the questions.

Sixth—Our decision as to the merits of the answers shall be final.

Seventh—Answers must be mailed us not later than one month after publication.

Eighth—The publication of the answers and names of persons to whom the prizes are awarded shall be considered sufficient notification. Successful competitors are requested to notify us as soon as possible as to what disposal they wish to make of their prizes.

Competition Questions for July.

QUES. 169. Our mine is situated in a region where clean soft water cannot be obtained for feeding the steam boilers, and we are therefore obliged to get our supply from the underground feeders that are highly charged with sulphate of iron, and as you no doubt expect, the boilers last a very short time and entail on us expense that we wish to avoid if we can. One of our operators has returned from South America and he says a mine superintendent there can neutralize sulphate of iron with common salt and he thinks I should do the same. Will you then explain to me the chemical action that takes place when salt is thrown into warm water containing sulphate of iron and how it is that as the water cools sulphate of soda crystalizes on the bottom and sides of the tank; and I will also be obliged if you will explain to me the chemical action (if any) of soda sulphate on the shell of the boiler.

QUES. 170. A wealthy land owner has just granted me a lease to mine a lignite bed 10 feet thick and making an angle 70° with the plane of the horizon. The lease confers on me the right of way and the power to utilize any of the surface or underlying strata. The surface is on a bed of sand 20 feet thick and at first sight that would appear to be an unfavorable condition, but the lignite coal is good, and can secure an open market at a high price; we have however certain difficulties that must be overcome in the mode of working; for example, this coal is exceedingly subject to spontaneous ignition, and any small in the gob, or pillars left in, takes fire as soon as subjected to increased pressure. Therefore we must extract the *whole* of the coal, and I wish you to instruct me how to do it with the use of very little timber, at a small cost per ton, and with safety to the miners. To secure a good plan, think over all the modes of *vein* and *bed* mining in general use.

QUES. 171. I am the principal director of a mining company, and we have the choice of one of two mine properties, and in either of which, we could work the same valuable seam of bituminous coal at a depth of 900 feet. There are two seams of coal overlying the one we wish to work and we will call the bottom one No. 3, and the one above it is No. 2, and the top one No. 1. All the seams are lying level and their depths are, No. 1, 450 feet; No. 2, 630 feet; and No. 3, 900 feet. Between Nos. 1 and 2, is a bed of coarse sandstone that sheds much water, and in one of the offered properties *A*, the top seam has been all worked out, but in the other property *B*, none of the seams have been worked. I will therefore deem it a great favor if you will say which of the properties *A* or *B* would be the safest investment, and for what reasons?

QUES. 172. In prospecting for coal, rotary tube boring is the best, because the cores furnish fine examples of the fossils peculiar to the strata in question. This being so, will you tell me the names of some of the fossils peculiar to Permian and Silurian rocks; for example, suppose you are boring in a bed of fine shale, and the core when broken shows a featherlike fossil, made up of cells arranged in regular order, after the manner of the structures of the hydrozoa. Which formation would that shale belong to? and what is the general name of that variety of fossils? Again you are boring in a limestone, and the core when broken shows several examples of a starlike netted structure, something like a spider's web, and undoubtedly belonging to the hydrozoa, which formation is this? and what is the name of the fossil in question?

QUES. 173. For the purpose of haulage in a level seam, a branching road has to be made, at a right angle with the main entry, and we have to make the connection with a curved entrance, the radii of which are to be 22 feet for the inside, and 29 feet for the outside of the curve. Give a plan with all the necessary explanation of how you would proceed to secure the correct curvature for this junction.

QUES. 174. My Uncle George is a mine superintendent and he asked me to-day if I had given due attention to the study of mine machinery, and steam engines and boilers? and I said oh! yes, I know all about them, and nobody can teach me any more than I know; and he said, "hem," and continued, solve me this question and let me have the answer in a few days.

We have a semi-portable hauling engine in the Burdock mine, and it is rather light for the work, and therefore, always runs with full steam. It is 80 horse power, and the highest pressure of the steam at blow-off is 90 pounds on the square inch.

The train has a speed of 10 miles an hour on the level road when the steam pressure falls to 50 pounds on the square inch, and on coming within 850 yards of the shaft the train of cars has to ascend an incline, when the speed reduces and the pressure of the steam in the boilers rises to 90 pounds on the square inch. Now the boiler fire (before the start) is banked up to keep the horse power of the boiler uniform throughout the journey.

The question makes three demands:

1st. Why does the boiler pressure vary?

2nd. What is the gradient of the incline?

3rd. What is the speed of the train on the incline?

I frankly confess, I have made a mistake in bouncing to my uncle George, and I hope you will help me out of the dilemma by answering the questions for me.

Solutions to Questions which Appeared in the June and Previous Numbers, and for which Prizes Have Been Awarded.

QUES. 137. It is said you can measure the velocities of air currents in mines with a thin light pine board 2 feet deep, 1.5 feet broad, and a ¼ inch thick, and weighing 3 pounds. The board is suspended at the top corners with two pieces of fine twine, tied to the top timber. The air current blows the bottom edge of the board out of line with the plumb-line hung up close to one side of it, and the velocity is found from the pressure per square foot of the moving air. Can you tell me three things: First, is the force producing the deflections of the board, proportionate to the sines, or the tangents of the vertical angles? Second, what is the velocity of the air current to deflect the board 42°, and how would you find the angles of deflection, with only a two-foot rule for a measure?

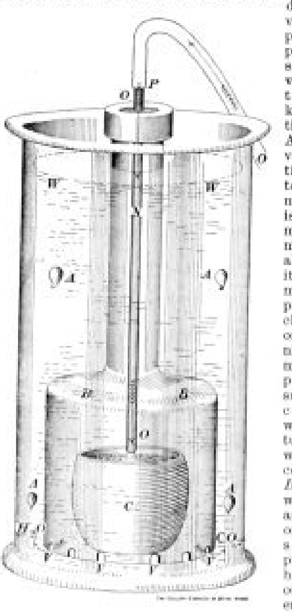
ANS. The force producing the deflection of the board is proportional to the tangent of the vertical angle of deflection, because if the surface of impingement always made a right angle with the direction of the current, the force would be proportionate to the sine of the angle, but the surface of impingement is canted, and therefore its effective surface varies as the cosine of the verticle angle and the force required for deflection is therefore $\frac{\text{sine}}{\text{cosine}} = T$.

Tangent of 42° = .900404 and $\frac{v^2 W}{2g} = F$. Now F is equal to the foot units of the force, and as the area of the board is 3 square feet and the weight of the board is 3 pounds, the weight per square foot is 1 pound, and the foot units required are $\frac{\text{Tan. } 42° \times 1.}{.076} = F = \frac{.900404 \times 1}{.076} = 11.847$. Again $\sqrt{F \times 2g} = v$, then $\sqrt{11.847 \times 64.32} = 27.605$. That is, the velocity of the current is equal to 27.605 feet per second. To find the angle of deflection measure a line from (and at a right angle with) the plumb line to the bottom edge of the board.

ADOLPHE COOK,
Houtzdale, Pa.

QUES. 157. You have given to you 23 grains of an average sample of coal, to find its evaporative power. Will you explain to me, however, before you begin, how you will proceed to do it, and further tell me how it occurs, that some samples of bituminous coal, show a greater evaporative power than some samples of anthracite coal, notwithstanding the fact that average samples of anthracite, have a greater evaporative power than average samples of bituminous coal.

ANS. To determine the evaporative power of coal, an instrument called a calorimeter is used of which the drawing is convenient for practical purposes. It consists of a glass vessel containing a known quantity of water. A weighed invariable quantity of the coal to be experimented with, is intimately mixed in a mortar with about ten times its weight of a mixture of 3 pts. potassic chlorate and one of potassic nitrate. This mixture is placed in a small copper cylinder C, which in its turn is covered with another copper vessel $B\,B$, furnished with a tube and stop-cock on the upper side, and pierced with holes V, V, V, on the lower end. A fuse is placed in the smaller cylinder containing the mixture, this is lighted, the stop-cock closed, and the apparatus let down to the bottom of the graduated flask containing the water. When combustion has ceased, the stop-cock is opened and the apparatus moved gently up and down, care being taken not to raise it out of the water. The temperature is noted at the beginning and end of the experiment, and from a table supplied with each instrument, the calorific power is found. The rise of the temperature, plus ten per cent. of this rise will give the number of pounds of water which 1 lb. of coal will convert into steam from and at 212° F. I should separate the coal given into as many parts, so that the mixture would very nearly fill my copper cylinder, the more tests taken a better average result could be found, and proceed with each experiment as given in the above description.



Some sample of bituminous coals that contain a small percentage of ash, show a higher evaporative power than some samples of anthracite coal that contain a high percentage of ash.

H. K. MOBERLY,
West Newton, Pa.

Second Prize, JOSEPH VIRGIN, Holsopple, Pa.

QUES. 158. I am a mine foreman, and the superintendent offers me promotion if I can obtain by skillful mining, all but ten per cent. of the coal in a given district that measures in plan, 200 by 300 yards. The seam is a bituminous one, 6 feet thick, and of moderate hardness; the roof stone is firm and strong but the floor is soft and tender, the under shale being as thick as the seam

Will you assist me with your advice by making it quite clear how I should proceed and be successful in working this coal at a depth of 600 feet from the surface?

ANS. I would work this coal by bord and pillar, and make the bords 120 feet long and 12 feet wide, and the headings 75 feet long and 6 feet wide. This would leave pillars having a base of 1,000 square yards, to rest securely on a *thick soft* bottom.

Having reached the boundry limits I would first commence to draw out the flanking pillars, and take great care to keep a long face on all the pillars in line, and to prevent a squeeze by subsidence into the soft bottom I would secure the face with chocks.

GEORGE BROWN,
Falls Creek, Clearfield Co., Pa.

Second Prize, H. K. MOBERLY, West Newton, Pa.

QUES. 159. I am about to try some experiments in the old workings of a certain district in a coal seam, where the coal has all been extracted and the roof and the floor have not yet broken. This vacant space measures in plan 250 by 312 yards, the area of the roof and floor being that of a rectangular parallelogram. To escape the risk of being lamed or killed, will you tell me, first, what will occur when the floor and the roof yield, after I have set up twelve props near the center of this space; second, what will take place if the coal face on all the four sides is timbered by props 6 feet apart and twelve feet from the coal face; third, what will occur if I set up back lines of props six feet apart, and twelve feet behind the face props, when the roof breaks? The seam is level; 6 feet thick, and 700 feet deep.

ANS. First, the center props will act like a buttress, and throw the weight of the cover unto the face.

Second, the row of props 12 feet from the face, will throw the weight onto the roof far into the goaf and cause a cave.

Third, the second row of props will tilt the weight over onto the coal fa e, and thus crush the side coal and and break the face props.

GEORGE BROWN,
Falls Creek, Clearfield Co., Pa.

Second Prize, JOSEPH VIRGIN, Holsopple, Pa.

QUES. 160. The main entry or gangway in a coal mine runs level along the strike of the inclined coal seam, and for facility in the haulage, a road has to be made along the pitch of a grade of 20 per cent. The junction of the main entry with the haulage road on the pitch, has to be made with a curve of 29 feet mean radius, and I will deem it a great favor if you will tell me how high the floor of the curve is above the floor of the main entry at 6 points equally distant along the line of the curve, and measured from the zero point where the curve begins in the main entry?

ANS. The six points along the curve being equidistant, will be 15° apart, then call them a, b, c, d, e and f and the point of junction, zero, then

zero to a = 15°
" to b = 30°
" to c = 45°
" to d = 60°
" to e = 75°
" to f = 90°

The heights of the different points above zero level will be proportionate to the versed sines of the angles, as

15° versed sine of a = .0340742
30° " " " b = .1339746
45° " " " c = .2928932
60° " " " d = .5000000
75° " " " e = .7411810
90° " " " f = 1.0000000

The elevation at the top of the curve will be $\frac{20}{100} \times 20 = 4$ feet, and the heights at each of the points will be in feet.

a = .0340742 × 4 = .1362968 feet.
b = .1339746 × 4 = .5358984 "
c = .2928932 × 4 = 1.1715728 "
d = .5000000 × 4 = 2.0000000 "
e = .7411810 × 4 = 2.9647240 "
f = 1.0000000 × 4 = 4.0000000 "

JOSEPH VIRGIN,
Holsopple, Pa.

Second Prize, H. K. MOBERLY, West Newton Pa.

QUES. 161. I am told that I as a professional miner should be able to identify at sight the characteristic fossils of the Carboniferous formation, and those of the formations directly above and beneath it, such as the old red sandstone and the Permian and new red sandstone. And I am dilligently seeking the knowledge required.

Some say that the fishes of the old red sandstone had peculiar tails, and they were covered with peculiar scales, will you please explain to me all these peculiarities as exemplified in four examples of the fishes of the period.

ANS. The fishes of old red-sandstone period had heterocercal tails that were vertebrated, that is the vertebral column was continued into the upper lobe of the tail, like the sharks and sturgeons in our seas now. These fishes where also placoid and their plates or scales were ganoid, that is, the horney scales or plates on the fishes had a pearly lustre.

Example 1. The *cephalaspus* of the lower series is remarkable for the great enlargement of the bony enameled plates of its head, that formed a kind of defensive shield.

Example 2. The *asterolepis* a very savage fish from 20 to 30 feet long, and coated with small placoid scales similar to the shark.

Example 3. Found in the upper series; the *holoptychius* a very large fish, distinguished for the peculiar wrinkles on its ganoid scales.

Example 4. The *pterychthys* of the upper *old red sandstone*; a remarkable fish having only *one* pair of fins, which extended from each side of the body like a pair of oars.

JOSEPH VIRGIN,
Holsopple, Pa.

Second Prize, THOS. WEST, Sherrodsville,
Carroll Co., O.

QUES. 162. How do you account for the fact that if one endless rope haulage is one mile long, and another is ten miles long, and the cars on the ropes of one haulage run at the same velocity as the cars on the other, that as many coals arrive at the shaft by the long, as by the short haulage in equal times, and with the cars at equal distances on the ropes?

While you are busy, please calculate for me the horse-power required to haul out with an endless rope haulage, 600 long tons in ten hours, the road having an upgrade to the shaft of 13 in 150, and a length of 1,500 yards.

ANS. There are ten times as many cars on the long haulage as on the short one, and the large number is moving at the same speed as the small one, consequently ten times the *number* is the exact equivalent of the small number moving with ten times the *speed*.

To find the horse-power notice that the cars will weigh as much as the coals there being two cars for one load, and taking the traction for coals, cars, and rope to be .013 of the load, and the modulus of the engine and sheaves to be .7 we thus find the H. P.

The descending cars are balanced by the ascending ones, therefore, the load only is raised, and the strain due to the grade is $\frac{600 \times 13}{150} = 52$ tons, and the strain due to traction only is, 1,200 × .013 = 15.6 tons, and the total strain is 15.6 + 52 = 67.6, we therefore find the horse-power to be

$$\frac{67.6 \times 2{,}240 \times 1{,}500 \times 3}{600 \times 33{,}000 \times .7} = 49.164 \text{ H. P.}$$

GEORGE BROWN,
Falls Creek, Clearfield Co., Pa.

Second Prize, WILLIAM DONALDSON, Kangley, Ill.

Electric Traction in Belgian Collieries.

The old horse tramway at the Amercoeur Colliery at Jumet, in the Charleroi district of Belgium, has recently been replaced by an electric tramway. The line is about a mile long, with a fairly uniform slope throughout in the direction the loaded trucks are taken of 2.7 mm. per metre, the gauge of the line being 1.64 ft. The line communicates between the Chaumonceau and Belle Vue shafts by a sloping gallery, at a depth of about 30 yards from the former, and is used for conveying the coal obtained in the Chaumonceau pit to the second-named, whence it is conveyed to the sorting plant. The first locomotive was put in use in July, 1893, and proved so successful that an order was given for a second one of an improved type. The first locomotive was designed for the haulage of 300 trucks per ten hours each train consisting of fifteen trucks, the normal speed being five miles per hour. It is 13 ft. long, 3 ft. 10 in. wide, and 3.77 ft. high. It has four wheels, and its total weight complete is 3 tons 2 cwt. 96 lb. The second one is 14.95 ft. long, 3.28 ft. wide and 4.34 ft. high, its weight being 4 tons 8 cwt. and 44 lbs. It has eight wheels arranged in two bogies, suspended on spiral springs. It was designed for the haulage of 400 trucks per ten hours, each train comprising twenty trucks, the speed being 5 miles per hour. The feature of this installation is that it is on what is known as the acumulator system, the supply of electrical energy being stored upon the locomotive, and not taken from conductors on the journey. The necessary electrical energy for charging the accumulators is supplied by the plant on the surface employed for the electric lighting of the pit bank, offices and works. It is conveyed down a service shaft by an insulated cable. Both locomotives carry a battery of Julien accumulators, comprising thirty-six cells. These are placed in ebonite boxes closed by a removable cover of the same material, and arranged in a chest on the framework of the locomotive. In the first locomotive the motor is in the center and runs at 1,020 revolutions per minute, while the wheel of the locomotive makes eighty-five revolutions per minute, so that the ratio is as 12 to 1. In this case the motor transmits its power to an intermediary shaft by means of wheels gearing in the ratio of 5 to 1, this intermediary shaft communicating with the axles of the locomotives by chain wheels and pitch chain. The second locomotive, however, has two motors, one connected to each bogey. These motors run at 680 revolutions per minute, this being reduced down by epicyclic gearing to eighty-five revolutions per minute of the wheels of the locomotive. The locomotives have platforms at each end, one of these only, however, being provided with starting and stopping arrangements, etc. Ample brake power and safety arrangements are of course provided. Unfortunately, accurate particulars as to the cost of working of the now defunct horse tramway at this time are not available, but from a careful estimate it may be put down at 1½ d. per metrical ton-kilometre. The cost of working by the first electric locomotive, works out at ¾ d. per metrical ton-kilometre, while that of the second and improved locomotive is only ½d. It may be added that the plant and locomotives were supplied by La Societe Electricite of Brussels, which concern is exhibiting a duplicate of one of the locomotives at the Antwerp Exhibition.—*Colliery Guardian.*

Coal in China.

A British consular report from Ichang states that no coal appears to have left the port during 1894, t ough in 1893, when there was seemingly less demand for it, there was an export of 10,937 piculs, valued at 3,255 taels (a tael = $1.). It is found in a number of places not far from Ichang, but the methods employed for its excavation are primitive and the mines are only workable during the dry season. When the rains set in they become flooded, and the owners have no means of pumping them free of water. No foreign machinery is employed, and, indeed, it is doubtful whether it would be tolerated by the country people, who still regard such innovations with superstitious dread. In the neighborhood of Ch'ang-yang coal is produced, some of the mines having a daily output of 30 or 40 tons of good anthracite coal. The royalty paid to the provincial government is said to be 10 tons out of every 40 tons brought to the pit's mouth. An expert in such matters, who has had long experience in the K'ai-p'ing mines, near Tientsin, gave it as his opinion recently that the country was rich in coal and only needed foreign appliances to make the production remunerative.

Did you ever stop to think why oil barrels are painted blue? Well, in making the barrels they are thoroughly soaked in water, then they are painted blue, as this is the best pigment which will hold the oil. Then when the cask is full you have oil on the ins de and on the outside with water between them, and oil won't come through water.—*Cooper's Journal.*

The Colliery Engineer

AND

METAL MINER.

ESTABLISHED 1881, INCORPORATED 1889.

PUBLISHED MONTHLY AT SCRANTON, PA.

WITH WHICH IS COMBINED THE MINING HERALD.

Entered at the Post-Office at Scranton, Pa., as second-class matter.

APPOINTMENT OF PENNA. ANTHRACITE MINE INSPECTORS.

THE examing board for Mine Inspectors for the Third, Fourth and Fifth Anthracite Inspection Districts of Penna., has completed its work and recommended for reappointment Messrs. Hugh McDonald of the Third District and G. M. Williams of the Fourth District.

In the Fifth District, Mr. John M. Lewis the recent inspector was beaten by Mr. James Roderick who resigned the office in 1889 to accept the superintendency of Messrs. Linderman & Skeer's Stockton collieries. While the State will secure in Mr. Roderick an official who made a splendid record during his former incumbency of the office, and a man who is recognized as one of the ablest practical mining men in America, we regret that Mr. Lewis, also a very able and conscientious official loses the position. In fact, it is a pity that the State can't have the services of both the gentlemen.

In the recommendation of Messrs. McDonald and Williams for reappointment, the State will continue to profit by the services of exceptionally good men. The coming term will be the fourth term for Mr. Williams and the third for Mr. McDonald. At the close of the term, Mr. Williams will have served the State twenty years as an inspector, and Mr. McDonald will have served fifteen years.

MINING MACHINERY FOR JAPAN.

THE following note from *The Mining Journal*, (London, England) is significant:—

"The makers of mining, rock-drilling, and other machinery should be informed of an important and novel step which the Government of Japan have just taken with a view to placing the Japanese people in direct communication with manufacturers in this country of goods likely to be needed in increased quantities under the new conditions of development which are likely to result from Japan's recent notable victories. One of the earliest requirements is certain to be in the direction of largely-augmented quantities of machinery of all sorts needed to assist in the further rapid industrial progress to which there is every evidence the Japanese have made up their minds. Mining, as well as other engineering plant, will be in extended demand. Hence the advisability that our mining machinery firms should be acquainted with the course the Government have taken. Mr. E. Perrot Forshaw has been appointed by the Mikado's Government to visit this country and propound a scheme "for better inter-working between Japanese merchants and others and British manufacturers direct." All financial arrangements are to be amply secured by the chief Japanese bank. The exact details of the proposal are not yet before us, but these, will, no doubt, be available as soon as Mr. Forshaw arrives in this country. In addition to manufacturers, the Chambers of Commerce and other of our trading bodies are to be interviewed and everything is to be done to promote direct trading. Mining machinery firms should be keenly on the look-out for the earliest expounding of Mr. Forshaw's commission."

It is evident that British manufacturers will make a strong effort to control the trade in machinery in Japan. With the cordial relations existing between the United States and Japan, together with the position of Great Britain during the recent China-Japan war, when, while not actively hostile to Japan, her sympathies were certainly with China, makes the present an excellent time for American manufacturers of mining machinery to endeavor to secure a large portion of the Japanese trade. But simply sitting still and waiting for the Japanese to come to us for mining appliances will not do. Active and well considered efforts should be made to bring them here. Our consular service should be instructed to aid in the work, and the same methods used by the British to capture trade should be pursued. With the good will of the Japanese people and the best mining machinery in the world, American manufacturers possess a great advantage over those of other nations. Will this advantage to followed up?

DEATH OF JAMES LEIBERT.

WE regret to announce the death of Mr. James Leibert, formerly chief clerk for THE COLLIERY ENGINEER Company. Mr. Leibert was a gentleman in whom the officers of the company had the utmost confidence and whose business ability was of a very high order. He was the only son of the Rev. Eugene M. Leibert, a Moravian clergyman who for twenty-five years was principal of Nazareth Hall, a Moravian academy for boys (the oldest institution of the kind in America) at Nazareth, Pa.

Mr. Leibert was born at New Dorp, Staten Island, N. Y., on September 23d, 1865, while his father was stationed as pastor of the Morvian congregation at that place. He received his academic education at Nazareth Hall from which institution he graduated in June, 1878. In the fall of that year he entered the Moravian College and Theological Seminary. He took the full classical and theological course and graduated with the degree B. D. on May 16th, 1884. After completing his education Mr. Leibert felt that the theological profession was not his calling and he therefore entered Nazareth Hall as a teacher within a month after his graduation from college. He developed great talents as a teacher and exercised a wonderful control over his pupils. It was while filling this position that he attracted the attention of the officials of THE COLLIERY ENGINEER Company.

When Rev. Eugene M. Leibert retired from the principalship of Nazareth Hall his son James likewise resigned his position and accepted the position of chief clerk in this office. During the early part of the winter of 1893-4 he was afflicted with an attack of the Grippe which developed into pulmonary tuberculosis. He was finally compelled to tender his resignation and return to his father's home in hopes of therein fighting off the disease by rest and care. Everything that the most skilled physicians and the loving care of devoted parents could do was done to stay the course of the disease, but in vain. He gradually grew weaker and finally, on the evening of July 4th, he passed peacefully away. Up till within a few months of his death Mr. Leibert entertained strong hopes of recovery and anxiously awaited the time when he could return to his work.

During his comparatively brief residence in this city he won many friends and was so popular that he was elected president of the Scranton Bicycle Club, one of the strongest and most influential organizations of wheelmen in the State. He was a member of the Masonic Fraternity and took great interest in Masonic literature, land-marks and traditions.

THE PROPOSED AMENDMENT TO THE BRITISH MINING LAW.

AS Great Britian for many years led the rest of the world in coal production, she also led in the enactment of laws intended to protect life and property in mines. As a consequence other nations profited by British experience in mining legislation, and even at this time the action of the British government in regard to such legislation is of interest to American mining men.

An effort to amend the British Mine Law of 1887 has recently been made, and to give our readers an idea of the proposed changes and a discussion of the advisability of making such changes, we employed a prominent English mining engineer and colliery manager to give us an opinion on the matter at issue. The gentleman to whom this duty was assigned is a man who thoroughly believes in rational mining laws, and whose years of experience, and deep knowledge of the history of mining legislation makes him a competent person to express such an opinion.

In arriving at a correct idea as to what is required in mining legislation, the natural difficulties incident to coal mining must be carefully considered. These difficulties our correspondent enumerates as follows:

1. Operations in connection with the search for coal, and removing it when found, from its bed or seam.
2. In all underground operations, there is the superincumbent strata to be considered, and the portion of this in the immediate vicinity of the coal is a constant source of danger, and always a certain amount of cost in supporting it.
3. The presence of poisonous and explosive gases and coal dust in many mines requiring artificial ventilation.
4. The necessity for artificial lights and of such a construction in mines where fire-damp is found, as to prevent explosions.
5. Difficulties in connection with water.
6. Difficulties in connection with the haulage of the coal from the working place until it is placed in railway wagons, etc.
7. Difficulties in connection with blasting.

All the accidents which happen in or about mines arise from difficulties which are included under the above heads, except those which occur on the surface works, where the dangers encountered are not exceptionally great. For the sake of convenience they may be tabulated in the same method as adopted by the Inspectors of mines in their annual report as follows:

1. Explosions of fire-damp and coal dust.
2. Falls of roof and sides.
3. In shafts.
4. Miscellaneous underground.
5. Above ground.

It has been suggested as desirable to include in the Inspector's reports, in case of an accident, the apportionment of the blame attachable to the management and to the workpeople separately, but there are obvious difficulties in the way of arriving at this correctly, especially having regard to legal actions which might follow, under the Employer's Liability Act.

Another reason which may be given as causing a desire on the part of the people for an amended Coal Mines Bill, is the intense public feeling produced after an accident resulting in many deaths, such as the explosion at the Albion colliery in South Wales on June 23rd of last year, when 290 lives were lost. This explosion has no doubt hastened the drafting of the amended Coal Mines Bill, which deals largely with protective measures against the dangers of coal-dust and fire-damp.

Wm. Robson, the Inspector of Mines for this district, says in his annual report, in reference to the Albion explosion:

"The Albion explosion on the 23rd June already referred to, having been the subject of special reports, and these reports having been printed and published, it does not appear necessary, to refer again to it at any length. I am still convinced that it was caused by blasting timbers, at the point mentioned in the special reports, viz. near the horse-dump dip, where the bodies of the overman, fireman, and the man in charge of explosives were all found.

"Upon the matter of blasting timbers, which was undoubtely practiced at the Albion colliery, although this was unknown to my assistants and myself, I think it is due to us, as Inspectors, to state that, for at least three years previous to this explosion, inquiry was made on each occasion of a general inspection, in every mine in the district as to (1) whether blasting was permitted, (2) what kind of explosive was used, (3) what the explosive was used for (4) how and by whom shots were fired, and (5) when fired, *i. e.* during shifts or between shifts. In no case did it come to our knowledge that such a thing as blasting timber took place in the Albion or any other mine in the district. Since the explosion, roburite has been substituted for the gelignite and gelatine-dynamite previously used, and no blasting is permitted except in rock, and this only between shifts. Spray jets have been introduced throughout the principal main roads."

He further says under the head of Prosecutions:—"Proceedings, arising from the inquiry held into the cause of the Albion explosions, took place, the charges being contraventions of the 12th General Rule, against the agent and manager in allowing shots to be fired, against the manager and the chargeman for storing explosive in the mine, and against the under manager for contravention of the 42nd Special Rule, in not seeing that officers and workmen under him properly discharged their duties during the night shift. After an investigation lasting two days, the manager was convicted and fined £10-0-0 for the second offence of permitting the storing of explosives; the chargeman £2-0-0 for storing explosives, while the charge against the manager for allowing shots to be fired contrary to the Act was dismissed, as was that against the under manager on a technical point. The remaining charge, that against the agent for allowing shots to be fired, was withdrawn.

"It is perhaps hardly necessary to observe, that in a case of this kind, where every person, who could, if alive, speak as to what actually took place, was killed, the prosecution labored under much difficulty, in trying to prove to the satisfaction of a court, that shots where fired while the men were in the mine."

The opinion expressed by Mr. Robson was that held by many other experts, as to the explosion having been caused by the blasting of timbers on a main haulage road, which was ordinarily very dusty, and particularly so at the time when the shots were fired, as a number of men were engaged removing the dust, so that the conditions existing at the time were very favorable to the commencement and spreading of an explosion by the firing of a shot.

To those readers who are not conversant with the Coal Mines Act of 1887 in England, it is necessary to explain that the 12th General Rule lays down the regulations with reference to blasting. The nature of the 42nd Special Rule explains itself in the charge.

With the evidence before the jury in this case, it seems very unfortunate that the manager escaped conviction under the principal charge, viz., that of firing shots on a main haulage road, which was dry and dusty, and so long as such contraventions of carefully drafted rules escape punishment, it is to be feared that disasters may continue, although the education afforded to managers who are sceptical as to the dangers of coal dust, by the explosion at the Albion colliery, should certainly make them careful to observe the law as it at present stands with reference to shot firing under similar conditions, even although they may not share the opinions of those who believe that coal dust under certain conditions, is a highly explosive agent.

This terrible accident is mentioned to show more particularly how useless legislation is if not properly carried out, and the question may with some amount of reason be asked, what is the use of a further mining law with reference to blasting, when the present one, if strictly enforced, is quite sufficient to avoid accidents?

If it had been carried out at the Albion colliery, there would certainly not have been an explosion to record with such a fearful death roll.

During the year 1894, the following lives were lost by fatal accidents in the coal mines of the United Kingdom:

1. Explosions of fire-damp and coal dust,	317	= 28.13	per cent.
2. Falls of roof and sides	444	= 39.39	per cent.
3. In Shafts	73	= 6.83	per cent.
4. Miscellaneous underground	177	= 15.71	per cent.
5. Above ground	112	= 9.94	per cent.
	1127	100.00	

But for the Albion disaster, the deaths from explosions would only have been 27 instead of 317, and the total would have been reduced from 1127 to 837.

From falls of roof and sides about 40 per cent. of lives are lost, taken over a long period of years. It is not so much additional legislation that will prevent this class of accidents, as increased care on the part of the officials and workmen themselves, in being careful to set sufficient timber to support the roof stone, as in many cases the accident is traceable to some want of necessary precaution on the part of the officials and workmen.

The ultimate objects of all Parliamentary regulations to control the working of mines in the British Islands are:

a. To ensure to the work people employed the maximum of safety.

b. To protect adult labor by regulating the hours they shall work, and the age at which they shall commence work in or about a mine.

c. To give to the work people, by the appointment of checkweighmen, facilities for ascertaining that they are being paid for the minerals gotten by them.

These objects are all aimed at in the Coal Mines Act, 1887, and the proposed new Mines Bill is intended to amend it, and is to a large extent due to the recommendations of the Royal Commission on Coal Dust, appointed in 1891.

The following is a summary of conclusions arrived at by this Commission:

1. The danger of explosion in a mine in which gas exists, even in very small quantities, is greatly increased by the presence of coal dust.

2. A gas explosion in a fiery mine may be intensified and carried on indefinitely by coal dust raised by the explosion itself.

3. Coal dust alone, without the presence of any gas at all may cause a dangerous explosion if ignited by a blown-out shot or other violent inflammation. To produce such a result, however, the conditions must be exceptional, and are only likely to be produced on rare occasions.

4. Different dusts are inflammable, and consequently dangerous in varying degrees; but it cannot be said with absolute certainty, that any dust is entirely free from risk.

5. There appears to be no probability that a dangerous explosion of coal dust alone, could ever be produced in a mine by a naked light or ordinary flame.

As before stated, the proposed new Mines Bill is based largely upon these conclusions, but having been drafted by men who are neither practical managers of mines nor miners, and as the Inspectors of mines opinions were not consulted in the framing of the bill, it may easily be understood that it requires altering in many important particulars before it can be ready for passing into law.

There have been several meetings between the representatives of owners and miners, with a view to arrive at a bill satisfactory to all, but there are still several points of difference.

The first section of the proposed new bill bristles with difficulties.

It is therein proposed to give to the Inspector power, if he thinks any mine dangerous, as being either fiery, dry or dusty, to serve a notification on the owner, agent or manager to that effect. After the lapse of fourteen days, if this notification is confirmed, such mine shall be subject to the provisions of the Act with respect to fiery or dry and dusty mines.

Under the Act the expression "fiery mine" means a mine or seam or part of a mine or seam, in the return air of which a dangerous percentage of fire-damp prevails.

What is a dangerous percentage of fire-damp in the return air? But this is a question to which in the present state of knowledge on the matter, no definite reply can be given. Under the varying conditions as to the presence of dust etc., the danger from gas also varies, and hence this is a very debatable point.

The expression "dry and dusty mine" means a mine or seam or part of a mine or seam, in which a dangerous amount of coal dust prevails. It is not by any means a decided point as to what may be called a "dangerous amount of dry coal dust," so that there is here further subject matter for dispute.

The power given to the Inspector under this section is not a desirable one, both because it is placing a responsibility on them personally, and more particularly so in those cases where their notifications afterwards form the subject of arbitration, and also because in the majority of districts the number of collieries is so large, that it is not fair play to any man, to place such a duty upon him. There are 3,419 coal mines in the United Kingdom or an average of 285 in each district.

The second section deals with the establishment of "Coal Mines Boards," one to be in each inspectors district, and composed of three persons. One of these, the chairman, shall be a person who is not and has not been, either a mine owner, manager or miner; another shall be a person who is or has been an owner or manager of a mine; and the third shall be a person who is or has been employed in or about a mine, and is not and has not been an owner or manager of a mine.

These District Boards shall be appointed until the end of 1898.

The principal duty of these Boards is that they shall adjudicate as to whether mines on which notifications have been served by the Inspector, if appealed against by the owner or manager, are in the terms of the Act "fiery, or dry and dusty." They will have power to enter and inspect mines or to authorize any person to do the same; to summon any persons as witnesses; to have all books, papers, plans etc., produced that may be considered necessary; and power to administer an oath and require any person to make and sign a declaration of the truth of the statements made by him. The Board may order how and by whom costs in any appeal are to be paid. Sections 3 and 4 also deal with the powers etc., of the District Boards.

Section 5 gives to the Secretary of State power to make special rules for the conduct and guidance of the persons acting in the management of any mine, subject to the provisions of this Act with respect to "fiery or dry and dusty mines," or employed in or about such mines, with respect to any of the following matters:

a. The lights to be used in the mine.

b. The description of explosives to be used, and the mode of storing the same, and the times at which, and the manner in which shots are to be fired; and the number of persons, (if any) to be permitted to remain in the mine whilst shots are being fired.

c. The watering or efficient damping of the mine, or any ways or places therein.

d. Generally the precautions to be adopted for the prevention of accidents from fire-damp and coal dust.

Any special rules made under this section shall be established unless the owner, agent or manager, or the miners or their representative do not within twenty days after the special rules are received by them, object to them in writing. If either side objects as described, the matter shall be referred to arbitration under the principal act.

Section 6 gives power to the workmen at any mine, where a matter is referred to arbitration, to appoint by a majority of two-thirds of their number, a representative to look after their interests on the Board of Appeal.

Section 7 refers to deductions for filling stones or substances other than the mineral contracted to be gotten, and need not be specially referred to here.

Section 8 refers to the appointment of checkweigher by the workmen, and a deputy checkweigher in his absence.

It also states:—"The facilities to be afforded to a checkweigher under Section 18 of the principal Act shall include a shelter from the weather, and a desk or table at which the checkweigher may write, and that the requisite number of cubic feet for two persons be allowed in such shelter, and a sufficient number of weights be provided at the colliery, to test the weighing machine."

It is only reasonable that the requests in this section should be granted, but even this may afford material for the District Board to adjudicate upon, for there may be differences of opinion between some owners and checkweighers as to the number of cubic feet capacity the shelter in the above should afford. The question as to the owners providing a shelter, has already been the subject of many differences in Scotland between the owners and the miners.

Section 9 refers to particulars to be furnished by the owner of a mine on its abandonment, to the Secretary of State.

Section 10 states that a safety lamp should not be used in any mine or part of a mine, unless it is the property of the owner of the mine, and no portion of any safety lamp shall be removed from any mine by any person, whilst the lamp is in ordinary use.

This will prevent men supplying their own lamps, or taking any part of them home, and is a very proper alteration.

Section 10 also states that "only clay or other non-inflammable substance shall be used for tamping."

These are the principal terms of the proposed new Mines Bill, but now that the Liberal Government is out of office, it will no doubt be shelved for a time.

If the Act of 1887 was more thoroughly carried out, such disasters as that at the Albion Colliery would not occur, and therefore there would be little necessity further legislation.

Written for THE COLLIERY ENGINEER AND METAL MINER.

"VENTILATION OF MINES."

Reply to Mr. Sperr, of The Michigan Mining School.

(By J. T. Beard, Ottumwa, Iowa.)

Mr. F. W. Sperr, of the Michigan Mining School, has written a second criticism of "Ventilation of Mines." We might pass over this second criticism, as having been already thoroughly answered in our former reply, but it is our privilege to close this involuntary discussion and we gladly accept Mr. Sperr's invitation.

We realize, moreover, the vital importance which the fair and unbiased determination of this question bears to mining physics and to physics in general; we realized all of this and anticipated the asking of just such questions as Mr. Sperr has raised, when three years ago we began the investigation. We have not been hasty in arriving at any conclusion and are not in any way alarmed but that the book will prove its own substantial defense. At present, the vital point at issue has received the endorsement of the Colliery Engineer and Metal Miner, which we consider the highest authority in American mining. Prof. Munroe, Professor of Mining in the School of Mines Columbia College, in his recent review of the book, takes no exception to the point at issue, but alludes to the book in words of the highest praise, when he says, "The author is qualified by education and experience to speak with authority"; and, futher, after pointing out some points in which he thinks the book could be improved, he adds, "It is perhaps captious and ungrateful to point out the shortcomings in a book which is in many respects one of the best that has yet appeared." The *Colliery Guardian*, London, Eng., in its review of the book, has only words of praise, alluding to its author as being "well fitted for the work he has taken in hand, having a love of his subject and a lucid style." These endorsements are alluded to here in passing, to show that the book has passed muster at some of the higher courts of criticism and established its right to an humble place in our mining literature; and now comes Mr. Sperr and tries to gainsay such right, by claiming that the fundamental principle has been wrongly stated. And, again, Mr. Sperr, by a play upon the common usage and acceptance of terms, endeavors to place the author in the absurd position of condemning his own work.

But, let us at once to the discussion of these vital points. Mr. Sperr asks that we explain the distinction between "*constant*" forces and "*uniformly accelerative*" forces. This we will do and make it so plain as not to be misunderstood. First, we understand *all* force to be the expression of an energy that is either inherent or developed. Second, such force may be either *constant* or *variable*; a force is *constant* when it continues to manifest a uniform intensity during all units of time. We are not concerned with the variable force at the present time. Now, a force may or may not be accelerative in its effect, this last depending upon the existing conditions or environment of the mass acted upon. (1.) The mass may be held intact, when the force acting upon it will manifest itself as a pressure or tension: such as gravity producing weight, or confined steam or gas, producing pressure. (2.) The mass may be impelled by the force against an opposing resistance. (3.) The mass may be free to move under the action of the force and opposed by little or no resistance. These three conditions under which force may act upon any mass are clearly set forth and their measure defined in Chapter II, "Force as Applied to Mine Ventilation." Now, if the force acts to increase the movement or velocity of the mass each unit of time, such force is accelerative in its effect and we term it an *accelerating* force (though this is slightly a misnomer, as the force may be a constant force). If this accelerative effect is uniform for each unit of time, we say the force is *uniformly accelerative*. Gravity acting upon a falling body is an example of a uniformly accelerative force; at the same time, it is a constant force. The steam pressure in the cylinder of an engine represents a constant force, moving at a constant velocity. Let us note the difference between the measures of these two types of constant forces; while the cylinder pressure acts under conditions that yield a constant velocity, the force of gravity acting upon the falling body yields an accelerated velocity:—The measure of the one is evidently Fv (v being the space passed over in a minute of time), (this measure being constant for all time); the measure of the other can only be taken for a differentiated unit of time (g being the space passed over during such unit of time) (this differentiated measure of the force is constant for each successive unit of time). And further, remembering that W or mg represents the force of gravity, and g the acceleration due to such force, Wg or mg^2 becomes the true measure of the force of the falling body, at the end of such unit of time; the work performed during such unit of time being $\frac{Wg}{2}$.

From these practical and familiar examples let us pass directly to the case of the centrifugal force (F) developed in one section of the fan. This centrifugal force is a constant force, as stated upon page 40, being developed from the uniform revolution of the same weight of air. The words to which Mr. Sperr has reference upon page 255 of the June issue should read, "were the velocity a constant velocity, etc.;" they refer to the velocity established by an accelerating force at the end of any unit of time, as not having been constant during that unit of time. Were this velocity a constant, instead of an accelerating velocity, Mr. Sperr's measure of the force, Fv, would be correct; the case would then be analogous to that of the cylinder pressure, or the moving pressure in the airway of a mine (Fv). Mr. Sperr rightly says that the equation (equa. 7, page 40)

$$u = F\frac{f}{2}$$

represents the work stored in a motor in developing a velocity f. And if stored by the fan, we ask, Stored how or where, if not in the established current and given out and responsible for the movement of that current through the airways of the mine? The movement of this air-current is the work of the fan and the work *stored* is the work *given out*, always in the dynamics of fluids. We do not know how there can be any question of this. The method adopted for the development of the fan formula (Chap. VI) approaches a practical differentiation of the work of the fan and its integration through the medium of the established *apv* of the airway. It reveals to us the important fact that the acceleration that a straight-paddle fan imparts to the contained air, in the establishment and maintenance of a current, may be expressed in terms of the velocity of the center of gravity of one section of the fan and the radius of that center of gravity, according to the equation (equa. 5, page 39)

$$f = \frac{v_1^2}{R_1}.$$

Again, in this equation, (equa. 5, page 39), v_1 represents the circumferential velocity of the center of gravity of one section of the fan. In the expression Fv, spoken of by Mr. Sperr, v represents a radial velocity due to the centrifugal force F, acting radially. Mr. Sperr confounds these two velocities when he says: "Since v varies as the $\sqrt{f}$, it varies as n, and Fv varies as n^3." This is not the case, as we said before. If the expression Fv is intended to represent the work of the centrifugal force, v is a radial velocity and varies as n^2, and the total work will then vary as n^4.

The vital point of difference upon which Mr. Sperr bases his whole criticism, in this regard, lies in his claim that "The fan acting with the force F, will start the air from a state of rest and continually accelerate its velocity until the resistances equal the force, when no further acceleration takes place. The velocity, then, is constant, and thereafter the work performed per unit of time is the force, F, multiplied by the space passed over in a unit of time, which space is represented by v." He then regards the force as as no longer accelerative and makes Fv its measure.

We will say in closing that the work of the fan is a continual work of acceleration, by which the inert air from the outside is transformed into an energized current. This work of transformation is continually going on; it is a continuous work of acceleration within the fan. And the measure of this work is as given by equation 7, page 40. Again combining equations 3 and 7, pages 39 and 40, we have

$$u = \tfrac{1}{2}\, mf^2.$$

This last equation agrees with the "fundamental principle," as enunciated by all the standard authorities. We quote from "Ganot's Elements de Physique," a profoundly simple work of upwards of 800 pages, as follows (page 38).

"*When a constant force acts on a mass so as to change its velocity, the work done by the force is equal to half the product of the mass into the change of the square of the velocity.*" The "change of the square of the velocity," for a unit of time, would be the square of the acceleration.

We will only add that Mr. Sperr has not quoted us right, when he says we admit that the tests applied were not "satisfactory and conclusive." We made no such statement, but did say that "The practical results arrived at have demonstrated beyond any reasonable doubt, their efficacy and the correctness of their trend."

We note in our experience that some investigators are easily satisfied with rough and approximate determinations and are prone to explain lack of conformity in their results, as due to this margin of exactness; while another often does himself a comparative injustice by the honesty of his expression. We will let the argument of the book answer the remainder of Mr. Sperr's criticism.

A Convenient Publication.

The Ohio Brass Co. of Mansfield, Ohio, has just issued a catalogue of electric railway supplies, which is called "Catalogue No. 3." It is a very complete and convenient publication which should be in the hands of every manager of a mine in which electric machinery of any kind is used. It is sent free on application.

THE PROGRESS IN MINING.

ABSTRACTS FROM THE PROCEEDINGS OF THE MINING SOCIETIES

And Journals of Europe and America, Illustrating the More Modern Developments in all Branches of the Mining Industry.

Cleaning and Concentrating Outcrop Iron Ores.—An article on this subject, by Walter J. May, has appeared in the *Colliery Guardian* and the reader cannot fail on due consideration to appreciate the importance of the matter from a mining point of view, for it is a fact, that an ore of poor yield is worth more near at hand, than a rich ore far off; and an outcrop ore of poor yield, may when assorted and dressed yield the highest percentage of metal of the finest quality. The object of the writer is to show how the value of outcrop ores can be increased and here are his plans.

Outcrop ores, however abundant, usually contain too low a metallic content to be worth working, while siliceous matters are often very high indeed, but where on examination these materials are found to be easily separable, and where sulphur and phosphorus are practically absent from the clean ore, it is worth while to consider such ores with a view to working them on a commercial scale. It is true that the value of the crude ore is a small one, but against the small value we have to set the small cost of working, which as opposed to underground working is a mere nothing, always providing that systematic and economical methods be adopted. In fact, as opposed to the underground working of low grade ores, the cost of working surface ore may be taken as from a fourth to a sixth of that underground, especially where there is little cover to be removed. Indeed, if one excludes the cost of uncovering, surface ore should be loaded into trams for less than 12c. per ton, the value for dressing ranging from 48c. to $1.08 per ton according to the amount of recoverable ore. Of course this refers to hematite ores, but others would have a considerable value in many cases, particularly where the means of transit are favorable, as often deposits occur which can be forwarded to the furnaces for a low rate if they could be made sufficiently high in metallic value. It must always be borne in mind that no matter what may be the metallic value of an ore, the cost of carriage is precisely the same, it costing just as much to convey a ton of 35 per cent. ore a certain distance as it does to convey one having a 60 per cent. metallic content, while the financial values are widely different. In fact, a 60 per cent. hematite in a clean state would find a ready sale, while the cost, if produced from some outcrops which the writer has inspected, would return a handsome margin of profit.

In conclusion, it is well to note that there is scarcely a low grade ore in this country but can be concentrated up to a high point of metallic content, and that profitably, if a sufficiently large supply of crude ore is provided and efficient plant is laid down, but in every case the plant must be suitable for the treatment of the particular ore in hand.

A Competive trial of Flue-heated Coke Ovens.—In Westphalia, Germany two of the most noted systems of flue-heated coke ovens have been put to a practical test, not only for by-products, percentage of coke, and speed of coking, but for the quality of the coke in actual use in smelting iron.

For the test a battery of 30 ovens was selected at each of two stations, and coals were brought from the same mine, and of first rate coking quality so that no doubt concerning the results could arise in reference to the coal used. The first battery consisted of 30 Otto-Hoffmann ovens with vertical heating flues and air-regenerators. These ovens are in use at Germania mine, the property of the Gelsenkirchen Mining Company at Marten, Westphalia. The second battery also consisted of 30 ovens belonging to the Carves-Hussener system and in use at the works of the Coal-distilling Company at Bulmke.

The trials commenced at 6 A. M. on the 7th, and finished at the same hour on August 18th, 1893. Total time 11 days or 264 hours. The time of coking each oven was limited to 48 hours. The trials were conducted under the inspection of controllers appointed by the competing companies.

The results are as follows: Highest temperatures of ovens, Carves-Hussener 1320° *C*; Otto-Hoffmann 1100° *C*. The following table is a test of coal and coke. *C-H* represents Carves-Hussener ovens. *O-H* represents Otto-Hoffmann ovens.

	O-H	*C-H*
Coal charged, tons	954.91	932.53
Water in coal, per cent	10.31	12.06
Coke drawn, tons	731.64	660.98
Water in coke drawn, tons	46.73	4.13
Total coke, (dry) tons	684.91	656.85
Percentage of yield, (dry)	80.65	81.10
Blast furnace coke, (dry) tons	609.89	616.21
Soft burnt	77.03	40.65
Water in blast furnace coke, per cent	6.35	.61
Water in soft burnt coke, per cent	6.49	.57
Percentage of blast furnace coke, (dry)	71.61	75.14
Percentage of soft coke, (dry)	9.04	4.96

31.67 tons less coal were charged into *C-H* ovens than went into the *O-H* ovens.

The chemical and physical properties of the two

	O-H.	*C-H.*
Ash, per cent	8.90	9.20
Total sulphur	1.40	1.50
Specific gravity of solid coke	1.87	1.87
Porosity	52.20	56.00
Volume (solid) per 100 grammes	52.00	53.00
Moisture, per cent. at furnace	2.51	5.14

classes of coke were determined by Dr. Thomer of Osnabruk, and were as shown above.

The manager at the smelting works considered the Carves-Hussener coke was the best.

A Creep in a French Coal Mine.—A translation of an article in the *Annales des Mines* by M. E. Coste lately appeared in the *Colliery Guardian*, and M. Coste seems to think that what occured in Montrambert colliery was unusual, whereas in fact the movements referred to, have been common experiences wherever deep mining has been practiced. The title of the article is "Alteration of Coal due to Subsidence," and as the description is well done, and cannot fail to give our readers that have never seen a creep a graphic idea of one, we give M. Coste's article with a qualifying remark, that where the "slack" or dust coal is gobbed, the outrush of air and gas from the goaf when the roof and the floor close, carries with it a stream of fine particles of coal, and hence the deposit referred to. The "earthquake" and the "noises" are well known, and require no further notice.

"In May last a sudden disruption of strata amounting to a small earthquake, occurred at the Montrambert colliery, Loire, France, producing an unusual crushing effect upon the coal. The working area is about 2,200 feet long, and the seam is 5 feet thick at one end of the lease, and thins down to 3 feet 6 inches at the other. Overlying the coal is a roof of coal-shale averaging 20 inches in thickness and above that a strong sandstone, while the floor consists of a highly siliceous fire-clay. The stalls had been carefully packed, but the roads leading to them were not fully gobbed. Loud detonations have been sometimes heard, tolerably rare as the lower portion of each panel is being worked, but becoming more frequent as the working advances. In 1888 a sudden displacement occurred to either the roof or floor of the seam, causing a shock that was felt for a considerable distance.

"The noises recently heard were attributed to the fracture of the floor, and they often corresponded with shocks sufficient to throw down the props. On May 5 1895 a very severe shock occurred, cracking the timbers and accompanied with a violent rush of air. Fortunately nearly all the miners were out of the workings at the time, but most of the lights of the few men in the roads were blown out, and the men tossed about. The inspection showed that the roof and floor were nearer together than before, the shale of the roof had fallen in, and in places the roads were blocked, and the stalls nearly filled. In the disturbed area all the cleavage planes of the coal were opened, and the coal was so tender that a mere touch brought it down, and a thick cloud of dust was formed, which had not been the case before. A small bed of very fine coal dust was found next the floor, that was not there before the occurence. Everywhere the coal was found to be in a crushed state and very friable, and the commotion was felt at the surface."

Modes of Working Coal.—A paper on the above by Mr. J. B. Hanford of West Monterey, was recently read before a meeting of the Mining Institute of Western Central Pennsylvania, and was as follows:

It must be obvious, that a thick seam of coal will yield more than a thin one, and that the greater the yield per acre the smaller must be the costs per ton for making and keeping the entries, etc. These premises being granted, it follows, that a thin seam cannot be worked so cheaply as a thick one, and therefore, to make the working of a thin seam a profitable transaction, the very best methods must be adopted in the extraction of the coal. As the double-entry system can be worked cheaper than the single entry, I conclude from observation, that if double-entry is the cheapest system of working a thick seam, there is nothing to prevent it from displacing the single-entry system in a thin seam, and thus as far as the advantages of a good system of working are concerned, the thin seam would secure as good results as the thick one. It is true the cost of making double entries is considerable at first, but this extra cost is a good investment, because it is at all times a difficult matter to properly ventilate a thin seam and especially where single-entry is the mode of working, because the great number of doors required is a prime source of waste of air current; and again it is clear that the increased sectional area of the double entries secures an increased ventilation, free from the waste produced by doors. Now as the law provides for an "Ample ventilation." Article IV, Section 1, Act of Bituminous Coal Mines of Pennsylvania, and again Article II, Section 3 provides for two entries or other passage ways, inferentially and on the face of this, it is clear we cannot adopt the single-entry system. To show the aim of my contention, however, let us assume that we have a lease of 300 acres, the seam being 3 feet thick with 6 inches of draw slate, and resting on a soft fire-clay floor, the cover or overlying strata being 300 feet thick. Further let us assume that the mine is operated by a drift of 3000 feet along the butt line, and that rooms are turned off every 36 feet and that the mine is ventilated with a furnace which provides 200 cubic feet for every man, and 700 cubic feet for every mule, and let us see what will be the aproximate cost of extracting the mineral by each of the systems of working that now are before our attention.

Leaving out the constantly recurring expense of maintaining the doors and roads, we have roughly the following cost in in each case.

Driving one entry 3000 ft. at $1.75 per yard	$1750.00
Driving airway 3000 ft. at 75c. per yard	750.00
Lumber for doors and roads	123.00
Labor for erecting doors, etc	106.60
Ties and railing for track	600.00
Hauling coal	7248.00
Allowing 10 per cent for loss due to single track	724.80
Coal for ventilation	1445.40
Total Cost	$12747.80

If the rooms are driven 75 yards long the main entry will give a tonage per annum of 181,239 tons or the cost of the roads on one year's haulage is 7 cents.

Taking the dimensions of the drift as already given, but the entries as now 40 yards apart.

Two entries	$3500.00
Ties and railing	1200.00
Hauling coal	9272.00
Breakthroughs at 75c. per yard	300.00
Coal for ventilation	730.17
Total Cost	$15002.17

Total tons of coals per annum by double-entry 231,801 tons. Costs per ton 6.4 cents or a total saving of $5500 for the double entry system.

By leaving a large chain pillar, the coal will not be so much crushed, thus securing a larger per centage of lump coal.

Blown-out Shots.—An article on the above subject by James Ashworth, M. E., has appeared in a recent issue of the *Colliery Guardian*.

Mr. Ashworth's article aims at showing that the blasting powder at present in use, is an inferior and cheap preparation in which an excess of nitre is used in its composition, hence the dangers attending its use, for it is now an established fact, that, in the absence of fire-damp, if the carbonic oxide and flame from a blown-out shot is projected into air holding in suspension only a little coal dust, an explosion ensues which is the nucleus of a greater one, for if the first explosion raises a cloud of inflammable dust, the second one fills the mine with flame.

Mr. Ashworth further shows that nothing has yet been done to compound the three ingredients in gunpowder in such proportions as will insure complete combustion, as is nearly done, in the burning of *sporting* powder. He chaffs at the old, old story "75 per cent. nitre, 15 per cent. charcoal, and 10 per cent. sulphur," as the true, and best proportions for good service, and he shows, that it has been demonstrated that a better blasting powder and cheaper, and perfectly safe, can be made by increasing the proportion of charcoal, and correspondingly reducing the per centage of nitre. No doubt there are reasons for the unwise continuance of the old proportions in blasting powder, and three of them are as follows:

First.—Nitrate of soda is very cheap.

Second.—You wish to buy in the cheapest market.

Third.—Manufacturers compete in price.

It will be seen, however, that 8 ounces of gunpowder having its ingredients properly proportioned for complete combustion exerts the same blasting force as 24 ounces of the imperfect and dangerous blasting powder in common use. The following is the most important portion of Mr. Ashworth's article.

That it is possible to manufacture a blasting powder which for all ordinary mines is quite safe to use, has been proved years ago by one firm of high standing, who introduced a powder called "extra strong mining" (E.S.M.), fired preferably by a detonator. This powder was of much the same composition as the best artillery powder, but it differed from it in its physical qualities—it was unglazed, it was soft, the charcoal was not common charcoal, and it was incorporated for a long time in the mill, and not merely rubbed together. Being unglazed a charge was readily ignited, and the combustion, by reason of the excellence of the ingredients and thorough incorporation and being fired by a detonator, was such that a charge of 8 oz. was fully equal to 1½ lbs. of ordinary powder.

This increase of force was not entirely due to the excellence of the ingredients, but also to the detonator, which had the effect of firing the whole charge instantaneously and not, as with a common fuse, allowing the ignition flame to pass from end to end of the charge at a comparatively slow speed.

These statements of practical experience with a high-class powder prove that the risk of accidents from blown-out shots may be reduced to a minimum if a proper and suitable article is demanded and its use enforced. It is, however, possible to show by the result of an actual experiment what change takes place in the resultant gases from a shot of high-class powder, by referring to the experiments made by Karolyi. He fired a charge of powder, composed of saltpetre 73.78, sulphur 12.80, carbon 13.39, in a very strong iron mortar and then tested the resultant gases, and he found that 1 lb. of powder produced only 10.1 litres of carbonic oxide and 42.3 litres of carbonic acid gas, and 37.3 litres of nitrogen, but he found also 2.6 litres of marsh gas, and 5.9 of hydrogen.

Both the latter resultant gases doubtless originated from the charcoal, and therefore if these gases can be reduced by the use of a more suitable charcoal, there is no doubt that we shall be able to blast with increased safety in non-dangerous mines if proper regulations are enforced by Act of Parliament, and the gunpowder-makers are made amenable for turning out a bad article.

The enforcement of blasting by electrical or other detonator would undoubtedly afford an extra point of safety as ensuring the ignition of the whole charge more quickly than by ordinary fuse, as if bobbins of powder are used and the fuse is turned up and fixed in the first cartridge and the rest of the bobbins threaded on above, the consequence is that the charge is ignited at the back, and if the hole is "fast" the front part of the charge is blown out when only partly consumed, and cannot fail to add to the extent of the flame and of the intense combustion which results when the carbonic oxide is burnt into carbonic acid.

If dust of any sort is present, the extent of the flame must be increased (*vide* Sir F. Abel's experiments in connection with the Seaham disaster), and if, as seems possible, there is any firedamp lurking about, as suggested at Malago Vale, it would be sucked out by the force of the blow-out and consumed at the same time that the carbonic oxide is burnt into carbonic acid.

In conclusion, if high-class gunpowders are alone used we may possibly still have blown-out shots, but there will be every difference in the world in the result, because the combustion will be already complete, and the flame will be limited to that which comes out of the hole, and not intensified by a second and more intense inflammation from the burning of the carbonic oxide, which is the principal resultant gas from a common miners' blasting powder.

Water Tube Boilers.—The water tube boiler is at present the general favorite, as it secures the greatest economy and efficiency in the raising of high pressure steam. Before, however, proceeding to give the details set forth in a very important paper lying before us, it may not be out of place to notice definitely the meanings of some of the terms employed. The *water* tube boiler is in contradistinction to the *fire* tube boiler. In the *fire* tube, such as the tubes of the Lancashire and Cornish boilers, and the multi-tubes of the locomotive and marine boilers, the flaming gases pass through the tubes, while the water within the boiler covers the exterior surfaces of the tubes. In the other, or contra-case, the water is within the tubes, and the flame acts on the exterior surfaces of the tubes, hence they are called "water tube boilers."

The Advantages of High-pressed Steam.—It requires nearly as much heat to generate steam at the pressure of the atmosphere, as it does to generate it at 200 pounds pressure on the square inch. Although in the latter case the temperature of the steam would be considerably above 212° F, yet as the sensible heat of the high pressed steam *increases* the latent heat *decreases*, and the result is, it requires very little more heat to produce a pound of steam at a pressure of 200 pounds on the square inch, than that required to make a pound of steam at a pressure of 15 pounds on the square inch.

We see then how it is that high pressed steam secures such economy, and in this we also see how it is that all steam users desire it; but there are important factors required in the *modus operandi*, and these are a *high* temperature, and a large heating surface for the boilers. The reason why these factors are required is found in the fact that for steam to be formed, the temperature of the burning gases of the fire must be somewhat above the temperature of the steam, to supply *latent* heat, and as the rapidity with which steam is produced is in proportion to the number of degrees the heat is *above* the temperature of the steam produced, we see at once why a high temperature is required and to still further impress the judgment let us notice and not forget, that:

The energy of vaprofication is directly proportionate to the units of heat absorbed per minute by the heating surface of a boiler. Now the absorption per minute of a square foot of heating surface is reckoned to be good in a multitubular boiler when it is equal to 8 units of heat, but to generate very high pressed steam we require an absorption per square foot per minute of not less than 12 units of heat, therefore the subject is one claiming universal attention, and Mr. Allen Stirling of Chicago, recently read a paper before a meeting of the Mining Institute of Scotland, on the subject, headed, "Water Tube Boilers." The principal points touched on by the paper are as follows:

"The Stirling boiler is practically self-cleaning, because the water is fed into the back upper-drum, and descends with a slow motion of 6 inches per minute to the mud drum through the back group of tubes, which have an area 100 times greater than that of the feed pipe.

"On entering the mud-drum the feed water has reached the boiling point corresponding to the pressure under which the boiler is working.

"The scale-forming matter, together with other solid matter held in suspension prior to the feed water entering the boiler, is deposited on the bottom of the mud-drum from which it is readily blown off. This arrangement ensures the supply of practically pure water to the front and middle groups of tubes, where the steam is made. The Stirling boilers are giving the highest results, and are only opened once in six months, and even then very little cleaning is necessary.

"The advantages of using high pressure steam are widely recognized, and its use in modern engines is increasing rapidly. The merits of the water tube as compared with other boilers for carrying high pressures, are conceded by the best engineering authorities and the Stirling water-tube boiler commends itself because, (1) there are no riveted joints exposed to the heat; (2) there are no flat surfaces, and consequently, no stays are required; (3) the outside surfaces of the tubes are the only parts with which flame comes in contact; (4) the ends of the tubes are in water; (5) there is no heating surface above the water line; (6) all the parts are of wrought steel; (7) the tube plates are made thicker to allow for drilling the tube-holes; (8) expansion and contraction have been thoroughly provided for; (9) the water is divided into small sections; (10) the circulation is steady and thorough; (11) it is practically self-cleaning, so that the boiler seldom requires to be opened; and (12) there are only four joints to break to get access to every part of the boiler."

The following are other advantages claimed by the author of the paper for this water-tube boiler.

"The Stirling water-tube boiler occupies less space than any other. The small space required for boilers and fire-room effects a saving in cost of ground."

The following are the principal dimensions of Sterling boilers recently erected in Scotland:

	Localities.		
	Kilmarnock.	Glasgow.	Motherwell.
Heating surface, square feet	621	2387	4370
Grate surface, square feet	11	34	90
Ratio of heating to grate surface	56	70	48
Number of water tubes	78	264	392
Diameters of water tubes in inches	3¾	3¼	3¼
Diameters of drums in feet	3	4	4
Lengths of drums in feet	5	9	11

A Lecture on Mining.—An important lecture was lately delivered by Mr. W. N. Atkinson, H. M. Inspector of Mines, before a meeting in London of the Federated Institute of Mining Engineers. This lecture is a reflex of the experience and aspirations of the Mining Engineers of Great Britain, and, therefore, claims special notice. The subject is treated under eight heads, as follows:

Safety in Mining.
Falls of Roof and Sides.
Explosion of Fire-damp and Coal-dust.
Accidents in Shafts.
Underground Accidents.
Surface Accidents.
Training of Mining Engineers.
Distribution of Power by Electricity.

Safety in Mining.—Mr. Atkinson proves with the following facts that safety in the practice of mining is progressively increasing. We may congratulate ourselves that, relatively, the miner's occupation is now much safer than it was during the earlier part of the period for which statistics are available. Thus, according to the official statistics relating to mines under the various Coal Mines Regulation Acts (which are the statistics always referred to) the ratio of persons employed in and about our coal mines to each death during the five years 1851–55 was 233 (death rate per 1,000 = 4.294), whilst in the five years 1890–94 the corresponding ratio was 624 (death rate per 1,000 = 1.602), so that during the latter quinquennium more than two and a-half times as many persons were employed per life lost as in the earlier period.

Explosions of Fire damp and Coal-dust.—The lecturer shows that during the last 44 years the loss of life from explosions has been greatly reduced. "Explosions of fire-damp and coal-dust account for 21 per cent. of all the deaths from accidents in and about the mines under the various Coal Mines Regulation Acts during the forty-four years, 1851–94. The annual loss of life from explosions varies more widely than that from any other class of accidents in mines. During the past forty-four years it has varied from 651 in 1866 to 49 in 1888, the average annual number of deaths from this cause being 220. For several years past explosions in coal mines have been the subject of much controversy and special investigation, owing to the advancement of the opinion that coal-dust is the chief source of danger in extensive explosions. This contention is now widely admitted, although there are still differences of opinion concerning the relative influence of fire-damp and coal-dust in mine explosions, and as to the conditions under which coal-dust may cause or extend explosions."

It is next shown that the occurrence of explosions has diminished since the dangerous character of coal-dust became known, and he says:

"On the other hand, we must remember that the average depth of coal mines is increasing, and this depth is accompanied by increased dryness, so that in the future a greater proportion of mines will be subject to danger from coal-dust than in the past. Statistics indicate that since the time when the influence of coal-dust in colliery explosions was seriously considered, there has been a great reduction in the loss of life from this cause."

He next treats on the subject of safety lamps by saying: "Improved safety lamps have now been universally adopted, but in this respect there is room for further progress. For some time we have appeared to be on the eve of obtaining a satisfactory electric mining lamp, but as yet it is not forthcoming. With respect to the lamps in use two points strike me as specially requiring attention. The first is the abolition of the old screw-lock and the adoption of a lock incapable of being opened surreptitiously without detection, and this is an improvement of easy attainment at small cost, applicable to most of the lamps now in use. The other point is the risk attending the use of lamps with close shields, that lamps may be taken into the mine without the gauze. That this is a real risk is proved by its occurrence in the experience of a number of persons. The remedy is not so obvious as the improved lock, and it involves some alteration in the construction of the lamps, but it is a danger deserving of serious attention. The introduction of improved gas-detecting lamps, capable of indicating the presence of very small proportions of inflammable gas, enables a more accurate estimate to be formed of the production and presence of fire-damp in mines. For some time I have used Dr. Clowes' hydrogen lamp for this purpose with much satisfaction.

Falls of Roof and Sides.—"Falls of roof and sides in mines have always been, and probably always will be, accountable for more accidents and deaths than are due to any other single cause. The reason is not far to seek. It is a danger common to all mines, and one to which every person engaged underground is to some extent continually exposed. About 40½ per cent. of all the deaths from accidents in mines under the Coal Mines Regulation Acts since 1851 were caused by falls of roof and sides. The statistics show, nevertheless, that there has been a steady decline in the death rate from falls. The methods of preventing accidents from falls are well known to all engaged in mining, and there is no prospect of the discovery of any new principle for the avoidance of these accidents. The only hope of improvement lies in the better application of the old methods. The substitution of iron or steel supports for timber is likely to extend for economical reasons, and may to some extent add to safety."

Accidents in Shafts.—Mr. Atkinson further makes the following wise remarks. Shaft accidents account for 13¾ per cent. of the deaths recorded since 1851. The statistics show a more marked decrease in the number of deaths by shaft accidents than from any other single cause. Although it cannot be shown by the figures it is probable that the decrease is due in a greater degree to lessened loss of life amongst persons simply using the shafts to pass to and from their work, than to increased safety to those engaged in sinking and repairing shafts and other work connected with shafts. As in the working of railways, it is the mere passenger who runs the least risk. The reduced number of shaft accidents is no doubt due to the great improvements which have been effected in the fittings of shafts, the almost universal use of guided cages, automatic fences and other improved appliances connected with the shafts and winding engines. In many cases a very high degree of perfection has been attained in this respect. Points to which attention should be directed in order to prevent loss of life in shafts are the maintenance of the sides of the shafts and the shaft fittings in thoroughly good repair; also the avoidance as far as possible of the use of hangings-on or hooking places in mid-shaft, and where that is unavoidable the adoption of special appliances for securing safety at such places. Then the use of good ropes of adequate strength vigilantly examined, oiled and cared for; periodical recapping, and, where there is the probability of internal corrosion, extra precaution with regard to the length of time during which the rope is used, as ropes outwardly perfectly sound, may break suddenly from this cause. The use of detaching hooks may now be recommended with confidence, and they should be supplemented by the provision of keps or catches to arrest the fall of the cage in case the chains are broken, as may occur by the fall of a cage carried up by its momentum after the rope is detached. Appliances for arresting the fall of the cage in case of the rope breaking have not arrived at such perfection as to warrant the recommendation of their general use.

Underground Accidents.—Accidents under this heading caused 17½ per cent. of the deaths recorded since 1851, and the death rate shows a tendency to increase rather than the contrary. They are usually single fatalities caused by the use of explosives, suffocation by gases, accidents in connections with the haulage of minerals and arising from sundry other miscellaneous causes; but occasionally a large loss of life occurs from fires underground and by sudden irruptions of water, both of which are included with miscellaneous underground accidents. A large proportion of these accidents occur in connection with the movement of tubs, and in many cases both safety and economy would be increased by the adoption of improved underground rolling stock and more perfect haulage roads. I will only refer further to accidents arising from fires and irruptions of water. Underground fires are of two classes—those due to spontaneous combustion, called gob-fires, and others caused by accidental ignitions. Fires of either class may result in loss of life either by suffocation by the products of combustion or by explosions caused by the fires. In seams free from firedamp gob-fires do not usually have fatal results, but in fiery and dusty seams they are a source of great danger on account of the risk of explosions. The causes of spontaneous combustion in mines are not clearly understood, and the liability of any seam to its occurrence is only discovered by experience.

During recent years there have been several very serious accidents from fires underground caused by accidental ignitions, most of which were due to the use of naked lights in dry workings, and especially by "torch" or "comet" lamps.

The work of surveying mines and making the plans has in the past often been confided to incompetent hands, and even now the importance of the subject is frequently underrated. It would not appear to be unreasonable to insist that persons entrusted with the making of mining plans should be required by law to hold some recognized proof of their capacity.

Surface Accidents.—Accidents on the surface in connection with mines amount to 7½ per cent. of all the accidents recorded since 1851, and for the last twenty years at least the statistics show no improvement, the average death rate being slightly under 1 per 1,000 of the persons employed above ground. These accidents are not of a character peculiar to mining, but are similar to those occurring at other works where machinery and boilers are used, and where railway wagons are moved in confined places. The number of accidents in connection with the movement of wagons about the screens might be reduced by the provision of greater clearance between the wagons and the structures near which they are moved.

Training of Mining Engineers.—This is an age of education and with the introduction of electrical, and the many other examples of scientific engineering, the British realise the importance of technical education as follows:

"In view of the continual development of the mining industry, and the increased difficulties and dangers to be overcome as mines become deeper and more extensive, and the introduction of complicated and costly machinery of various kinds, it is more than ever requisite that, to be successful, the mining engineer should have a very efficient training in both the practical and scientific knowledge of his profession. There is no reason why a thoroughly practical knowledge of mining should not be accompanied by considerable scientific attainments, and the mining engineer will find it advantageous to have some acquaintance with nearly all the exact and physical sciences."

Distribution of Power by Electricity.—Mr. Atkinson seems to be in touch with the idea so many entertain, concerning the transmission of the energy in fuel. Some have proposed for years, that the combustible elements in coal should be converted into gas and transmitted through pipes to the points where heat, light, and energy were required. But he proposes a cheaper mode of transit, by despatching the energy in a spiritual form as electricity through cables, where it could be used at all points as heat, light, and a mechanical agent.

A subject of interest to colliery-owners and mining engineers which appears to be looming in the not very distant future, is the establishment of large central installations situated in coalfields, for the distribution of power to distant places by electricity. If this is found practicable there will be an immense saving in the cost of carriage of coal to the consumer, and a mitigation of the smoke-plague afflicting so many manufacturing towns. In some cases it might even be to the advantage of colliery owners to initiate the system for the distribution of energy to groups of mines. A much more speculative question refers to the possibility of utilizing the interior heat of the earth by means of deep shafts and boreholes. A few weeks ago I read of a scheme for attempting to solve the question by a series of shafts and borings in connection with the Paris Exhibition of 1900. If this source of heat and power ever became available on a large scale it might materially reduce the demand for both miners and mining engineers; hence there is solace in the reflection that many things are likely to happen before we get deep enough to be able utilize the heat of the nether regions.

Written for THE COLLIERY ENGINEER AND METAL MINER.

A NOVEL STEEL TIPPLE.

Description of the Tipple at Forest Hill Mine, Near Douglass Station, Pa.

The steel tipple at the Forest Hill mine, owned by Messrs. Ellsworth, Morris & Co. of Cleveland, Ohio, and located near Douglass Station on the Pittsburg, McKeesport and Youghiogheny R. R., possesses some novel features. It was built to replace a wooden tipple, which was destroyed by fire. The original tipple was about 30 ft. high from the rail to the tipple platform, and was connected with the pit mouth by a double track incline. The distance between the tipple and pit mouth was short and the incline was very steep. There was room for but two cars on either track between the foot of the incline and the tipple dump. This, of necessity, limited the trips on the incline to two cars, and consequently limited the capacity of the tipple. In designing the new tipple it was decided to do away with the incline and increase the height of the tipple house bents to about sixty feet, so that the mine cars could be run directly to the dump from the pit mouth. There are two loaded tracks on the tipple, each holding ten cars between the cross over and the switch at the pit mouth. These tracks have a descending grade to the dump of 1½%. The dump is the Phillips Automatic Cross Over Dump, (manufactured by the Phillips Mine Supply Co. of Pittsburgh, Pa.), and the cars after dumping, run automatically to the switch back and back to the foot of an incline, up which they are taken by a sprocket chain to the head of the incline. At this point they are automatically released from the sprocket and run by gravity down the empty track into the main entry of the mine, where the empty trips are made up. The sprocket on the incline is run by a ten horse power engine situated on the lower floor of the tipple.

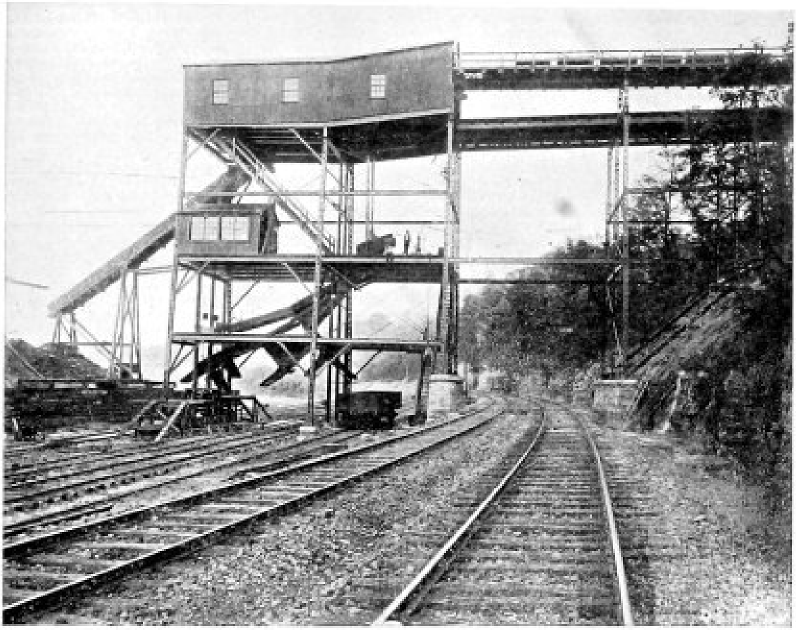
The coal, instead of being dumped directly into the screens, which is the case in tipples as usually built, goes into a counter-weighted drop basket, which is lowered, by the weight of the coal, about thirty feet, to the screens below. The gate at the lower end of the basket is opened by check chains just before it reaches the lump screen and the coal slides out of the basket over the screen. The descent of this drop basket is controlled by friction brakes on the drum, and to prevent too great a shock at the bottom, the basket is checked by spiral springs on the end of the chains. The guides on which the basket runs are six by eight inch yellow pine, and on the basket there are four friction rollers on each side, working on the sides of the guides. The time of lowering the basket, dumping the coal on the screens, and raising again for the next load is less than one-half minute.

By increasing the distance between the two outer tracks to 17 feet, from center to center, and the addition of the second fly to the lump coal chute, it is possible to load box cars with lump or run of mine coal on either of the two outside tracks, instead of the outer track only, as is generally done. This saves considerable time and increases the capacity of the tipple when loading box cars, as while trimming the coal in the outer car, coal may be run into the car on the inner track, and *vice versa*. The introduction of the nut and slack bins is also a source of time saving, as they allow lump coal to be loaded while shifting a car already loaded with nut or slack, and dropping empty cars into place on the nut and slack tracks.

The coal is all weighed on the track scales, the weigh office being on the first floor of the tipple, and the scales are connected by rods running from the track level to the beams in the weigh office.

The miners' checks are taken from the mine cars at the dump and dropped into a tin tube leading to the weighing office on the floor below. The brakes on the drop basket drums can be operated from either floor.

The tipple is at present equipped with a single set of screens, and its capacity is twelve hundred tons of lump coal in ten hours, but the structure is so designed that a second set of screens may be added in the future, should the output of the mine demand it. Messrs. Wilkins and Davison of Pittsburgh, Pa., were the designing engineers, the structural work being built and erected by the Schultz Bridge and Iron Company of Pittsburg, the screen equipment by the Phillips Mine Supply Company, and the incline sprocket by Messrs. Heyl and Patterson of Pittsburg.



STEEL TIPPLE AT FOREST HILL MINE.

Jeffrey Conveying Machinery for Coal Vessels.

The accompanying illustration represents a coal conveyor, installed by the Jeffrey Manufacturing Company, of Columbus, Ohio, for the Mobile Coal Company, Mobile, Ala., on their wharf, for the purpose of coaling steamers. It receives the coal from bottom dump cars on the trestle conveying same to a height of about forty-five feet into a storage pocket from which it is delivered into vessels by means of chutes at a rate of about 250 tons per hour.

This conveyor is about 175 ft. in length, is constructed of double steel chain of great strength and durability, to which iron scrapers are fastened by means of special swivel attachments. The coal is carried by the scrapers referred to through a steel trough, so constructed as to present a smooth and continuous surface, offering no impediment to the passage of the coal. The chain operates in iron guides, away from the material, supporting the scrapers clear of the trough bottom, thus greatly reducing the friction and wear, without being attended with that unbearable screeching noise, produced by ordinary conveyors where the scrapers slide on the bottom of trough. The operation of this conveyor is perfect, carrying 120 tons run of mine coal continuously, with the least amount of breakage and minimum amount of power. All of the working parts are simple, strong and durable, and easy of access in case of repairs.

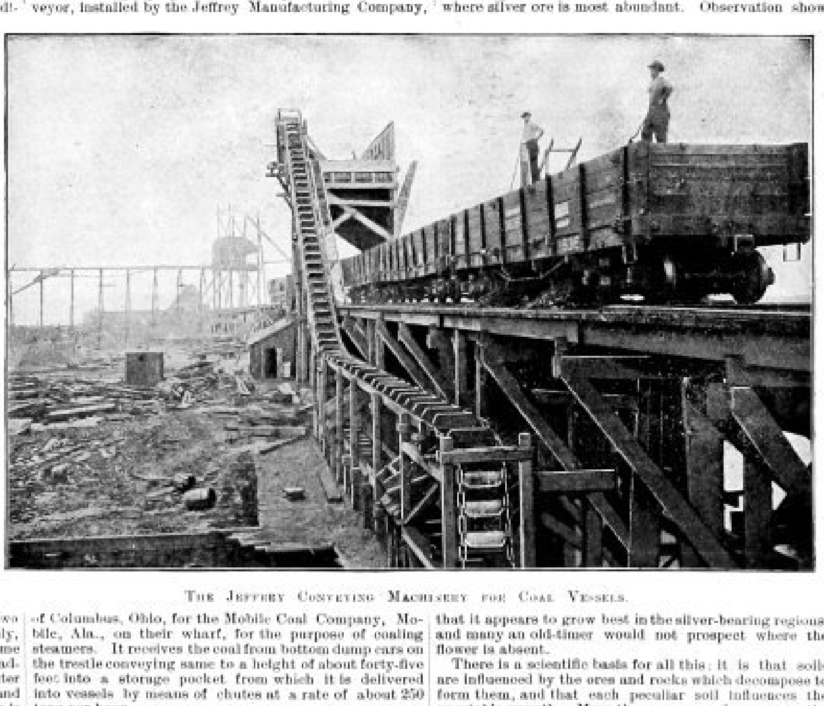
The conveyor is driven from the delivery end by an engine located on the ground, the connection, (owing to the distance), being made by wire cable operating over rubber filled sheaves.

In connection with this The Jeffrey Company also furnished a car puller, which is not shown in the illustration. This car puller consists of a friction drum, driven by the same engine that operates the conveyor, by means of which the empty cars are pulled away and the loaded cars into position for unloading.

The results obtained by the use of this machinery could not be accomplished nearly so rapidly and economically by any other known method. The saving in labor is very great, to say nothing about the safe handling of the coal and the very short time vessels are obliged to wait for their supply of fuel.

The installation of machinery, as represented in the illustration, is only a small part of the Jeffrey Manufacturing Company's extensive business. This company equips coal mines complete with coal cutters and drills for mining the coal, electric locomotives for hauling it, elevators, conveyors and screens for preparing and loading it into cars ready for shipment. It also furnishes appliances for the mechanical handling of material in straw board, pulp and paper mills, canning factories, saw and lumber mills, tanneries, smelting and refining works and numerous other industries. All who are interested in this class of machinery and desire to obtain the latest and most approved appliances are invited to write for full particulars and prices.

A large and handsomely illustrated catalogue will be mailed to any part of the world upon application.



THE JEFFREY CONVEYING MACHINERY FOR COAL VESSELS.

Plants and Minerals.

The man who thinks a knowledge of botany cannot aid a prospector does not know much about the science. The truth is that the mineral characteristics of a soil influence very greatly the plant growth in the soil. They change the shade and color of leaves and grass and blossoms, as well as often dictate what plants shall and shall not grow there. There are plants which grow only where there is considerable zinc in the soil, and others which apparently grow best, or only, where there is lead in the earth. In the lead regions of Illinois and Wisconsin the old-time prospectors looked as much for the vegetable growth as an indication of ore as they did for float. Old-time Colorado prospectors remember the little "silver flower" found so abundantly in the mountains in parts of Clear Creek and Boulder Counties, where silver ore is most abundant. Observation shows that it appears to grow best in the silver-bearing regions, and many an old-timer would not prospect where the flower is absent.

There is a scientific basis for all this; it is that soils are influenced by the ores and rocks which decompose to form them, and that each peculiar soil influences the vegetable growth. More than once we have seen the course of a lode clearly marked by the vegetable growth along its entire length. The old prospector sees sermons in grass and trees as well as stones.—*Mining Industry and Tradesman.*

EASY LESSONS ON MINING.

This Department contains articles to assist ambitious Miners to educate themselves, and obtain Certificates of Competency as Mine Foremen, or to become Mine Superintendents.

The articles are written to be understood by the unlearned and the learned alike. Plain language is used, no obscure terms are employed, and each subject treated, is made as clear and easy to understand as possible.

Further: The Questions asked at the different Examinations for Mine Foremen and Mine Inspectors, are printed and answered.

☞ The Series of Articles "Geology of Coal," "Chemistry of Mining," "Mining Methods" and "Mining Machinery" was commenced in the issue of March 1894. Back numbers can be obtained at twenty-five cents per single copy, $1.00 for six copies, and $2.00 for twelve copies.

MINING MACHINERY.

Velocities on Inclines.—Laws of Resistance on Inclines.—Times and Velocities on Inclines.

58. **Velocites on Inclines.**—Figure 102 is introduced to still farther explain how the gradient of an incline may be found when the length and time for the incline are given, and how to find the time when the gradient is given.

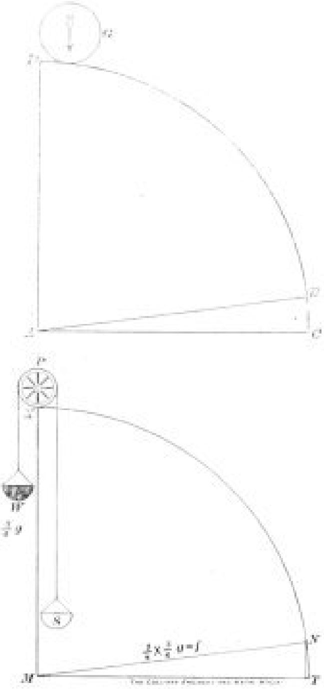


Fig. 102.

In the upper example in the figure, $A\ D$, $A\ B$, and $A\ C$ are radii of the same circle, consequently they are equal, and if a body is found to roll down the incline from B to A in 5.657 seconds what is the gradient for this time. We know that the height $B\ C$ will be in proportion to $B\ A$, as the square of the time of G in falling from D to A is in proportion to the square of the given time 5.657 seconds. The length of the radius $D\ A$ is 64.32 feet, or the height h from which the body will fall is 64.32 feet, and as $\frac{g\,t^2}{2} = h$, is must follow that $h \div \frac{g}{2} = t^2$, therefore $\frac{64.32}{16.08} = t^2 = 4$; and the square of 5.657 is equal to 32, and from this we see that the gradient is at the rate of 4 in 32 or 1 in 8, or if $A\ B$ is 64.32 feet long the height of $C\ B$ is $\frac{64.32}{8} = 8.04$ feet.

When the length of the incline and the ratio of the gradient are given, the time is easily found, because it is only required to reduce $\frac{g}{2}$ by multiplying it by the fraction of the gradient as in this case $16.08 \times \frac{1}{8} = 2.01 = f$ and therefore $\sqrt{64.32 \div 2.01} = t = 5.657$ seconds the time for a body to roll down an incline of one in eight, or the length $B\ A$.

The example at the bottom of the figure is to show that nothing falls but the load in cars running on an incline.

Here are two pans each weighing 1.5 tons, and marked W and S; W carries a load of 3 tons, therefore the pans and their load weigh conjointly 6 tons but only 3 tons fall, while the two pans balance each other, and are moved by the load. The pans are seen to be suspended by the rope passing over the pulley P. We see then that 3 tons have while falling, to set 6 tons in motion, therefore it is clear that the load will only acquire $\frac{3}{6}$ of the square of the velocity that would be attained, if the load fell alone.

It is clear then that the time on $N\ M$ must be longer than it was on $B\ A$ where a ball rolled down. In the first case f was $= \frac{g}{2} \times \frac{1}{8}$, now it is equal to $\frac{g}{2} \times \frac{1}{8} \times \frac{3}{6} = \frac{g}{2} \times \frac{1}{8} \times \frac{1}{2} = \frac{g}{2} \times \frac{1}{16} = \frac{g}{32} = 1.005$, and the time is $\frac{64.32}{f} = \frac{64.32}{1.005} = t^2 = 64$ and t is therefore equal to $\sqrt{64} = 8$ for the incline $N\ M$ with balanced pans, whereas, with the simple fall on $B\ A$, the time was 5.657 seconds. The gradient of the incline $N\ M$ can be found, as was explained in a former example, with this qualification however; the time of the fall from X to M must now be found by $\frac{g}{2} \times \frac{3}{6} = \frac{g}{2} \times \frac{1}{2} = \frac{g}{4} = 8.04 = f$, then $\frac{64.32}{8.04} = 8$, equal the square of the time in seconds for a body to fall from X to M with f force and it has been shown that it would require 8 seconds for the cars to perform the journey from N to M, but the height and hypotenuse of the gradient are as the squares of the times, therefore $\frac{8^2}{8} = \frac{64}{8} = \frac{8}{1}$, and if $N\ M$ is 64.32 feet, $T\ N$ must be $\frac{64.32}{8} = 8.04$ feet.

59. **Laws of Resistance on Inclines.**—Fig. 103 is to show that a self acting incline will run as fast with two, as with a hundred and two cars, if the friction of the rope and rollers, and the weight of the rope is neglected, because f is the same; and to make the matter clear, suppose the weight of each pan in the figure to be 1 as at B, and suppose the load to be 2, then $2 + 1 + 1 = 4$ the weight to be moved, and 2 is the weight that falls, therefore f must be $\frac{g}{2} \times \frac{2}{4} = \frac{g}{2} \times \frac{1}{2} = \frac{g}{4} = f = 8.04$. This value applies to the pans $A\ B$ on the pulleys P_1 P_2, and we will find the same value for f on the load on the pulleys P_3 and P_4. On the end of the rope C are four empty pans, and on the end of the rope D are four laden pans, but 4 pans balance 4 pans and the load falls, therefore f must be $\left(\frac{2 \times 4}{(2 \times 4) + (1 \times 8)}\right)\frac{g}{2} = \frac{g}{2} \times \frac{8}{16} = \frac{g}{2} \times \frac{1}{2} = \frac{g}{4} = f = 8.04$ as before. It is possible that two cars with one load could not overcome the friction of the rope and rollers, or lift the fraction of the weight of the rope due to the inclination. Any acceleration then due to an increased number of cars in a train is the result of a reduced proportion of friction, and not to any increase of f. We cannot dismiss this figure without showing that it is a beautiful illustration of Ohm's law, as applied to the current strength of the cells in a galvanic battery.

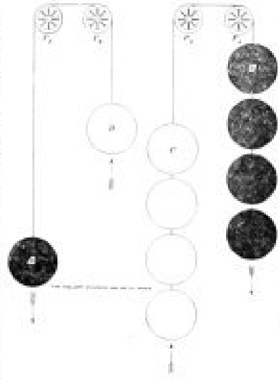

Fig. 103.

Ohm's law is this: "The current strength is equal to the electro-motive force divided by the external plus the internal resistance."

On a self acting incline the *motive* force is $\frac{g}{2}$ and the haulage strength is equal to $\frac{g}{2}$ multiplied by the load and divided by the load plus the weight of the cars, plus the proporton of the load due to the friction of cars, rope, and rollers. Now the friction of rope and rollers, corresponds to the external resistance, or resistance of the circuit wire, and the friction per car corresponds to the internal resistance per cell, therefore, we clearly see that as g and f represent inert force, Ohm's law could not apply to the conduct of an electric current unless that current was subject to the laws of inertia.

For example, suppose we have 10 cars in each of the two trains and that each load is equal to 2 tons and that each car weighed 1 ton as in the former example then,

$$\frac{2 \times 10}{(2 \times 10) + (1 \times 20)} = \frac{20}{40} = \frac{1}{2},$$

that is, f is equal to $\frac{g}{2} \times \frac{1}{2} = \frac{g}{4}$. Take a Leclanche battery of 20 cells and let the electro-motive force per cell be equal to 1.5 volts, and let the internal resistance be .5 ohms, the current strength for one cell is $\frac{1.5}{.5} = 3$ when the external resistance is *nil*, so $\frac{1.5 \times 20}{.5 \times 20} = 3$ as before; but suppose the external resistance is 5 ohms, then for one cell $\frac{1.5}{(.5 + 5)} = \frac{1.5}{5.5} = .27$ ampere and for 20 cells the external resistance remaining the same we have $\frac{1.5 \times 20}{(.5 \times 20) + 5} = 2$ amperes.

In precisely the same way, the friction of rope and rollers is easier overcome by larger trains; or suppose the resistance due to the friction of the rope and rollers is equal to 100 pounds, then for one load to move or run it must first overcome the resistance of 100 pounds, and if there are 20 loads, or 20 cars in a train instead of one, the 100 pounds will be equally shared among them and $\frac{100}{20} = 5$ pounds per loaded car.

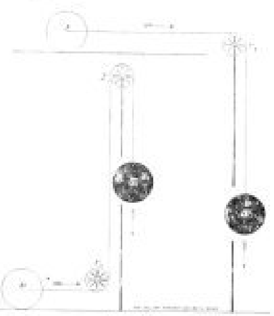

Fig. 104.

Fig. 104 illustrates how the time on an incline can be reduced by accelerating the velocity of the falling load at the beginning of its descent by making the empty cars first move along a short level. To explain the matter, let the load be 2 as before, and the weight of an empty car 1. Then by the figure at $A\ C$ or $B\ D$ we see that B and its load fall, while D is only moved along a horizontal plane, and therefore its center of gravity is neither raised nor lowered, and we now see that 4 tons are moved while 3 tons fall, thus making the value of f equal to $\frac{g}{2} \times \frac{3}{4} = \frac{3g}{8} = 12.06$.

By the figure, P_1 and P_2 are two pulleys for one rope, and therefore set up an increased resistance, which if duly allowed for, should reduce the value of f.

Fig. 105 shows in contrast two modes of accelerating the initial speed of trains on self-acting inclines, and in some cases both the "level foot" and "cycloidal head" are combined in one haulage. At $B\ D$ we have the cycloidal or quick fall at the head of the incline. This quick fall at the head however is not at all times possible in a mine, consequently the level at the foot is substituted, as $E\ H$ is easier made, but like all such artifices their advantages are very doubtful, for to obtain increased grade at the head you must reduce the grade at the foot of the incline, and when the laden train is near the bottom its energy is often so exhausted with the brake or some other resistance, that it is unable to raise the empty train onto the brow of the incline, and the consequence is, such stoppages waste more time than that gained by acceleration with "cycloids" or "foot levels," as $B\ D$ and $E\ H$; and the result of all this is that $A\ B$ with a mean fall $B\ C$, or $E\ F$ with a mean fall of $F\ G$, often give the best practical results. There are however special cases where the "foot level" and the "cycloid" can be used with advantage.

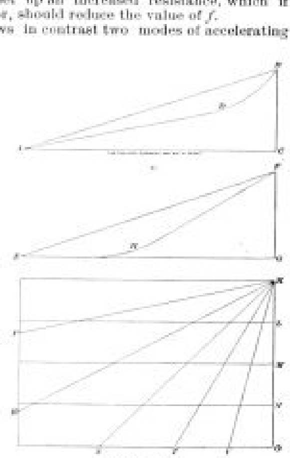

Fig. 105.

60. Times and Velocities on Inclines.—The lower part of the figure is to illustrate a point wherein it is manifest, that nature never conflicts with herself; and to make the point clear, let us notice that the same weight or mass of matter always contains the same amount of energy when moving at the same velocity as that at which it has moved before, or every time a one pound mass moves with a velocity of 32.16 feet per second, it has stored up in itself neither more or less than 16.08 foot pounds of energy, and with equal truth it can be said that when a mass has fallen (without friction) to a depth of 16.08 feet, whatever may have been the angle of the inclination or the grade, in every case, without exception, when the descent has become equal to a vertical fall of 16.08 feet, the velocity at which the mass is moving is 32.16 feet per second. *L*, *M*, *N* and *O*, are horizontal lines to indicate the depth of fall. *P*, *R*, *S*, *T* and *V*, are inclined lines from *K*, to indicate different grades of inclination. Now *P*, *R*, *S*, *T*, *V* and *O*, all cut the horizontal line *L*, and if bodies were made to roll down *K O*, *K V*, *K T*, *K S*, *K R* and *K P*, to *L* they would arrive at different times, and all the times would be found to be proportionate to the square roots of the lengths of the inclines. The velocities would also be found to be the same when the bodies rolled down the inclines to the levels *M*, *N* and *O*. It does no doubt appear to a student strange, that the times are different, and yet the velocities are the same, when all the bodies have fallen from the same elevation to the same level; but the strangeness disappears when we learn that it *must be so*, for if the velocities were different, the stored up energy would be different, it therefore follows, that, whether the time is long or short, when a body has fallen through a given vertical depth, the velocity at the end of the time is same as though it had fallen in a vertical line instead of an inclined one.

Nothing perhaps is more interesting in relation to the behavior of falling bodies, than the fact, that a body will roll along the line of a curve in less time than it will do the same fall along a shorter path in a straight line; or a body will roll along a curve *B*, *L*, *C*, *H*, *A*, in less time than it will roll along the straight line *B*, *A*, Fig. 106. This is the noted example of the "law of the cycloid" in relation to falling bodies, and to explain the matter with clearness, let us by "plain figures" for "easy lessons" work it out, step by step.

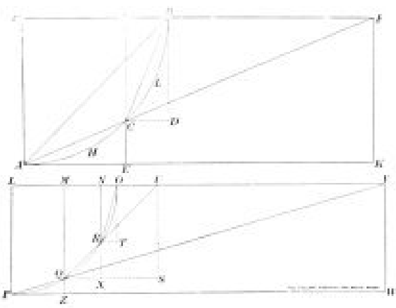

FIG. 106.

The angle *BAE* is one of 45° therefore the sine is .7071 and f is $= \frac{g}{2} \times .7071 = 16.08 \times .7071 = 11.37 +$

Let the vertical line $GA = 100$ feet then BA will be equal to 141.42 feet and as l is the length,

$$\sqrt{\frac{l}{f}} = \sqrt{\frac{141.42}{11.37}} = t = 3.53 \text{ seconds nearly,}$$

the time for a body to roll down the straight line *BA*.

To attain accuracy for the time on the curve, we would have to plunge into very advanced mathematics, but we can come very near to the time with plain figures, and by this means explain the case better.

Let us then try first to find the time required for a body to fall along the line *BC*, and we will therefore require to know the length of *BC* and *BD*.

Now *BGC* is an angle of 45° therefore the sine is .7071 and the chord *B C* is .76536 or the actual length is 76.536 feet, and f is in this case $= \frac{g}{2} \times \frac{.7071}{.76536} = 14.85$, then the time for *BC* is equal to

$$\sqrt{\frac{76.536}{14.85}} = t = 2.274 \text{ seconds.}$$

It would be thought by the uninitiated that the body would be longer in rolling from *C* to *A*, than in rolling from *B* to *C*, but such is not the case, because the velocity the body has attained at *C*, is twice that of its mean velocity in rolling down *BC*, for it started with no velocity, and if it had no fall from *C* to *A*, it would still move through that distance in less time than it required in falling from *B* to *C*; indeed it would do it in less than half the time, as we will just now prove.

By the figure, the vertical line *F K* is equal to *G A*, and as *A C* must be equal to *C B*, it follows that *A C* is 76.536 feet, and as *C E* is proportionate to the versed sine of 45°, it is 29.289 feet long. We are now in a position to find the time a body will be in rolling down *C A*, because if a body rolls down *F A*, by the time it reaches *C* it will be moving with the same velocity it would have at *C*, if it rolled down *BC*. Again, if we could find the times for *FC* and *FA*, the difference would be the time for *C A*. The length of *A F* is found as follows: $AC = 76.536$, $CE = 29.289$, and $FK = 100$. Therefore,

$$AF = \frac{76.536 \times 100}{29.289} = 261.35 \text{ feet.}$$

Now f will be equal to $\frac{g}{2} \times \frac{29.289}{76.536} = 6.1535$, and the time for *F A* is $\sqrt{\frac{l}{f}} = \sqrt{\frac{261.35}{6.1535}} = 6.5171$, and the time for *F C* is $\sqrt{\frac{l}{f}} = \sqrt{\frac{(261.35 - 76.536)}{6.1535}} = \sqrt{\frac{184.814}{6.1535}} = 5.4803$.

Time from *F* to *A* = 6.5171
Time from *F* to *C* = 5.4803

Time from *C* to *A* = 1.0368 seconds.

Time from *B* to *C* plus *C* to *A* is equal to 2.274 + 1.0368 = 3.3108 seconds, and the time for *B A* was 3.53 seconds, and the difference is 3.53 − 3.3108 = .2192, or rather less than a quarter of a second. In the lower portion of the diagram, the times for *O R*, *R Q* and *Q P* are found by the same process as *B C* and *B A*.

It is true that the curve we have used was not a strictly correct cycloid, nor have the advantages of the cycloid been shown in reducing the time on a longer line after leaving the curve, but for mining purposes, it may be said that all we require for an incline is a good fall at the top and a short level at the bottom.

[TO BE CONTINUED.]

MINING METHODS.

Local Ventilation—Pressure in Ventilation.

54. Local Ventilation.—In mining coal by different methods of long-wall working we soon find that special conditions require appropriate treatment, for we cannot work the coal in many cases by ideal plans, but by such modifications as will adapt the method to the requirements that arise in each case.

Longwall workings are said to be easier ventilated than those of pillar and chamber, or otherwise board and pillar, or room and pillar, and this statement is quite true so far as the removal of fire-damp is concerned when the working face is advancing up-grade, but you may so run the line of the face as to make a *pool* for the collection of gas, and actually make danger where it ought not to exist. We admit that longwall is easy to ventilate, but for all that, the system has its peculiarities and if they are not understood, they cause trouble; for example, the roof breaks and falls, and the fissures and cavities thus made become reservoirs for the storage of very large volumes of gas, which float out of the old rear workings during the progress of a depression in the atmospheric pressure; the result is, it is at all times dangerous to fire shots either in the gateways or at a longwall face, so that "easy to ventilate" does not at the same time mean freedom from danger, unless due care is exercised to prevent the possibility of gas stratifying at the working face. In Fig. 99 we have an example of this kind; the working face is advancing up-grade, as shown by the pitch arrow at *P*, and the ingoing air is seen to be conducted up the principal gateway *F H*, and the impure air is made to return by the two flanking gateways *A* and *C*. Now the danger in a longwall working of this kind arises when the middle intake airways are advanced too far ahead of the flanking gateways, for then gas accumulates as in a pool or bay contained within the dotted line *A*, *B*, *C*.

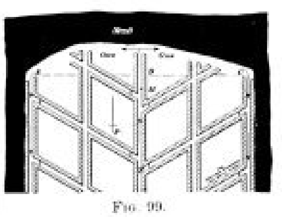

FIG. 99.

Fig. 100 represents a longwall face under conditions the opposite of that of the previous figure; for here, the flanking gateways are in advance of the middle and principal gateway, and as far as the ventilation is concerned, it appears to correct the defect shown in the previous figure, but on closer inspection it will be observed, that one defect has been substituted for another; for now we destroy the coal to remove the gas, for it will be seen that to keep the advance of the middle gateway behind that of the flanking returns, the coal "jetties" or juts out in front of the dotted line *A*, *B*, *C*, and under such a condition of strain it is crushed and spoiled. The pitch of the bed in this case is indicated by the arrow *P*, the main intake is shown by *D G*, and the return gateways are seen at *E* and *F*.

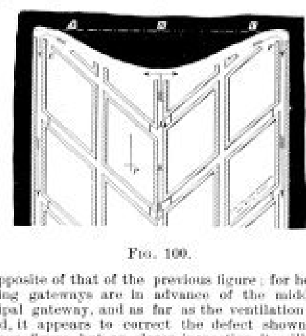

FIG. 100.

The ventilation of a longwall face may be "easy," but it cannot be well done without a well matured judgment and in a case like that shown in the last figure or the previous one, where the face is advancing upgrade the greatest defect is found in conducting the ingoing air up the middle gateway instead of up one of the flanking gateways, say in the figure before us *E*. Now if *E* has to be the principal intake airway, for the best possible ventilation of the working face it must be kept in the rear of *F*, or *F* must at all times be advanced higher upgrade than *E*, so that all gas will *rise* along the face on its way to the return. This then is another example of the fact that in mining, to secure success, careful and critical judgment is required to find one condition that will not conflict with the other unalterable ones.

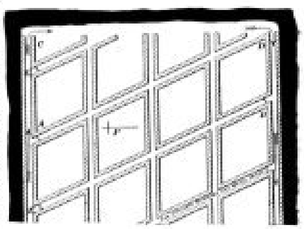

FIG. 101.

Fig. 101 is an example of a longwall working face advancing along the strike instead of upgrade on the line of pitch; and where such an arrangement can be carried out, the very best results are obtained, in so far as ventilation and the removal of gas is concerned; pack walls are never gas or air tight, and any gas escaping out of the old workings can always be collected in the return airway that skirts the top edge of the goaf, beside, no gas can loiter in the neighborhood of the working face as it must float up to *D*.

In good mining practice longwall working is varied to meet all the conditions that are met with in the roof and the floor, and all the variations in the "texture" or quality, or the closeness or openness of the cleavage planes in the seam, and the tenderness or toughness of the coal. Such being the case we must never prefer any system or any modification of a system, but practice all or any system, or any modification of a system that best fits the conditions that we are confronted with.

The arrow *P* gives the direction of the line of dip; *D B*, is the main return airway; *E A G*, is the main intake airway. At *G*, *A* and *B* we have doors; at *E* is a permanent brick stopping. At *C* we have the dip or lowest point of the face, and at *D* is situated the rise or highest point of the face.

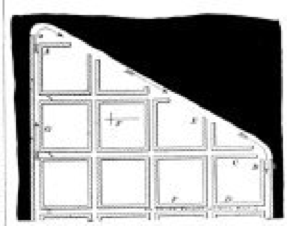

FIG. 102.

Fig. 102, brings before our notice another modification of longwall. In the shales we find cleavage planes that are common in slate and coal deposits, the shales and the slates may, however, be classed as one, because true slate is only metamorphosed shale. The cleavage planes were made before the constituent clay of the shales, or the bog of the coal seams, was indurated.

We can quite account for the cleavage planes in shales and coals, but to the uninitiated it will appear strange to learn that the faults, fissures, and master joints in the limestones and sandstones were produced by lateral pressure in the earth's crust just as were the cleavage planes, but let us clearly comprehend that the fine lamination produced in plastic clay, must be different from the cracks and fissures in a *broken* solid, and it is with the latter we have to deal in explaining the reason of this modification of longwall working in coal.

We cannot but expect that the common parallelism of the faults and joints in the rocks overlying the coal seams will seriously affect the cost of obtaining the coal, unless the mode of working is adapted to the conditions of the roof; for example, if the line of the face is parallel to the lines of the faults and roof joints, the cost for labor in removing fallen stone, in the timbering and retimbering of the workings, and the extra labor and danger attending the cutting and filling of the coal will conjointly render the working of such a mine an unprofitable transaction.

The modification shown in the last figure is adopted where the master joints are running from *C* to *D*, and from *E* to *F*, and are not parallel to the lines of any of the pack-walls, but have a direction making very nearly a right angle with the line of the working face.

It will be seen that the principal intake airway is *G A*, and the return is at *B*, and that the cover will fall off the coal face and thus prevent undue pressure and damage, while any gas from the goaf will be carried off at once into the return. The arrow *P* shows as before the direction of the pitch.

55. Pressure in Ventilation.—Pressure is an important factor in mine ventilation, and however much men may err in judgment concerning it, the law of its action is constant. Many years ago bore holes were suggested and tried as channels for the escape of the light gases given off by coal. It was said "marsh gas is light," therefore if a bore hole is drilled down into the highest point in a goaf where this gas accumulates it will float up the hole and thus clean out all the gas, but the gas never would rise because the hole was invariably a downcast for air, and if we pause for a moment to consider the case we cannot fail to see, that the behavior of the air was neither eccentric nor erratic, but subject to the action of an invariable law; the air was pressed down the bore hole because the pressure in the mine was less than the atmospheric pressure at the surface. There can be no doubt that the bore-hole will in the near future be an important aid to ventilation, because it furnishes the cheapest and most efficient way of removing inflammable gases from old workings or goafs with a very small quantity of air.

Where mines are not very deep and the holes can be readily made, we can discover without much argument that they must be a good investment. With the furnace and the exhaust fan, bore-holes cannot be adopted as aides to ventilation, for the current pressure at the bottom of the downcast shaft will always be less than at the surface, and in the case of an exhaust fan the pressure in the mine near the upcast will be considerably less than at the surface; this fact is clearly illustrated by Fig. 103, where for illustration, a recess is seen at R W to illustrate rise workings where gas has accumulated, and a bore-hole has been drilled for the escape of the gas, but the result is contrary to the intention, for the hole is a downcast as shown by the arrow at H.

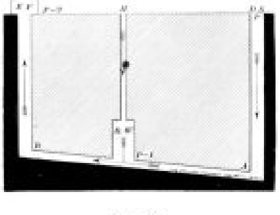

FIG. 103.

At the top of the upcast shaft the exhaust fan E F is seen, and let P represent the surface pressure, and $P - 1$ represent the reduced pressure in the chamber R W, and further let $P - 2$ represent the depression in the fan drift, a moments consideration will satisfy us that the air cannot do any other than rush down the bore hole into an inferior pressure as is shown in the illustration. Again let us reverse the ventilating action by using a blowing, instead of an exhausting fan, as at B F Fig. 104, the blowing fan at the mouth of the downcast shaft. It will now be seen that instead of $P - 2$ we have $P + 2$, and instead of $P - 1$ we have $P + 1$ the result is as we may expect, the gas is blown up the bore-hole H, as shown by the arrow.

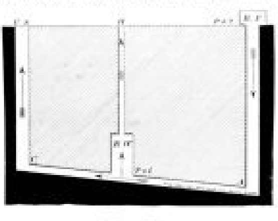

FIG. 104.

[TO BE CONTINUED.]

CHEMISTRY OF MINING.

Electro Metallurgy of Copper.—Electric Polarity.

57. Electro-Metallurgy of Copper.—Copper ores yielding about 6 per cent. of metal, can only be made to yield a profit in two ways; first, when the ore is available in the "open," and labor is very cheap; and second, when the metal can be cheaply separated from its stony matrix and chemical combination by electrolysis, or electro metallurgy as applied in mining. It is to explain the second process that the subject illustrated by Fig. 94 has been introduced. At D we have an electrolytic or really a Daniels cell, for in the porous pot or diaphragm is a week solution of sulphuric acid along with the zinc element B, and along with the carbon or copper element is a solution of copper sulphate $CuSO_4$, at A. During the action of the cell (which is very slow) unless it is aided with a current of some voltage, a deposition of the metal copper takes place on the carbon or copper element, and if copper plating is required, the metal can be made to deposit on the surface of another metal, or even on the surface of wood coated with charcoal or any other electric conductor. The voltaic current is seen to circulate through the wire W, beginning at C, and returning by Z. T T is a tank such as is used for separating metallic copper from a solution which may be a chloride or a sulphate. G G is the surface of the liquid and pieces of scrap or pig iron are seen covered with the solution. In Spain and Portugal it pays sometimes to flood the copper mines, and pump the sulphate into such tanks as we illustrate and deposit the metal copper on pig iron, from which it is afterward removed by water when the metal is collected as a brown powder. Sometimes advantage is taken of electrolytic action by first pouring onto large heaps of the ore considerable volumes of water, after which the drainage from the heaps is pumped up into tanks containing pig iron as before.

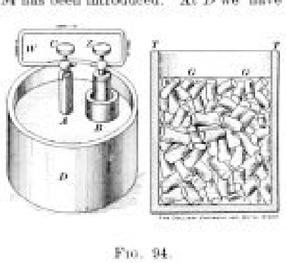

FIG. 94.

The tanks are really electrolytic cells, and the mine and the watered heap are in fact the laboratories where the sulphate of copper is prepared to feed the cells.

Fig. 95 is introduced to illustrate the laws of electric and chemical polarity.

In making a first acquaintance with magnetic, electric and molecular polarity, the student is surprised to find the strong co-relationship of (what shall I say) the polarities or the the polarity of force. At A we have a simple cell and the carbon C and the zinc rod Z, are called the poles in reference to the wire or galvanic circuit, and in reference to chemical action they are called the elements, and the positive pole $+P$ is in the cell, the negative element —, and the negative pole —N is in the cell the positive element as shown at E and E, and the current is seen to start at Z in the cell and pass on to C, and to pass out of the cell from C to Z. At B we find an example of chemical polarity, the exciting liquid is dilute sulphuric acid H_2SO_4 and the positive element zinc is seen to repel the positive hydrogen which clings to the copper plate as globules H, H, H, while the negative SO_4 combines with the zinc as sulphate of zinc, $ZnSO_4$. In this and all other examples in chemical action, the atoms and molecules combine by polarity. Positive combines with negative, and in this case the positive zinc has displaced by repulsion, just as a magnet would do, the positive hydrogen. C is an example of a battery of cells and to secure an increased electro-motive force the cells are combined on the basis of a correct polarity, by connecting the negative pole of one cell with the positive pole of the other.

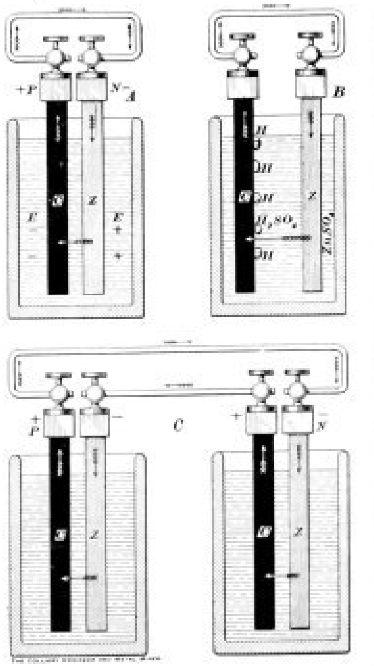

FIG. 95.

58. Electric Polarity.—Fig. 96 brings before our attention an example of electric polarity as manifested by the same current when a part of it is moving in one direction and the other part is moving in the opposite direction by an arrangement of the circuit wire. When currents are made to move in parallel lines, the laws of polar action are: currents moving in the same direction repel each other, and currents moving in opposite directions attract each other, and the case before us is one of repulsion.

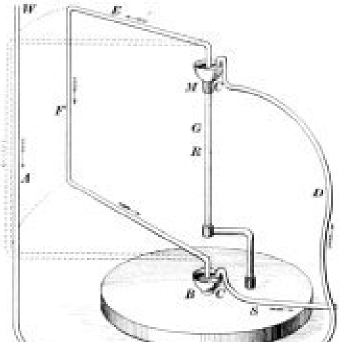

FIG. 96.

The construction and mode of action of the instrument requires some notice: In the first place it will be seen that to prevent a break in the continuity of the current two cups of mercury are used as at M and B or C and C. The movable loop B F E is made to dip with both its ends into mercury, while the downgoing portion of the circuit, or electric channel W is made to conduct the current into the upper cup of mercury, when it enters the upper end of the movable loop and flows down into the lower cup, from where it passes on to the battery. The rod G R is an insulator. The current is seen in this case to act repulsively on itself, or the fixed portion of the circuit W is repelling, and is itself repelled by the side of the movable loop. It will be seen that W D C is the electric channel leading to the upper cup and the continuation is M F B S. Fig. 97 is an illustration of the arrangement of the circuit wires in the same instrument to set up attraction; and now the wire W is put into circuit with the bottom cup B, the result is the electric stream flows up the side of the movable loop B F E, while the return wire D becomes S in this arrangement. This polariscope therefore establishes the fact that currents in the same direction repel and currents moving in opposite directions attract each other as in the figure.

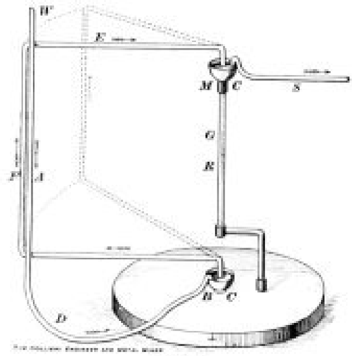

FIG. 97.

59. The Magnetic Tick.—That the modes of motion known as electricity and magnetism are the results of certain harmonic movements of the molecules in the mass of a magnet or an electrical conductor, cannot be doubted, because the conclusion is sustained with direct proof. Construct an apparatus such as that shown by Fig. 98 and by this means we are made able to hear molecules striking each other.

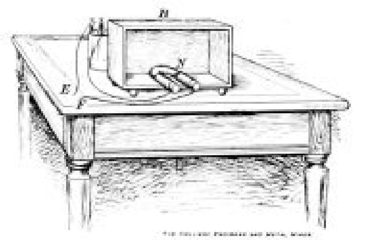

FIG. 98.

The construction and mode of action are as follows: The resonance chamber is adapted out of a cigar box as shown at B, and nothing better can be used for reflecting and conducting otherwise inaudible sounds than dry wood, as notice the microphonic sounds heard with the telephone. Lying on one side of the resonance chamber or cigar box, is an electro magnet and helix N, and the circuit wires are seen to come from a galvanic cell, and the circuit is broken at E F.

If the ear is held close to the resonance chamber, the moment the wires E and F are made to touch each other a distinct *tick* is heard, and the moment the wires are detached and the circuit is broken the tick is heard again. The tick produced, as we may imagine, with a strong current, is louder than that produced with a weak one. The tick has a peculiar ring and has to be heard to recognize its true character. When iron is magnetized it expands as though it was heated. There are no doubt some simple laws controlling and differentiating motion to produce its modes, and if our eyes were sufficiently microscopic that we could see the molecule-dance for light, heat, electricity, magnetism, and chemical action, we would be able to identify these inflections and associate them with well-known mechanical laws. From all these experiments it is obvious that to master this subject we must clearly comprehend that we are dealing with manifestations of force, that are only different in their mode of action. This brings us to consider again the polarity of attraction and repulsion as we find it in generating "magneto electricity," and here be it observed that, as has been already shown, if a circuit wire is coiled on the *soft iron* legs of a revolving armature, as the ends of the legs approach the opposite poles of a *permanent* magnet a momentary induced current flows in the directions of the arrows at A, Fig. 99. N is the north and S is the pole of the inducing permanent magnet; M and P are the legs of the revolving armature, and G is the spindle on which the armature revolves.

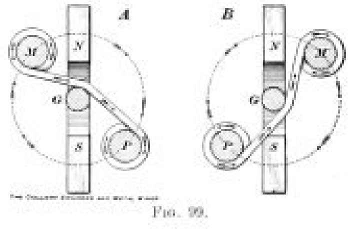

FIG. 99.

At B the legs of the armature M and P are leaving the poles of the permanent magnet N and S as before, and the result is, the induced current moves in the opposite direction, but it must be *very* carefully noticed that there are not four positive and four negative electric pulses in one revolution of the armature; for, see at *B*, *M* moves from *N* onto *S* without changing the sign of the pulse, and *P* moves from *S* on to *N* without changing the sign of the pulse. At *B*, *M* from *N* is the same direction of the current as at *A*, where *P* is advancing on to *S*. In the next figure we have to notice that there are minimum and maximum points of induction. At the moment when the poles of the armature begin to depart from the poles of the magnet, induction begins and swells up to the crest of the electric wave, as graphically denoted by the letters *N* and *S* at the top of Fig. 100 where *D*, *N*, *Z*,

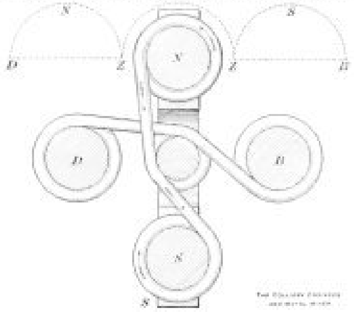

FIG. 100.

is one pulse wave and *Z*, *S*, *B*, is another. Suppose the armature to be revolving in the direction of the hands of a watch, then the tendency is for the current to flow one way, and yet if there is a considerable distance between the poles one pulse tends to have two maximum and one minimum point, and this, we shall afterwards have to show develops waste of energy.

Fig. 101 is an illustration of the mode of action of the

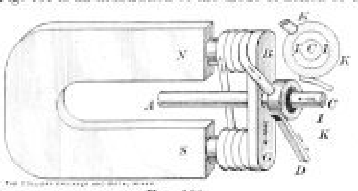

FIG. 101.

magneto electric machine used for generating either muscular or nervous action, or both, in the bodies of sick people. *B G* is the armature which revolves on the spindle *A C*, one terminal of the wire coils is seen at *B*, to be in electric contact with a brass ring *K* which is insulated either with a wooden or gutta percha ring *I I* in perspective and vertical section, or on the spindle *C*, is a wood jacket to isolate *K*. The other end of the wire of the coils is in electric contact with the arm of the armature, and by that means with the spindle. Now a spring *D* is made to rest in contact with *K*, and the frame of the machine is in contact with the spindle, therefore the loop in the complete circuit has its terminals connected with *C* and *D*, and the body of the patient is made by means of handles on the outside wires to form part of the circuit. Further on a modification of *K* brings us to what will be called the commutator.

GEOLOGY OF COAL.

Life Conditions of the Earth.

48. Life Conditions of the Earth.—The life conditions that have characterized each successive period during the earth's long age have been the environments of the faunas and floras that were peculiar to the times; or it may be said, the life conditions of any one period were unfavorable to the characteristic life of all the other periods before it or after it. Just as now the great zones of the earth establish different environments for different varieties of plant and animal life, and if by any change the temperature of the torrid zone was lowered, its characteristic life would perish and become extinct for ever, for plants from the torrid zone can only be kept alive in the temperate zones with the help of heat artificially applied, and the plants of the temperate zones can only be kept alive in the torrid zone by cold artificially applied.

The torrid zone is the home of reptiles that live on the flesh of other animals that obtain their food almost without an effort; the temperate zones are the homes of the higher orders of mammals, that obtain their food by vigorous efforts, intelligently directed. The frigid zones are the homes of carnivorous birds, carnivorous beasts and carnivorous fishes, while the vigor of the climate is totally unfavorable to the growth of the plants of the temperate zones.

Had the earth's environment of life never changed, almost the same life forms would have been engraven on the bedding faces of the laminæ of the same varieties of the rocks; but such is not the case, because each period was subject to different climatic conditions that favored some and disfavored other life forms.

That different climates characterized different periods cannot be doubted, and it is evident that the whole earth at one period was subject to a tropical temperature, and this was especially so during the Carboniferous period. Rocks of this age are found in all the zones, even the frigid ones, and they are all marked with imprints like those of the tropical tree ferns and their associate cryptogams; indeed, the very existence of coal is an index of life conditions such as prevail in the torrid zone now. As practical men, we would not trouble about the climatic characteristics of the Carboniferous period, were it not for the fact that we can only distinguish the fossils of the period from those of other periods by intimately connecting them with the cause of their individuality. The climate then of the period is a peg on which hangs all our facts, and we cannot, therefore, consider the time ill-spent in a little more investigation of the matter.

Geology and astronomy are mutually dependent sciences. The one will never be understood until the other is made to harmonize with it by tracing geological changes to astronomical causes. For example, we have two theories concerning the relative ages of the planets; by the first one, the oldest planets are nearest the sun; by the second one, the youngest planets are nearest the sun. By the first theory the climate of the whole earth should be much warmer than it once was; by the second theory the climate of the whole earth should be colder than it once was. Geology furnishes unmistakable proof that the climate of the whole earth was hotter than it now is, and the first theory dispenses with this fact by pointing out that the young earth was a ball of liquid fire covered with a hard crust that was sufficiently hot to produce a warm climate, even when the planet was at a much greater distance from the sun; but geology entirely sets aside that conclusion and proves to us that glacial periods have been repeated during all the ages that have passed while the deposition of the stratified rocks was taking place, and we therefore discover that to have a comprehensive view of the earth's life history, we must be able to grasp with ease the peculiarities of the fossils that give to each group of rocks their special individuality; and for this purpose the entire series of rocks that constitute the crust of the earth have been divided into three great groups each of which are distinguished not only for stratigraphical traits but for their progressive successions of life, namely, the paleozoic, mesozoic, and cainozoic periods.

The fossils of the paleozoic period are the remains of such organisms as could only live in the waters of relatively hot seas, as notice the great prevalence of coral and crinoidal remains.

To show the entire dependency of the coral and crinoidal organisms on a high temperature for their existence, we must notice two great facts, first, the coral insects *cannot* live now in the waters of seas whose temperature is less than 60° *F*; and, second, the solubility of carbonate of lime varies as the temperature inversely, the result is as the temperature increases the solubility decreases, until lime is insoluble in boiling water.

Knowing this last fact we cannot wonder when we are told that the minimum temperature at which the coral insects can encrust themselves with their shell of lime is 60°F, because at lower temperatures the lime is increasingly soluble, and so much so, that the crust of the insect would dissolve as fast as it was secreted; and if heat is a prime necessity in the coralline seas, how much more must it be an indispensable condition in the environment of encrinital life. From the "testimony of the rocks" we learn that the floors of some of the paleozoic seas were covered with a stone flora.

We do not look for such life in our seas to day because we know this is a period that environs another variety of life. Lime in our cold waters is very soluble, but during Carboniferous times the high temperatures of the atmospheric and oceanic currents carried the heat factor of the environment of encrinital life within the polar circles, hence from pole to pole the rocks and their contents manifestly prove that the temperature of the paleozoic period was high. During the deposition of the Carboniferous series of rocks and especially the Lower Carboniferous limestone measures, the floors of some of the seas were like veritable submarine gardens of stone lilies, classed as echinoderms, indeed the calcareous peduncles supporting the corollas of the lilies, would resemble the spectacle of fields of grain.

We now know that we owe to corals, crinoids and foramanifers, the selection, collection and deposition of all the limestone strata of paleozoic times.

Many of the present most rudimentary life forms have come down from Cambrian times, their survival being due to their adaptability to the ever changing life conditions on the earth, and Fig. 77 furnishes two examples. At *S* we have a radiate organism or star fish; round about the central region is a circular nervous cord, and at the base of each finger or ray a nervous cord branches off from a ganglion or knot of nervous matter into the ray to control its movements. These creatures have rudimentary organs of vision, and altogether furnish a good illustration of that division of animal life called *radiata*. At *N* we have another living example of the survival of the oldest organisms, and this is one of the present representatives of the orthoceras called the nautilus, both belonging to the order cephalapoda or head-footed molluscs. It will be interesting to observe the successive changes in the organism of this creature in its survival of the mighty climatic oscillations through which it has passed.

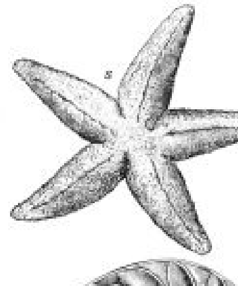

FIG. 77.

Fig. 78 is characteristic of the mesozoic, middle life,

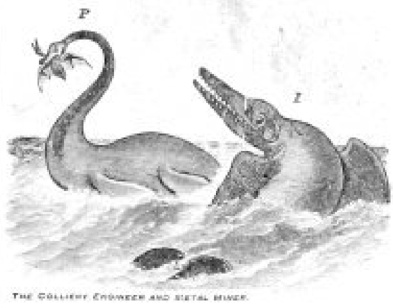

FIG. 78.

or really the reptilian peroid. Reptiles made their first appearance during Carboniferous times, but during the secondary period they swarmed in the air on wings and were the principal life forms on the land, the shallow waters, and the deep seas. The bird and the the reptile are closely allied, and the first bird form we are acquainted with, appeared during this period; its mandibles or jaws contained teeth, and in its wings were claws, so that it was after all allied to the reptiles such as the plesiosaurus *P*. The modern crocodile and the alligator are the modern representatives of the ichthyosaurus *I*.

The mesozoic period was the reptilian age *par excellence*, and this furnishes strong proof of the prevailing high temperature of the period, for these cold blooded creatures are only represented by diminutive examples in high latitudes. In hot regions, however, reptilian life is prolific, and it is here also that the most powerful representatives are found.

Fig. 79 introduces us to the life and climate of the

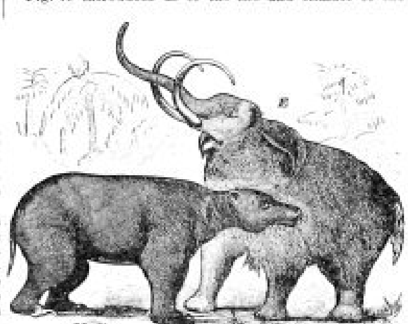

FIG. 79.

cainozoic period, and here the mammalia replace the reptilia, or reduce them to the representative examples we know, such as the lizards, snakes and serpents, and especially those of the region of the torrid zone. Many of the forerunners of the true mammals, the marsupials, have become extinct, and many species of mammals have perished during great climatic changes. The megatherium *M* was one of this class, and the genus elephanti, of which the mammoth *E* is an example, once consisted of a number of species, all of which have become extinct except the elephant. It is clear that the mammoth perished during the last glacial period, for an example, covered with hair and flesh in a state of considerable preservation was found a few years ago locked up in frozen ice and mud. The life of the cainozoic period is the highest in the organic scale, and is subject to the conditions of a lower mean temperature; and as we have urged the importance of studying the past life of the earth from the stand-point of higher temperatures than prevail now, we will continue the subject as far as it will assist the learner to grasp and retain the recollection of the life forms that are of undoubted importance in the interpretation of that geology that especially concerns us in mining.

[TO BE CONTINUED.]

The Niagara Power number of Cassier's Magazine is unquestionably the handsomest special edition of any publication ever issued in America. Its literary merit is fully equal to its artistic appearance. In the matter of illustrations the number is particularly remarkable. The contributors are all men of national reputation in their several specialties, and they have prepared their articles in a manner that makes them not only very instructive, but entertaining as well. The publishers and editor in getting out this special number have won for themselves great reputations for enterprise and liberality. Long life to Cassier's.

MISCELLANEOUS.

THE DEPTHS OF SPACE.

Of all the sciences there is none which makes such vast demands upon the powers of the human imagination as the science of astronomy. We have to brace our minds to the conception of distances and magnitudes so utterly transcending all ordinary human experience, that special means have to be invoked to render them intelligible. Each advance in our knowledge of the heavens reveals to us the grandeur of the celestial spaces on an ever-growing scale.

The great majority of the stars are situated at distances so enormous that it is utterly hopeless to attempt to determine how far away they are. In fact, only comparatively few stars happen to lie sufficiently close to the earth to permit of making any accurate determination of their positions. Nor is it by any means an easy task to choose out these particular objects which do lie within range. It not unfrequently happens that after much labor has been expended on observations of some particular star, it has been found that the work is fruitless, and that the star is so remote that there is no possibility of learning what its distance actually amounts to. It might naturally be supposed that the brightest stars are those nearest the earth; and no doubt if all the stars were intrinsically equally bright their apparent brightness would be a safe guide in placing those objects at their true relative distances. But there is no such simple connection between brightness and proximity as this would imply.

There is, however, another indication of position which is very frequently accepted by astronomers when discussing whether a star is likely to lie within such a degree of proximity to the earth as to make it worth their while to try to determine its distance. When we are looking at a steamer near the horizon the vessel seems to change its place but slowly, though we may know as a matter of fact that it is traveling at a rate of perhaps more than ten miles an hour. The nearer we are to the steamer the more rapidly does it seem to move. In like manner, if a star were animated by what is called proper motion, that is to say, if the star shifted its position on the sky with reference to the other stars, and if the amount of this shift was unusually great, then there would be a presumption that the star was comparatively near. It will, indeed, be obvious that if all the stars were really travelling at the same speed, those which lie nearest the earth would move over an appreciable part of the sky in a shorter time than those which were more remote. Of course, we are not entitled to assume that the stars are moving with equal rapidity in space. Indeed, we know well, that such is not the case. But, speaking generally, we may fairly argue that if a star does appear to be moving rapidly, it is a presumption that the body is one of the sun's nearer neighbors.

The star whose distance is to be sought having been chosen, the astronomer measures in his telescope the sky interval by which that star is separated from a neighboring star, which, though apparently close by, is in reality much further away. It is however, essential that the two shall lie so nearly in the same direction as to be both visible together in the same telescopic field. By means of a delicate instrument applied to the telescope we measure the width of the bit of sky between the two stars, and these measurements are repeated night after night for a twelvemonth. This years' series of observations is absolutely necessary, for the astronomer is gradually shifting his own position, and in six months' time this shift will amount to nearly 200,000,000 miles, the earth having moved during this period round to the opposite point of its orbit. The displacement of the observer alters the position of the near star in relation to its more distant companion. We thus find that the sky interval between the two objects changes periodically, and by observations such as these it is possible, by the magic of mathematics, to determine the distances of some of the stars from the earth.

A due appreciation of the magnitude of these distances is poorly conveyed by strings of figures representing millions of miles. Electricians know that the speed of the electric current on a telegraph wire is about 180,000 miles a second. If then an electric wire encircled the globe seven times, we should then find that an electric signal sent into the wire at one end, would accomplish the seven circuits in one second of time. Provided with this conception we can now give suitable illustrations of the results at which astronomers have arrived in their researches on the distances of the stars.

Let us suppose that the telegraph lines, instead of being merely confined to the earth, were extended throughout the length and depth of space. Let us now see what the very shortest time would be in which a message might be transmitted to each of these several destinations. First with respect to the moon, our satellite is comparatively speaking so near to us that but little more than a second would be required for a signal to travel thither from the earth. The sun is, however, so far away that when the key had been pressed down, and the electric wave had shot forth along the solar wire to pursue its route at that stupendous speed which would permit it to place a girdle seven times around this earth in a second, yet eight minutes would have to elapse ere the electric wave, had passed from the earth to the sun.

Telegraphing to the stars would be a much more tedious matter. Take first the case of the very nearest of those twinkling points of light, namely, Alpha Centauri. The transmission of a telegraphic message to this distant sun would indeed tax the patience of all concerned. The key is pressed down, the circuit is complete, the message bounds off on its journey to a distance so overwhelming that the time required for the journey is not a question of seconds, or of minutes, not of hours, not of days, not of weeks, nor even of months, for no less than four years would have to pass by before the electricity, trembling along the wire with its unapproachable speed, had accomplished this stupendous journey.

Alpha Centauri is, however, merely the nearest of these stars. We have yet to indicate the distance of those which are more remote. Look up to-night toward the heavens, and among the thousands of twinkling points which delight our eyes there is many a one up there so far off that if, after the battle of Waterloo had been won in 1815, the Duke of Wellington had telegraphed the news to these stellar depths, the message would not yet have been received there.

Over our heads there are thousands of stars, which can only be seen through the telescope, and they are so remote that if the news of the discovery of America by Columbus had been circulated far and wide through the universe by the instrumentality of the telegraph, the announcement would not yet have reached them; and it seems certain that many of the stars, which are known to us only by the impressions they make on a photographic plate, are so remote that if the glad tidings of the first Christmas at Bethlehem, 1,894 years ago, had been disseminated through the universe by the swiftest electric current ever known, yet—those stars are so inconceivably remote—all the seconds which have elapsed in the 1,894 years of our present era would not have sufficed for the journey.

Some there are who may be inclined to doubt these facts, and of course to doubt wisely is a most wholesome attitude to take with respect to all scientific work. But such should remember that space seems to us to be boundless, for our imagination can conceive no limits. There must, it would seem, be depths of space thousands of times, or indeed millions of times greater than those of which I have spoken. We can conceive of no boundary; for even if that celestial vault of crystal existed which the ancients supposed, our imaginations could pierce through it to the other side, and then in thought we could start afresh, and on and on indefinitely. And seeing that space seems to us to be infinite, what wonder is it if the stars should lie at the distances I have named, or at distances millions of times greater still? Indeed, I would rather say that we have good reason to feel thankful that so many of the stars have come so near to us as to allow of their being glimpsed by our eyes, or caught on our photographic plates. There is ample room to permit of their retreat so far into space that the heavens would have append an absolute void, instead of presenting that glorious spectacle which now makes our nightly skies an abounding delight.—*Condensed from Article by Sir Robert Ball, in the N. Y. Sun.*

HIGH ALTITUDES.

The following account of the ascension of Dr. Berson in the balloon Phœnix, gives a vivid idea of the conditions prevailing at lofty altitudes.

The air in general was foggy, and thick flocks of small clouds hid the earth now and then. At first the temperature rose. At a height of 4,920 ft. it was more than 41° F. above zero. Dr. Berson made double notes of the readings of the instruments, cast a glance at the balloon and its ropes, looked down at the earth, and threw out two sacks of ballast. An hour after the start he had risen higher than 16,400 ft., and the temperature sunk to 2° below zero, and the air became dry. The sun's rays were weak. When a height of 13,776 ft. was reached the aeronaut felt the first slight increase of his heart's action after lifting the heavy sandbags. At 11:49 A. M., one hour and 21 minutes after starting, he reached the height of 19,680 ft., and the temperature sank to 17.9° below zero. He felt a slight palpitation of the heart and slight general discomfort, but was otherwise well. At 12 o'clock, one hour and a half after the start, he began, at a height of 22,140 ft. and a temperature of 20° below zero, to breathe artificial oxygen from the bags he had with him, and with excellent effect. At 12:25 the bold aeronaut had outpassed 27,320 ft., at a temperature of 28° below zero. He was now higher than he had been in the preceding May, when his highest point had been 25,910 ft., and this time he felt much better than then.

He now never dared to cease breathing the bags of oxygen except for a few seconds at a time, and during those brief pauses he felt dizzy and dangerously weak. But while continuing the artificial breathing he constantly and with relative ease fulfilled all necessary work. Only once did his eyes close in spite of himself, but the next moment he roused himself, scolding at his own negligence; his voice in the rarified air sounded strangely muffled.

When at the height of 25,584 ft. he had already risen higher than Glashier when the latter aeronaut took his last note of the temperature. At the height of 26,896 ft. Dr. Berson thought of the two French scientists who had died at that height. At about 27,880 ft. Berson reached the greatest height arrived at by Glashier on Sept. 5, 1862, when the latter fainted away, only to awake after his companions had stopped the balloon from rising any higher. But Dr. Berson, after momentary examination of his own strength and his provision of ballast, ventured to rise higher. The temperature had already sunk to 43° F below zero. At the height of 29,520 ft. his balloon passed through and above the thin stratum of high cirrus clouds which he had noticed high in the sky at his start. The veil-like stratum consisted not of ice crystals, but of well formed small snowflakes. At 12:45 P. M., two and a half hours after the start, the barometer indicated only 9.08 inches which corresponds with a sea height of 29,520 ft. and a true height of 30,012 ft. The thermometer stood at 56° below zero. The balloon now stopped. There were only six large and one small sack of ballast left, which were necessary for descending and landing. The balloon stood above the thin snow clouds in a clear sky which stretched faintly blue above. Dr. Berson felt so well that he could certainly have risen another 3,280 ft. But he could not have done so without risking the whole of his successful journey. At this immense height—30,012 ft.—he felt much better than a short time before. Dr. Berson opened the gas valve now and then, and the Phœnix gradually descended, till at the height of 24,600 ft. it stopped, and again began to rise. Another pull at the valve caused it to redescend. At the height of 27,880 ft. it sailed over a river with mighty curves. It was the Elbe at the part, as was afterward found, near Domitz.

But now the terrible cold began to have effect. Dr. Berson, clothed as he was in thick furs, began to shake in every limb so violently that sometimes he was obliged to hold on to the rim of the basket. In slow, waving motion the balloon sank and sank, and during the whole descent only one sack of ballast was thrown out, at the height of 11,480 ft. to moderate the rapidity. Meanwhile a close stratum of heavy clouds had hidden the earth and prevented any ascertaining of the balloon's position. The slow descent, however, allowed of another set of observations being taken, and now the highest temperature, about 42° above zero, was found at the height of 4,592 ft. Thence down to the earth it sank again nine degrees. A whole hour after Herr Berson had been at the greatest height of his trip two of his fingers were frozen, but he brought them to life again by energetic friction. In the enormous cold the barograph had stopped for a while. In the afternoon at 3 o'clock the northern skies showed unmistakable signs of "water," and Dr. Berson decided that he must descend more rapidly. After a few more gentle ups and downs he could distinguish the noise and steam whistles of some large town. When 820 ft. high there appeared at last below him the gray earth, covered by a cloudy sky. Now with the drag strap the balloon passed over a lake, and presently landed, with the help of some countrymen who came up at 3:45 P. M., on a stubblefield at Schonwohld, in the west of Kiel, on the very evening when the German Emperor, the founder of the Phœnix, happened to be staying in that city.—*From the Journal of Aeronautics and Atmospheric Physics.*

ART OF KEEPING COOL.

The comfort of the individual during dog days and those equally oppressive periods which precede dog days, depends not so much upon the position of the mercury in the thermometer as upon the state of mind and body of the person. The reason why Thomas Jones works with more or less vigor at cleaning the streets while John Smith is prostrated beside him is to be found in the difference between John and Thomas, and not in the climatic differences of the two places. The reason why Clara Vere de Vere is cool while her neighbor Fanny Flutter, is very hot is to be found in Clara's superior philosophy.

The woman who worries about the heat, who nervously consults the thermometer every hour, who reads the weather reports with feverish avidity and declares violently that she cannot endure the heat, is acting in a way to make her prophecy come true. Over-activity, mental as well as physical, must be avoided by the seeker after an even temperature. The first requisite of comfort in hot weather is a calm and philosophic mind, which refuses to agitate itself over the vagaries of the thermometer.

Next in importance to one's mental condition comes her physical. Weakness is an ally of heat, and renders the work of the sun effective. It, therefore, behooves the woman who would keep cool to keep strong. She should avoid the feminine pitfall of not lunching or of lunching on odds and ends. She must court strength-giving sleep as she does not need to in the winter. She must stifle her natural impulse to spend a large part of the day in the bath tub, for more than one tub bath a day is weakening. The desire for extra cleanliness must be satisfied by sponge baths, which do not impair her strength.

Clothing plays a more or less important part in inducing coolness. Lightness of weight, as well as thinness of texture, is necessary. The clothes worn next her skin should be very light of weight, and absorbent. Over it the lightest, loosest, thinnest underwear should be worn, and finally light, loose outer garments. A loose collar and loose sleeves are more conducive of coolness than mere airiness of fabric. Loose shoes, which should be changed frequently, are among other cooling necessities.

As to food, extreme abstinence is not to be countenanced. Meat and fatty viands are to be eschewed, but plenty of vegetables, fruits, fish and the like should be eaten. Iced drinks and dishes should be partaken of sparingly. They are bad for the digestion and consequently to be avoided. Besides, they are not cooling. Whatever makes the body so warm that the outside air seems cool to it is cooling. The dwellers in the tropics eat curries and other highly flavored food, and they know more about the science of keeping cool than any other people. Hot drinks, which induce perspiration, are the proper warm weather drinks.—*N. Y. World.*

TWO REMARKABLE LONG-DISTANCE POWER TRANSMISSIONS

There are two remarkable long-distance transmissions of power in successful operation in the United States, although neither are electric transmissions, and each differs materially from the other. One is the transmission of oil by pipe-line, from the natural oil fields of New York, Ohio and Pennsylvania, to tide-water, a distance of over 400 miles. The other is the transmission of natural gas, also by pipe-line, from the the Indiana fields to the city of Chicago, a distance of about 120 miles.

The piping of oil, first from the individual oil wells to storage centers, and then from these storage centers to tide-water, has been a process of gradual development for the last thirty years. The individual wells were gradually connected by feed pipes to larger trunk lines, which carry the oil to the storage centres.

There are twelve pumping stations along this line, situated about 35 miles apart. The pumps operate at a pressure of about 1,000 pounds per square inch, and the capacity of the line is about 30,000 barrels a day.

The main pipe-line is divided into divisions and sections, much like a trunk railway system, and has, similarly, its division superintendents and engineers, section foremen, line gangs and line walkers, telegraph stations and daily reports.

The natural gas pipe-line is, perhaps, a more simple example of long distance power transmissions, and bears many striking points of resemblance to transmission by electricity. In the Indiana gas field about 60 wells are in operation, having an average daily capacity of about 5,000,000 cubic feet each. As in the oil fields, so here, the individual wells are connected by feed pipes to a supply line, which collects the gas and carries it to a pumping station. There large compressors, capable of producing and sustaining a pressure of 2,000 pounds per square inch, force the gas into the transmisson line to Chicago. The normal pressure carried on this line is 300 pounds per square inch, which admits of a daily delivery of from 10,000,000 to 12,000,000 cubic feet of gas to Chicago, where it is sold at a price much below that of ordinary illuminating gas.—*S. Dana Greene, in the Niagara Power Number of Cassier's Magazine.*

CATALINA'S PIGEON POST.

So far as I can learn, the only regular pigeon post service on this side of the continent or the other is that which bears messages every day in the summer season between Los Angeles and the little town of Avalon, on Catalina Island, and bears them at a speed which can be beaten only by the telegraph or telephone.

The steamer runs once a day between island and mainland, and once it has cast loose from the wharf, the island, with a summer population of perhaps several thousands, is as completely cut off from the world as though it were in mid-ocean, and yet the shore is a scant twenty miles away. The demand for some additional service grew. Often there were men of affairs among the visitors, and they were not infrequently sore distressed to find means of communication. I remember hearing one financier declare: "I'd give $500 gladly to get a despatch to Los Angeles; it would be worth $5,000 to me easy."

It remained for two young men of Los Angeles, Otto and Oswald Zahn, to relieve the island visitors and residents from their embarrassing isolation. This was accomplished by the establishment of a carrier-pigeon post between Avalon and Los Angeles. The service was inaugurated last summer and conducted for several weeks with unequivocal success. It was feared at first that the pigeons, which are distinctly "land birds," might hesitate to fly across so large a body of water; but, as far as known, there need have been no cause for anxiety on this point. The message bearers usually started without delay, arriving at their destination with a certainty and promptness almost incredible. The air-line distance from Avalon to Los Angeles is about fifty miles. This was accomplished by some of the Catalina flyers in fifty minutes. From three to four hours is required to make the trip by railroad and steamer.

Last year a considerable revenue was earned in the forwarding of despatches from Catalina by the winged messengers. Small bills posted conspicuously about the town of Avalon convey the somewhat startling information to the non resident islander that "private messages and business orders may be forwarded at any hour of the day, and, in connection with the telephone, telegraph, and cable lines, to any part of the world."

The young pigeon fanciers also add to their income by supplying the daily press of Los Angeles with the latest news from Catalina.

Last year the Zahns had not more than a dozen homers in the service, and it was found by repeated flyings at short intervals that the birds toward the end of the season became less reliable. It is not the flight across the water that exhausts them, but the boxing and shipping on the return trip. The Zahn lofts at Avalon and Los Angeles number this year nearly 100 birds of high degree, and these will insure constant and efficient service to and from the island thoughout the summer.

In a very few instances the birds have been wounded by pot-hunters or thoughtless sportsmen.—*From the San Francisco Chronicle.*

WHY WE ARE HEALTHY.

We are constantly told by those who have discovered that the origin of at least some diseases lies within the boundaries of the germ theory, that we are in constant danger from attacks of these disorders. There is hardly one of us, we are assured, but could furnish from the lining membrane of his own mouth and nose sufficient germs to create a fair-sized epidemic of diphtheria or pneumonia.

Indeed, so generally diffused are such germs, that it might seem almost hopeless to contend with them except by transforming oneself into a walking repository for antiseptics of all kinds.

Theses statements no doubt sound alarming, yet we need not be greatly disturbed by them, although they are in every respect true. By recent investigations, the whole theory of the development and growth of germ diseases may be said to have been changed.

Not only that, but the theory that in their treatment it is necessary to introduce into the system some agent directly antagonistic to the germ in question, has been entirely superseded by the later one, that the normally healthy blood is itself one of the best known destroyers of all classes of germs.

In this fact is contained the answer to those who ask how it is possible to escape the infection with such opportunities for it all about us. The blood of all animals contains a substance which is as deadly a poison to the disease germ as strychnine is to a human being.

The substance is not always present in animals to the same extent; or, rather,—and this is perhaps the better way of expressing it,—the substance does not evince the same power of antagonism toward the same diseases in different animals. In this way is explained the ability of some animals to take a disease with which it is impossible to inoculate a human being, and *vice versa*. The horse can stand an amount of diphtheria poison which would probably prove fatal to a man.

More important still, is the fact that this substance is manufactured by the blood itself, and varies in amount and power in direct proportion to the quantity and richness of the blood.

As we know, the blood is susceptible to many changes. It is when the vitality has been lowered from any cause, that the germs which are lurking about us get a foothold, and begin their deadly work. The lesson is obvious. To secure ourselves against infection, we must keep in good condition.—*Youths' Companion.*

SEA BATHING.

Sea bathing gives more pleasure, and for many is more promotive of health than almost any other form of bathing. As July and August are the months when it is most practiced, a few suggestions may be useful. Those who are in the prime of life and have good constitutions may indulge in sea bathing freely and to advantage. Those who have much adipose tissue, and generate abundant heat, endure a long continued bath, if the water is warm, with profit. We have known such to remain in the bath one or two hours daily for weeks and grow stronger every day. Those who are thin in flesh and generate less heat must not remain in so long. The length of time, however, should be determined by the temperature of the water and the vigor of the person. Experience is generally a good guide. Old people and very young ones must not remain in the water very long, but they may wade along the beach and lie on the warm sand as long as they like, if they are careful not to get cold. Very delicate persons of either sex must be guided by experience; and for such, as a rule, a short bath of ten or fifteen minutes is better than a long one. They may, however, remain on the beach longer, often for an hour or two. There are many who cannot take the sea bath at all. Let these go barefooted on the beach in bathing costume, wet their feet, play in the sand and be like children, when it is warm enough.

In some places there is still sea bathing, that is, there are no ocean waves and swells. This is most suitable for weakly persons and those not skilled in swimming or meeting the waves and swells as they come up on the shore, but for the strong, these waves dashing in on the body produce more powerful reactions on the nervous system and on the movement of the blood, and accelerate the metabolic changes which go on in the tissues. A little skill enables one to enjoy the rougher sea bathing very greatly. It is one of the finest forms of exercise known, but it tires one sooner than still water bathing.

The effects of sea bathing are generally exhilarating both to body and mind. One leaves his depression and low spirits in the briny water, and feels as if his physical sins had all been washed away. The appetite increases and digestion improves. The skin becomes tougher, often rougher, in which case an oiling is beneficial. The scalp and the hair on the head become more vigorous and the step more elastic.

It is better, generally, after the bath, to take a fresh water shower to wash off the salt that might other wise remain on the skin and, when dry, irritate it.

After dressing, a sun bath is generally very agreeable and profitable, or a gentle walk in the sunshine. A half hour or more should elapse before eating.

Those who cannot have the advantage of sea bathing may get nearly or quite the same good by fresh water baths in lake or river. Much of the benefit comes from being out of doors, lightly clad, and from throwing off care and becoming like a child once more.

LIGHTNING.

In this season of thunder storms it will be a welcome consolation to most people to be assured that they are in many respects unnecessarily alarmed by lightning. Human fears are always intermixed with many superstitions, and Forecaster Alexander McAdie of the United States Weather Bureau, exposes a number of these fallacious beliefs in the popular dread of the flashing bolt. Many of the high potential oscillatory currents which dart from the thundering clouds are not of such intensity as mortals imagine; and even should a person be struck to the earth, it would be a serious mistake for bystanders to take death for granted. There is ample reason for the belief that lightning often brings about suspended animation instead of somatic death, and in every case—no matter howsoever apparently hopeless—energetic measures of stimulation and resuscitation should be instantly undertaken, and continued unceasingly for at least one hour. The mechanical expansion and compression of the chest should be performed.

Housewives should not, during a thunderstorm, hide their scissors, thimbles and small articles of steel, as these trifling things will not attract the lightning. It is also idle to seek insulation in a feather bed. On the other hand, terrified wayfarers should not seek refuge under trees, in the doorways of barns, close to cattle or near chimneys. If shelter be sought under a tree as the only comfortable spot, an ash, beech, birch or maple should be selected, as these species are very rarely struck. The oak is frequently hit, and so are the elm and the chestnut.

Lightning rods should be erected upon houses, especially in the country. It is an error to believe that rods are an added peril. The record of lightning bolts for the decade from 1883 to 1893 shows that 2,769 barns, 129 churches, and 831 dwellings were struck. Churches are a particular favorite. There are about 600 fires caused yearly in the United States by lightning. When lightning rods are erected, the conductors should be surrounded by points. Any disastrous discharge of the imprisoned current is thus prevented, and the bolt is forced to the earth.—*Philadelphia Record.*

STRUCK BY A WATERSPOUT.

The bark Wandering Jew left Philadelphia on Saturday, June 1, and went out of the Delaware Capes the same night under a full pressure of canvas, carrying her through the water at a good eight knots an hour. The next day the wind died out and light airs and calms prevailed until the night of the 9th, the vessel's position then being seventy miles east southeast from Cape Hatteras. At midnight the wind freshened and sail was shortened. The vessel was diving in a "nasty" sea, and as morning wore on Capt. Little considered it advisable to take in some more sail. This was about 2:30 A. M., and all hands were sent aloft to take in the upper sails.

While thus engaged Capt. Little and the mate, who were pacing the poop deck, observed through the gloom what appeared to them to be a large white cloud. Suddenly the wind died and this huge white object drew nearer rapidly, when it was seen at its true light. It was a mammoth waterspout, making directly for the vessel's side. All hands had now seen it and realizing their danger, became panic-stricken; but before they had time to move it was upon the vessel, and none remembers further until awakening from a sort of a dream and finding their vessel a helpless wreck and all hands, sailors and officers, badly bruised and crippled.

They had the closest call of any crew that was ever spared to relate the thrilling tale of being struck by a waterspout. The vessel's foremast and maintopmast, with the sails and rigging attached, were wrenched out by the immense spiral of water which came down upon them. For fully thirty seconds the vessel was completely engulfed, and when it passed over her she lay helpless, and all hands that were on deck lay in the scuppers and beneath the top-gallant forecastle, where they had been washed by the great volume of water. It was an experience that no other living sailors have passed through, and the old barkentine, as she lies swinging to her port anchor off Knighn's Point, was the object of curiosity to all passing up and down the river yesterday.

Such frequent appearances of waterspouts in the locality of Hatteras is unusual, and the Wandering Jew is the second vessel to have met them in a few days. The British steamship Ferdnene, narrowly escaped being struck by one of these huge spirals of water.—*Philadelphia Press.*

IN A ROTHSCHILD STRONG BOX.

"The largest shipment of United States bonds to Europe, so far as I can remember," said Mr. J. K. Upton, former Assistant Secretary of the Treasury, "was made in 1875, and consisted of 20,000,000 coupon 4s. It was made under my charge, and I presume my experience was about the same as that of others serving in like capacity. The bonds were in five steel boxes, weighing when packed about four hundred pounds each, all fastened by combination locks, of which we had no key.

"We rode with the boxes to New York in a postal car. At Jersey City station we were met by the superintendent of the Sub-Treasury of New York, who had had secured for us the necessary transportation to the boat, where the bonds were deposited in the specie vault, under the immediate control of the purser, but until the boat left the pier some one of our party kept an eye on the boxes. Once at sea, however, we relaxed our vigilance, and renewed it only when again approaching land. At Liverpool, where we arrived after a pleasant passage, I had some trouble in getting the boxes through the Custom House, not being able to declare under oath that I personally knew their contents, and their being no way to open them. A compromise was finally effected by my taking with me a customs official, who should see that the boxes reached the consignees undisturbed, and when opened contained the bonds as alleged, his expenses to be paid by the syndicate. This delay caused us to remain all night in Liverpool. We had the boxes taken to our rooms, and there we took turns in watching them through the night. The English official, however, had no relief from his vigils. In the morning, through a little British gold, I obtained the practical control of a passenger car, in which we put our personal baggage and the five boxes, for which we paid as extra-weight baggage. The exclusive use of the car was deemed important, the bonds representing such an enormous amount of wealth.

"At London we were met by other Treasury officials temporarily employed at the headquarters of the syndicate, Messrs. Rothschild & Sons, in scheduling and counting bonds and coupons received in payment of the new bonds. We went with our boxes to the office of the firm mentioned, and in its money vaults our bonds were counted, found correct, and a receipt given showing that our duty had been performed, much to my relief.

"This money vault, as I remember it, opened only at the top, through the floor of the room above, and we descended by a little 'lift.' It was not an imposing sight, but it contained an enormous amount of securities issued by nearly every nation in Europe. Two men were employed there all the time receiving and sending out securities or in cutting off the coupons."—*From the Washington Evening Star.*

PURE WATER.

In determining the suitability of water for drinking purposes it is necessary, for practical purposes, to ascertain not what are its true constituents, but whether it contains an excess of animal matter.

Of course this rule applies only to the "soft" waters in general use, and not to the "mineral" waters, which form a class by themselves. All "soft" waters, unless they have been distilled, contain more or less of the lower forms of animal or vegetable life. It is the presence of these that gives the water its peculiar taste, just as the peculiar taste of the so-called mineral waters is due to the presence of different minerals, like iron and sulphur, in solution.

These low forms of life are in themselves of no particular detriment to the water, as long as they remain healthy or are unmixed with germs of disease. But if the water is allowed to stand, or is contaminated by foreign substances, it immediately assumes a dangerous aspect, owing to these same low forms of matter. The greater their number, the more dangerous does the water finally become.

There are two general methods in vogue for the purifying of water known to be more or less polluted.

The first of these, filtration, is employed usually where there are immense quantities to be handled, as in the case of water-supply of a city. It can be made as thorough as is desired by simply repeating the process, or by passing the water through finer material; and is generally sufficiently effective.

In the household, however, this process is not so practicable, partly for the lack of proper means, but more especially because, the subject not being understood, the end in veiw is defeated by the very measures taken to secure it.

We have all noticed the little bags of muslin which are often tied around the end of faucets, and most of us have probably wondered what advantage was to be gained from their use. All faucet-filters are necessarily imperfect in their operation. It is possible, however; by boiling the water, to destroy all source of danger from any form of animal life which may be present.

By this method, to be sure, many of the minerals which are of use will be separated out, but they will again be taken up if the water is allowed to cool in the same utensil in which it has been heated. The water should never be boiled for any great length of time, and should be kept covered while it is cooling.—*Youth's Companion.*

THE PROPER USE OF A SHOT-GUN.

A good sportsman is familiar with his piece, and brave enough to be afraid of it. From the time he takes it out of the case the muzzle of the barrels is on his mind until he has taken it to pieces, cleaned it, and put it away in his case. When he starts out in the morning, he takes out the barrels, and pointing them towards the earth as he holds them in his left hand, he springs the stock into its place with his right. Then having fixed on the little piece of wood which clinches the two parts together, he passes his right arm around the barrels, so that as he carries it the stock points up and behind him at an angle of about forty-five degrees, and the barrels point down toward the earth at a similar angle in front of him. Around his waist or in his pockets he carries cartridges. No charge goes into his gun until he has not only left the house but actually arrived on the grounds where he expects to find game. If he has to drive to the proper woods or the shooting-stands or blinds, he places the piece in the bottom of the wagon, pointing out towards the rear, never once allowing it to point towards himself or any one else who may be standing by. If he is near enough to the woods or shore to walk he carries the gun as described, unloaded, until he reaches the proper place. When climbing over fences, whether with cartridges in place or not, he places the gun under the fence flat on the ground, climbs over or under, and then picks it up from the other side. Resting a shooting-piece against a fence or wall in an up-right position shows the greenhorn or the careless and therefore poor sportsman. —*From Harper's Round Table.*

PERSONALITY.

"Business is business," says the man vowed to that life, and so it is unquestionably, but equally personality is personality. Leaving the latter out of consideration will throw business calculations about as far astray as those of the astronomer who does not allow for personal equations. This the successful man of affairs fully understands.

When it can be recognized there is nothing more interesting than watching the actual consultation of a business man with the promptings of his own soul's equations. Such power of consultation is not possessed by all, and is invisible with many of those who have it.

I remember hearing a young business man describe such a rare revelation in an interview with an older business friend known as the keenest financier. The proposition which the young man had to present was reasonable, seemingly sure of success, and he himself believed in it enthusiastically.

"I laid it before the old fellow," he said "one by one meeting and explaining the vexed points he raised. He ceased questioning me finally because the patent value of the proposition seemed proved as far as words go. He nodded affirmation as each heading was checked off. I felt emboldened to ask, 'What do you think of it, sir?' And then I saw a curious sight. The old fellow sat motionless, looking away into space, his blue eyes growing innocent and far away as a child's who is listening for a distant and familiar voice. I could have sworn he heard something which I did not. Finally he turned to me with a smile and shook his head. 'I can't exactly believe in your plan,' he said. I sat staring at him. I knew, and he knew, that his reason was convinced: it was an instinct alone that held the old man back—an instinct in which he superstitiously trusted and on which he obstinately acted. It was the most extraordinary thing I ever saw. The more so, that events have proved the warning voice gave him a private information which was more than correct. The plan failed dismally, as I too well know."

Extraordinary or not, those who come in contact with successful business men will see the same phenomenon repeated over and over in greater or less degree. Call it a genius for affairs, or what you will, this curious power of divination remains still as unexplained a mystery as any other kind of second-sight.—*From Harper's Bazaar.*

A FEW NOTES ABOUT COIN.

The rei of Brazil, like the mill of our own money table, is an imaginary coin, no piece of that denomination being coined. Ten thousand reis equal $5.45.

Vermont was the first State to issue a coinage on its own authority. Copper coins were issued in 1785.

The first woman's face represented on a coin was that of Pulchera, the Empress of the Eastern Empire.

The Chinese stamp bars or ingots of gold or silver with their weight and fineness, and pass them from hand to hand as coin.

The first Maryland coins were minted in 1662, and were put in circulation by act of Council ordering every house-holder to bring in sixty pounds of tobacco and receive ten shillings of the new money in exchange for it.

In 1634 the Massachusetts General Assembly made bullets a legal tender by the following enactment: "It is likewise ordered that muskett bulletts of a full boare shall pass currently for a farthing apiece. Provided that noe man be compelled to take above XIId att a tyme in them."—*From Harper's Round Table.*

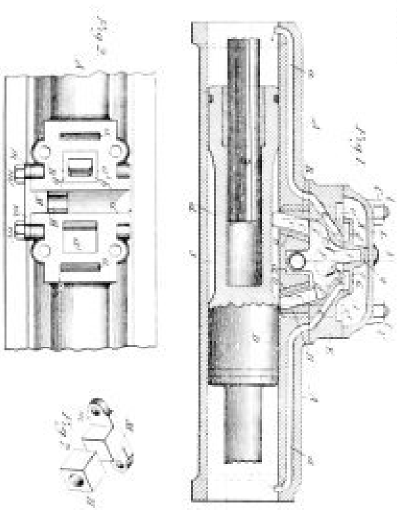
BURROS FIND WATER

The Mexican burros have good horse-sense; they know in a "dry and thirsty land" where to dig for water. A correspondent of the Pittsburg Dispatch describes their close observation of the surface of the ground and subsequent discovery. "We had found in an arroyo a sufficient quantity of water to make coffee, when we observed three burros searching for water. They passed several damp places, examined the ground closely, when the leader halted near us and commenced to paw a hole in the dry, hot sand with his right forefoot. After awhile he used his left forefoot. Having dug a hole something over a foot in depth, he backed out and watched it intently.

To our surprise it soon commenced to fill with water. Then he advanced and took a drink, and stepping aside, invited, I think, the others to take a drink; at all events they promptly did so, and then went away, when we got down and took a drink from their well. This water was cool and refreshing; much better, in fact, than we had found for many a day.

VALVE MOTION FOR ROCK DRILLS.

No. 540,330. Thomas J. Murphy, New York, N. Y. *Patented June 4th*, 1895. Fig. 1 is a sectional view, along the center of the cylinder; Fig. 2 is a partial top view of the valve face; and Fig. 7 shows the bushings in which the valve lever is journaled. The valve *G* is a double *D* valve, working on a flat face. It is moved by means of a rocker *F*, and slide blocks *C*. The rocker is pivoted in bushings *H*, which are confined in the cross groove *a'*, by the port plate *E*, and the caps *M*. The sliding blocks *C* are rounded on their lower ends where they touch the drill piston *D*, and



they slide through removable bushings *B*. The cavity which contains the rocker, is also the exhaust port. The reduction of the diameter of the piston, in order to operate the blocks *C*, is so little that the strength is not sacrificed, and the diameter of the turning bar 3 can be made as large as necessary. The bearing of the block *C* is upon the extreme end of the rocker, at the beginning of the movement of the valve, consequently the valve starts slowly and easily, gradually quickening its motion as it proceeds. The bushings *H* and *B*, and the pins *C* are quickly and easily renewable, without skilled labor.

BOILER FURNACE.

No. 540,718. Robert B. Carsley and John H. Betts, Keyport, N. J. *Patented June 11th*, 1895. Fig. 1 is a sectional top plan of the grate; and Fig. 2 is a sectional side

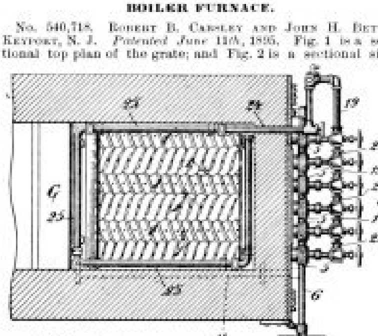


Fig. 1

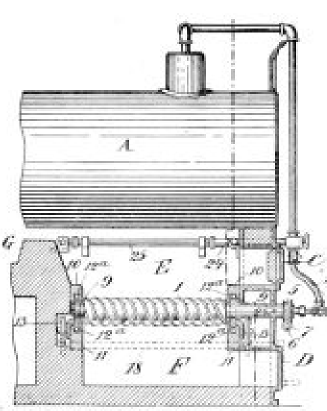

Fig. 2

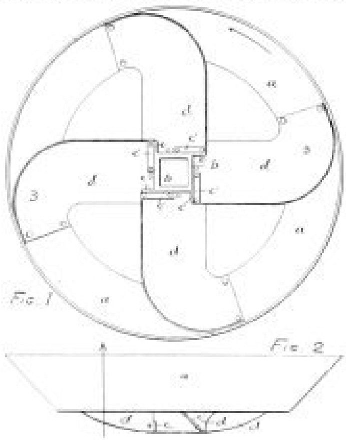
view of the apparatus in working position. The grate is composed of spiral bars, the spirals being alternately right and left handed. Each bar has four spiral threads, the right hand spirals being concave, and the left hand ones being convex; the convex and concave spirals roll closely one into the other. The bars are hollow, and perforations extend outward from the central bore to the grooves. Each bar rests in suitable trunnions at the ends, and can be rotated by means of worm wheels 5, worms 7, shaft 6 and wheel 8. These are turned at intervals, not continuously. A blast of air is blown into the hollow bore of each bar by means of an independent steam jet as shown in Fig. 1. Combustion is also aided by superheated steam, which is blown in jets from the cross pipe 24 into the upper part of the fire. The steam for this purpose is led through the superheating pipes 25, which are made of hard bronze to endure the intense heat. It is claimed that the jets of air which are distributed all over the area of the grate, make a very strong fire, which in connection with the superheated steam jets, enables soft coal to be burned rapidly without any smoke whatever.

FAN WHEEL.

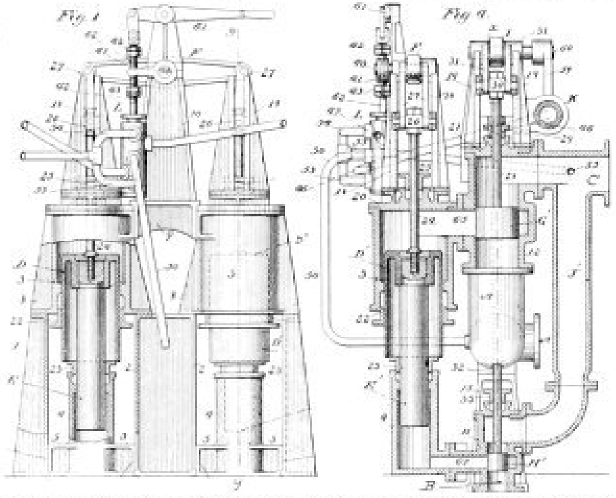
No. 536,998. Darius Bennett, Nelsonville, Ohio. *Patented April 9th*, 1895. Fig. 1 is a side view of the fan wheel; and Fig. 2 is a top view of the same. The rim of the wheel, *a*, is made cone shaped as shown clearly in Fig. 2. The vanes *d*, extend radially from the hub *b*, and are united to the rim by curved elbows 3. They are inclined at an angle



of 45° to the axis of the shaft, and they are so wide that they project beyond the edge of the rim, as in Fig. 2. The air enters at the small end of the cone, and passes through in the direction of the arrow, while the wheel rotates as shown by the arrow in Fig. 1. It is claimed that this wheel is very effective for mine ventilation.

HYDRAULIC PUMPING ENGINE.

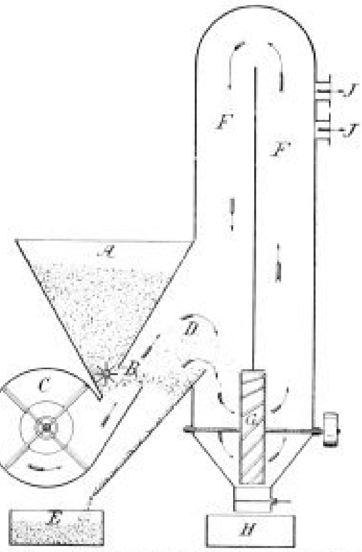
No. 538,880. Ernest W. Naylor, Bound Brook, N. J. *Patented May 7th*, 1895. Fig. 1 is a side elevation, partly in section; and Fig. 4 is a vertical cross section on the line *y y*, of Fig. 1. This machine is designed to pump water against heavy pressure, by means of water of much less pressure and is intended for mining purposes. The water for driving enters at *A*, and passes alternately to the top of the working chambers 3. The plungers *D*, *D'* are connected by rods 24 and links 27, to a beam *F*. Each driving plunger is connected to a smaller forcing plunger *E*, *E'* which forces water into the delivery pipe *B*. The admission of water to the driving plungers *D*, and the escape of water from the forcing plungers *E'*, is controlled by the piston valves *G'* and *H'*, all of which are connected by suitable rods to the beam *I*. These valves are moved simultaneously by means of a motor *K*,



which operates the beam *L*, and moves independently of the plungers *D*. This motor is composed mainly of a double acting plunger which is attached to the arm 59, and is controlled by the valve *L*. This valve is operated by an arm 41, upon the shaft 40 of the main beam *F*, or it can be operated by means of the hand lever 61. The stroke of the main plungers can be regulated by adjusting the nuts 42, 43 upon the rod of valve *L*. The inventor claims that in using an engine of this variety having main plungers of 62 inches diameter, and 72 inches stroke an efficiency of 85 per cent. is attained. The motor *K* is driven by water taken from the driving pipe *A*, through the tube 50. The spent driving water escapes at *C*, and some of it passes down the pipe *J*, forming the supply for the forcing plungers below.

MIXER FOR AIR AND COAL DUST.

No. 540,114. Constanz Schmitz, Berlin, Germany. *Patented May 28th*, 1895. To burn powdered fuel advantageously the proper amount of air must be supplied at all times. Too much air must be avoided as carefully as too little, the former cools and dilutes the gases, while the latter results in imperfect combustion. This apparatus is designed to maintain at all times a proper proportion between the coal dust and the air necessary to burn it effectively. From a funnel *A*, the ground coal is led by means of a feeding roller *B*, into an air current produced by a fan *C*, or by any other suitable means. This air current carries the coal through a channel *D*, into the store-room *F*. The air current, with which it moves, allows all the parts heavier than the fine coal dust to



fall down. These parts, say coarser coal pieces, mineral admixtures and the like, are collected in a vessel *E*. In the store-room *F*, the the air is put in motion by means of a fan *G*. The velocity of the air is such that it maintains in suspension exactly such a quantity of coal dust as, under the conditions obtaining, can be burned in the most advantageous manner. When a larger quantity of coal dust is introduced than the air in motion is capable of maintaining in suspension, it falls down and is collected on the bottom of the store-room, whence from time to time it is discharged into a vessel *H*, placed underneath the store-room *F*. From the store-room the mixture of coal dust and air is carried off through one or more conduit pipes *J*, to the furnaces, where it is consumed.

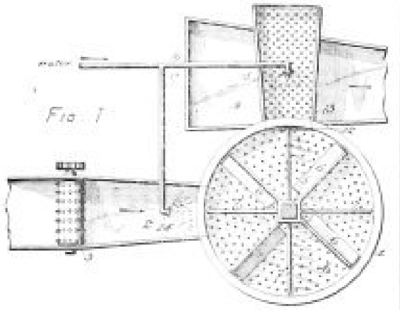
SPOONING TOOL.

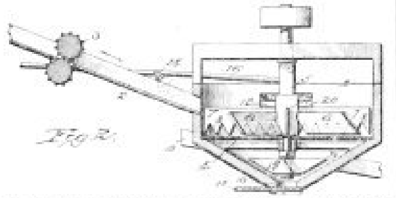
No. 540,201. Nathan E. Varney, Denver, Colo. *Patented May 28th*, 1895. The end *B* is an ordinary drill spoon, attached to the same handle with the improved spoon *D*. This is made of a conical coil of steel wire, which projects three or four inches beyond the end of the handle. The point of the coil is made flat, and is split to make two teeth. The inner edges of these teeth are made rugged, so that they will take a good hold of the rags, paper, etc., which is used for tamping shots. The tool is very useful for removing charges that have missed fire, the toothed end being well adapted to

seize and fasten to the paper covering of giant powder cartridges, enabling them to be removed from the hole with safety. It is also very useful for bringing up the fragments which are broken off from over tempered drills, etc., which must be removed before the drilling can be resumed.

COAL WASHER.

No. 541,324. George E. Giles, Carbondale, Pa. *Patented June 18th*, 1895. Fig. 1 is a top plan of the machine; and Fig. 2 is a vertical section of the same. The coal is passed through crushing rolls 3, which reduce any lumps that may be amongst it, and thence through the chute 2, to the tank 1. The tank is divided into two chambers by a perfo rated plate or grating 4, and is filled with water to the sill of the delivery spout 12. The coal is swept over the grating 4, by a set of rotating paddles 6 and 7, which are alternately inclined and vertical as shown. The clean coal escapes from the tank through the door 12, and the dirt passes downward

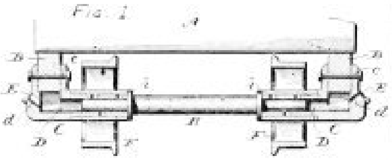




through the grating into the lower chamber. A small propeller wheel 19 stirs the sediment and keep it from lodging, so that when the slide 11 is opened, it will run out freely with the water. The coal passes down the perforated chute 13, under the sprinkler 15, to a rotary screen of ordinary construction.

MINE CAR JOURNAL.

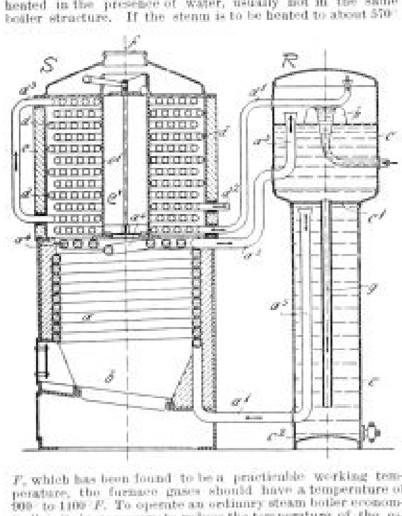
No. 537,131. JOSEPH STEPHENS, FOREST CITY, PENN'A. *Patented April 9th*, 1895. Fig. 1 is a section through a pair of wheels and journal bearings; Fig. 3 is a detail view of the bearing. Each bearing consists of a hollow cast-iron sleeve which is provided with suitable flanges by which it can be bolted to the car frame. The projecting part of the sleeve



is turned to fit the bore of the wheel *F*, and is bored to fit the dummy axle *H*. This axle serves only as a brace to maintain the bearings in proper alignment, and does not receive the wheels. Therefore it never wears out. The interior part of the casting is used as an oil box, being provided with oil holes *K*, and a filling hole *d*, and cover *E*.

SUPERHEATING BOILER.

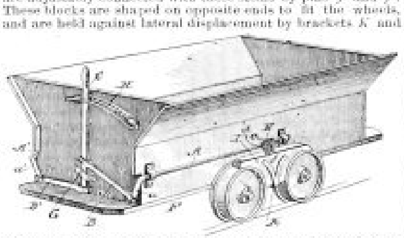
No. 539,827. WILHELM SCHMIDT, WILHEMSHOHE, GERMANY. *Patented May 28th*, 1895. It has been found by extensive experiments that the use of superheated steam is attended with considerable economy. But steam cannot be superheated in the presence of water, usually not in the same boiler structure. If the steam is to be heated to about 570°



F, which has been found to be a practicable working temperature, the furnace gases should have a temperature of 900° to 1100° *F*. To operate an ordinary steam boiler economically, it is necessary to reduce the temperature of the escaping gases to about 480° *F*. It has also been found that more than half of the steam generated in a locomotive boiler is generated from the fire box sheets alone, and that the remainder of the heating surface, although exceeding the fire box surface in extent many times; is far less efficient because of the lower temperature of the gases passing over them. All of these facts have been duly considered in designing the boiler here shown. Steam is generated only in the coils *a*, which constitute the fire box. The circulation is very rapid, and the mingled steam and water is delivered through the pipes a^2 and a', into the top of the receiver *R*. Here the steam parts from the entrained water, and passes through the pipe d' to the coils *d*, in the superheating chamber *S*. The steam passes through alternate coils until it reaches the top of the chamber, then downwards through the intermediate coils, and out through the pipe d^2. The hot gases fill the upper chamber, and escape through the central flue *e'*, being controlled by the dampers shown. The head of water in the receiver is sufficient to keep the coils *a* always full, and the coils being intensely hot, the steam is generated under the most economical conditions. The heat remaining in the hot gases after they pass above the coils a^4, is extracted by the superheating coils *d*, and the temperature of the escaping gases is made as low as desired. Thus the receiver serves, not only to catch and deposit the impurities of the feed water which enters and overflows at *h*, but to separate the steam generating from the superheating chamber, and to free the steam from the entrained water which usually makes superheating impracticable.

BRAKE FOR MINE CAR.

No. 540,248. SCOTT HAIRE, REDSTONE, PA. *Patented June 4th*, 1895. The shafts *A* and *A'* on each side of he car *F*, are journaled in suitable bearings and have arms *d* and *d'* and cranks *a* and *a'* respectively. The operating lever *C* is pivoted to the front of the car at *G*, and is connected with the cranks *a* and *a'* by the links *B* and *B'*, which are connected to said lever on opposite sides of and equi-distant from pivot *G*. The upper end of lever *C* passes through notched keeper *H*, by which it is held in position. The brake blocks *I* and *I'* have vertical stems, *E* and *E'* respectively, which have a series of pin holes *e* and *e'*. The arms from the shafts are adjustably connected with these stems by pins *f* and *f'*. These blocks are shaped on opposite ends to fit the wheels, and are held against lateral displacement by brackets *K* and



K', which are fastened to the bottom of the car and have their outer ends spread, as shown, to obtain a broad hold on the blocks. By operating lever *C*, in the proper direction, the shafts *A* and *A'* will thrust the brake blocks firmly down between the wheels, upon both sides of the car.

COAL DRILL.

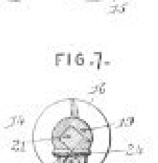
No. 541,171. LEWIS W. LEGRAND, WILKES-BARRE, PA. *Patented June 18th*, 1895. Fig. 4 shows the form of the joint which is used to connect sections of the auger; Fig. 6 shows the drill with the bits in place; Fig. 8 shows the cutting bits; and Fig. 7 is a section across the socket, showing the bits in place. The auger is made with a hollow or tubular body 15,

FIG. 4.

FIG. 6.

FIG. 8.

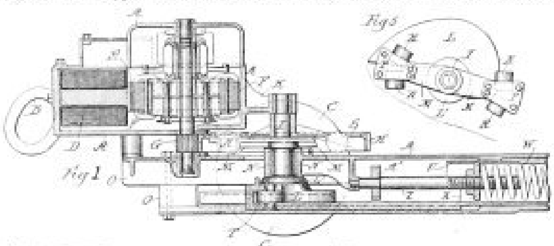
FIG. 7.

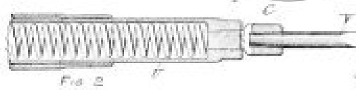


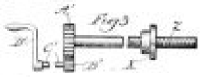
and a spiral blade 16, which may be either double or single, as preferred. Each section is formed with a conical socket 17, having a T slot 18. The end of the feed screw, and of each extra section or lengthening piece, is provided with a round taper shank, which is secured by means of a pin 32, and which has a stud 31. This stud catches in the corners of the T slot 18, and prevents the parts from separating, either when drilling or backing out of the hole. A leading bit 21, is held in a central socket 19, and a smaller enlarging bit 22, is held in a side socket 20. Both bits are notched on their edges so that they may be held in place by the single pin 24. This combination of bits makes a very rapid, free cutting tool.

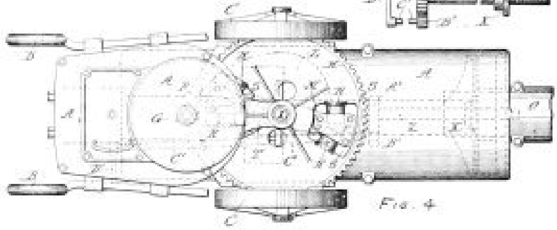
MINING MACHINE.

No. 536,438. EDMUND C. MORGAN, CHICAGO, ILL. *Patented March 26th*, 1895. Fig. 1 is a vertical section of the machine; Fig. 2 shows the pick, and its holder; Fig. 3 shows the means of adjusting the tension of the striking spring; Fig. 4 is a top view of the machine and Fig. 5 shows a top view of the main





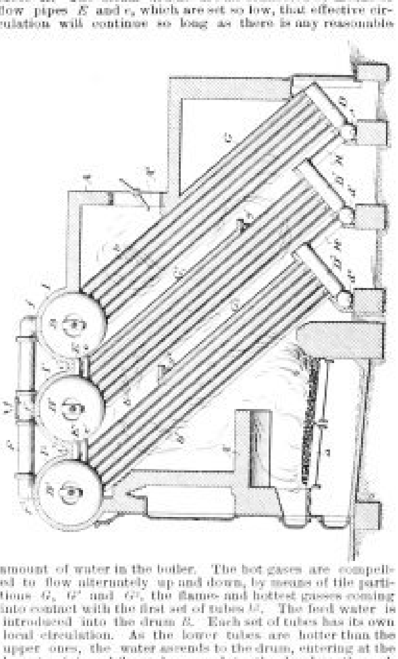




cam. The machine is driven by an electric motor consisting of the magnet *D*, armature *F*, and pinion *G*, which gears into the horizontal gear wheel *H*. The tool *V* is socketed in the end of a hollow plunger *U*, which slides within the guide tube 3. The pick is shot forward by a strong spiral spring *W*, and is drawn back by a large cam *L*, which engages the roller *T*, at the back end of the plunger *U*. The cam is cast in one piece with the spindle *I* and buffer arms *M*. The wheel *H* is loose upon *I*, and has large pockets *S*, in which the buffers *P* and *R* have some play, thus the connection between the motor and cam is made elastic. The rubber blocks *R* absorb the most of the shocks. The spring *W* bears against the circular nut *X*, and the tension may be adjusted while running by rotating the screw *Z*. This may be done turning the handle *D'*, and pinion *B'*, which are shown in Fig. 3 and 4 by dotted lines. The machine is mounted upon two wheels *C*, and steered by two handles *B*, in the usual manner.

WATER TUBE BOILER.

No. 541,330. LAURIE M. MOYES, PHILADELPHIA, PA. *Patented June 18th*, 1895. The water tubes are divided into three groups, *b*, *b'* and b^2, and they are connected to the three steam drums *B*, *B'* and B^2. Each vertical row of pipes is connected to a header *D*, and the headers are connected to the mud drums *d*, *d'* and d^2. The headers are connected at the top, to the next mud drum, by means of the tubes *H*. The steam drums are all connected by means of flow pipes *E* and *e*, which are set so low, that effective circulation will continue so long as there is any reasonable



amount of water in the boiler. The hot gases are compelled to flow alternately up and down, by means of the partitions *G*, *G'* and G^2, the flame and hottest gasses coming into contact with the first set of tubes b^2. The feed water is introduced into the drum *B*. Each set of tubes has its own local circulation. As the lower tubes are hotter than the upper ones, the water ascends to the drum, entering at the lowest point, and flows downward to the headers through the upper tubes. The sections of the boiler being amply connected at both top and bottom, there is no danger that any section may become unduly empty or overheated.

The Colliery Engineer

AND

METAL MINER.

VOL. XVI.—NO. 2. SCRANTON, PA., SEPTEMBER, 1895. WITH WHICH IS COMBINED THE MINING HERALD.

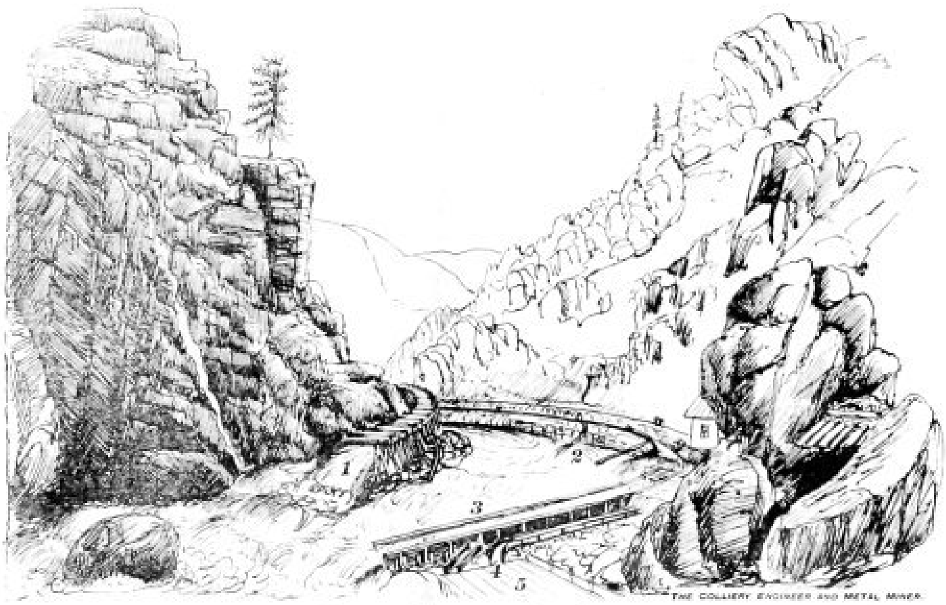
Written for THE COLLIERY ENGINEER AND METAL MINER.

PROSPECTING FOR PLACER GOLD.

A NOVEL AND GIGANTIC SCHEME IN CLEAR CREEK CANYON, COLORADO.

Showing how Gold is Obtained on a Large Scale from Gold Bearing Gravels under Favorable Conditions.

"Prospecting" may roughly be defined as looking for precious metal we hope and believe exists, but of whose actual presence, we have no positive assurance. "Mining" on the other hand is when we have actually found ore and are following and developing it. Under this definition there are many kinds of prospecting. There is prospecting for mineral leads with pick and shovel and for placer gold with a gold pan and rocker. There is prospecting on a bigger scale by diamond drills, such as are now puncturing the mountains above Leadville in search of the gold belt. It is prospecting on a gigantic scale when a large company, like one at work at Idaho Springs, drives a tunnel for five miles through the mountains in search of veins of gold, some of which they know to exist, and others they hope to find. It is prospecting still when, as in the present case, a company undertakes to work the gold bearing sands of Clear Creek on a gigantic scale and with gigantic and novel appliances. Instead of the miner's little ditch or sluice, they have constructed a flume a mile or more in length, twelve feet wide and eight feet deep to turn the course of the primeval torrent and carry its waters bodily on one side, so as to expose and lay bare an interval of a mile and more of the river bed for their operations. Instead of the miner's little pipe short tom or long tom and driblet of water, the latest invention, Allen's big stave pipe over three feet in diameter, is brought to bear and has been laid down for a mile, whilst attached to it is another mile of black steel 16 inch pipe forking at the end to accomodate two giant nozzles with a pressure of 125 feet vertical head and a force like that of a cannon. These powerful nozzles are to wash and blow the gravel out of the creek bed and up through an elevator pipe into a double flume above them where, as the gravel washes rapidly over the floor of the sluice, the heavy gold drops to the bottom and is caught in the interstices between square blocks of wood, called riffles, with which part of the floor of the sluice is lined, or failing in this it passes over a perforated iron floor and drops through to a smaller sluice a little below and along side it, lined with brussels carpet to catch the finer and residual gold that may have escaped the riffles and perforations of the larger sluice; finally contributions from both find their way to a wide troughlike sluice called an "undercurrent" lined with hundreds of small riffle bars and with carpet. Here it is treated further and collected with amalgam or quicksilver, which by its peculiar affinity for gold collects it in its silvery body, from which later it is easily extracted by retort. But we are anticipating.



SLUICES AND FLUME AT THE STONE DAM.

1, FLUME; 2, PIPES AND NOZZLES; 3, GOLD SLUICE; 4, SMALL SLUICE FOR FINE GOLD; 5, UNDERCURRENT SLUICE.

CLEAR CREEK CANYON.

Clear Creek Canyon is one of the steepest and grandest canyons in these mountains. It is cut through granitic rocks for a distance of forty miles and to a depth of upwards of a thousand feet from its commencement above Georgetown, to its outlet on the plains at Golden. This was the work of ancient glaciers and of the present stream.

About 13 miles above its outlet, on the foothills, the creek forks, one branch going up towards the gold mining town of Central City, the other to the gold and silver mining town of Idaho Springs, heading above the silver mining town of Georgetown. Thus it drains two gold bearing areas. At Central in addition to what it may bring down in the way of gold from the veins and rocks direct, it brings down also a great deal of fine flour gold, the refuse of the stamp mills who lose on an average upward of 40 per cent. by their crude methods. This refuse gold has been accumulating for the past thirty years from the mills alone, not to say what for ages has been derived from the rocks themselves. The first paying placer was opened where Central and Blackhawk now stand. The bed rock was very rich and miners are said to have averaged $100 or more per day with their rockers and "short toms" as long as their small claims lasted.

CHOICE OF LOCALITY.

We may assume, then, that the gold bearing streams unite with their freight at the forks of the creek, hence, the reason why the originators of the present scheme selected a site for their operations a little below this at a point now called Roscoe. The other reasons why the originators of the scheme and their engineer, after having looked the creek over from end to end, selected the present location above all others, will appear when we describe the locality in question.

As we ascend Clear creek about eight miles, we reach a point where its scenery reaches its grandest, by reason of the precipitious character of the granite walls and the narrowness of the canyon between them.

Tier upon tier of massive layers of granite and gneiss rise above one another, forming steep cliffs, which at this point begin to be intersected by great red dikes and veins of feldspar and quartz, which are suggestive of mineral, the more so as some of them are rusty and oxidized. At Roscoe there are several such veins, some of which, near the surface, are being worked successfully for gold.

THE STONE DAM.

It is by the breaking down of a huge vein of this kind that lay right across the canyon that we enter the grand portal to the Roscoe property. The great vein originally was thrown, like a natural dam, across the creek till, the waters undermining it, it fell through and the stream now dashes down a foaming rapid with a vertical fall of thirty feet between great boulders.

This struck the engineer as an excellent point. Here was a splendid place for a dumping ground of the material dug out above. One of the first things to be looked for in a large placer property is convenience for dumping the excavated gravel, otherwise the property will soon become choked up by its own refuse and have to be abandoned, no matter how much gold may still be there.

Here, then, was both a drop of some thirty feet and a powerful rapid torrent to carry away the debris as fast as it collected.

Passing through this wild and most picturesque gateway, worthy of the brush of a Bierstadt, now known as the "Stone Dam," we come upon a long stretch of upwards of a mile or more of comparatively quietly moving water, underlaid by deep gravel, locally called a "bar," part of fine gravel, part of good sized boulders. As gold is generally found either amongst the large boulders or the fine gravel, this combination of circumstances was further in favor of the choice of the location. As a secondary consideration, there were the gold "leads" we have alluded to, which doubtless contributed some of the coarse gold to the placer. Again, the railroad ran conveniently close to the stream and the projected works on the bank, just about the right height for using its grade for the pipe lines to work the great giant nozzles in the stream bed below. The opposite bank, too, was here low and gentle, and well adapted for constructing the great flume along its margin. And, as if nature herself had foreseen the undertaking, a natural bend and widening outwards of the bank at one point for upwards of a hundred yards contracted the main waters of the stream into a natural mill sluice, which later proved most advantageous for beginning the construction of the flume. But what of all these natural advantages if there is no reasonable assurance of gold along this stretch? This question has been satisfactorily answered.

Placer Mining at Clear Creek.

PROSPECTIVE GOLD IN THE AREA.

The area is an old prospect ground, prospectors have poked about and scratched its surface at times of low water and there are wrecks of old wheels and primitive sluices. These wheel pumps were used to pump water out of the pit from which miners were taking gravel but were never successful in handling water to a depth of more than four or five feet. By them the whole surface has been washed over and still one can make a days wages by washing in some places.

Thirteen prospect holes have been sunk to bed rock which lies at a depth of 20 to 30 feet. The gold grew coarser the nearer bed rock was approached and on bed rock the dirt was very rich. The lowest amount taken from any hole was $26.30 and the highest $87.60. The bed rock averaged from 2 to 4 to 10 dollars per yard. The largest nugget weighed a little over an ounce." The Mining Industry of Denver institutes comparisons between these sands of Clear Creek and those of other parts of the world. New South Wales is accredited with $6.66 per yard; California 10 to 20 dollars; Canada $1.34; Alder Gulch, Idaho, estimated product at bed rock at $10.00 per yard and a total production for six miles of work at $80,000,000. One pan of dirt in Clear Creek is said to have yielded over 15 ounces in gold. The average yield of the paying placer mines of California worked by hydraulics is about 6 cents per yard. Clear Creek has been worked all along its length by prospectors since the days of '59 but on a most superficial small scale. In few cases has the deeplying bed rock, the favorite repository for the richest and coarsest gold, been reached, or even attempted owing to the great depth at which it generally lies, consequently, the present undertaking will be upon practically "virgin" and unexplored ground. The main aim is to reach bed rock and expose and clear it up and even penetrate some depth into it in search of gold that may sink through crevices. This will be done over an area at least a mile long and from 50 to 250 feet wide.

PLAN OF SCHEME.

The *Mining Industry* gives a concise account of the programme of the undertaking illustrating it by a somewhat ideal sketch giving a rough idea of how it may appear in a month or so. The cut (which we reproduce) shows a giant and hydraulic elevator at work in the dry bed of Clear Creek from which the water has been removed to one side of the big flume. The *Industry* says: "A great flume is constructed by the side of the creek capable of carrying all its water, which is turned into it by means of a dam. Then a pit is dug to bed rock at the lower end of the ground to be washed which may require a pump. A gravel lifter consisting of a pipe through which rock, gravel and water is forced by the water jetted from a hydraulic nozzle below it, carries the rock and gravel to the height above the surface necessary to get needed grade, down which it is washed to the canyon below using the needed "under current" sluice to secure the fine gold. A sluice box is meanwhile carried along in the bed rock of the pit. A pipe giving a head of over 100 feet and carrying a thousand inches of water gives the needed hydraulic head. When the working has advanced far enough up the stream, the pit left behind can be used for a dump. The flume by the side of the stream will furnish the power to run a dynamo which will operate a derrick and pump and by large railway "headlight" lanterns the ground will be lighted at night."

As the incipient stages of a big concern like this are amongst the most interesting and instructive part of its history we have given in our illustrations a view of things as they are at present in their incomplete state and when operations are at a standstill, owing to an unusual and protracted flood and very high water. Later we propose to give the details of the work and construction from its inception to its completion which should be within the course of the coming month.

OHIO COAL STATISTICS FOR 1894.

Interesting Figures Compiled From the Report of the Chief Inspector of Mines.

A summary of the report of Chief Inspector of Mines, R. M. Haseltine, of Ohio, shows that in 1894, the production of coal was 11,910,219 tons, a decrease of 2,917,878 tons as compared with the previous year.

By analysing the tables we find that the production of lump coal decreased 2,311,009 tons; nut coal, 373,268 tons; and pea and slack 233,601 tons. Of the total amount of coal produced, 4,371,801 tons, or 36.7%, came from Perry, Athens, and Hocking counties, a district known all over the country as "The Hocking Valley Coal Field." Jackson county produced 1,499,287 tons, the largest production of any single county. This county and the three previously mentioned, are the four leading coal counties of the State.

Of the year's production 2,555,466 tons were mined by machinery. This is a gain of 2,392 tons as compared with 1893, and is the only gain in production found in the report. Machine mining is confined to 9 of the 30 coal producing counties of the State. The largest production occurred in Hocking county which is given as 1,343,188 tons or 52½% of the entire amount of machine mined coal. This is followed by Athens with 22⅐ and Perry with 20⅘%. The three counties of Athens, Hocking and Perry produced 96% of the machine mined coal of the State. 452 hands were employed in operating the machines and 3,207 hands in blasting down and loading the coal after it had been undermined by the machines. Installations of mining machines were made at six mines during the year. There are 36 mines in the State equipped with machines of which 19 are supplied by compressed air and 16 use electricity. Of these 175 machines of various types, 171 were on the active list during the year, an increase of 23 over 1893. Of this number 60 are of the electric type, and 112 compressed air, which is a gain in electric machines of 19 and an increase of 5 in those operated by compressed air.

There were 31,493 persons employed in and about the mines during 1894; of this number 25,163 are classed as miners, a gain of 2,700 as compared with 1893. Seventeen counties showed gains in the number of employes aggregating 3,337, while thirteen counties showed losses aggregating 675. One-third of the gain in number of miners occurred in Hocking county. The reason assigned for this is that only machine mines could be profitably operated under the intense competition which prevailed during the year, and Hocking, being the leading machine mining county in the State, collected the greatest number of miners.

There were 119 new mines opened during the year, 67 remained idle, and 59 were either exhausted or abandoned. At the close of 1894 there were 1,163 mines in the State, of which number 1,096 were in operation a greater or less portion of the year. Of this number 411 employed more than ten men each, and 685 a less number.

257 accidents occurred in and about the mines during the year. Of this number 45 were fatal, 116 serious and 96 of a minor character. There was one accident for each 46,343 tons of coal mined; 264,672 tons were mined to each life lost and 102,674 tons to each serious injury. 38% of the year's casualties were due to falls of roof, 15% to falls of coal, 23% to contact with the mine cars, 7½% to premature explosions of powder and one fatal and four serious were due to fire-damp.

The Iron Ore production was confined to the three counties of Jackson, Lawrence and Scioto in which there were mined 58,043 tons which is the lowest of any year since the department has had cognizance of the industry. The fire clay industry has also suffered keenly from the commercial depression. The production amounted to 942,913 tons, a loss of 89,435 tons over 1893. That it was quite general will be seen when out of 15 counties that reported, 12 returned losses in production. There was a loss of three weeks in the time worked, 75 in the number of miners and 162 in the number of hands employed in the manufacture. In the production of limestone the returns for the year show a loss about proportionate to that which occurred in the other statistical branches of the report. The industry was carried on in 39 counties of the State. The average time worked was 25 weeks, a loss of two as compared to the previous year. The number of men engaged is given at 2,384, a loss of 544, the heaviest that has occurred during the time that the industry has been under the care of the department.

The report contains an article on the quality of oil used for illuminating purposes in the mines, and one on the quantity of powder consumed, and the amount of coal produced to the keg in the several counties. There is an auxiliary article on mine fires, their origin, prevention and extinguishment, and one on electricity in bituminous coal mining which contains many interesting figures obtained by absolute experiment.

Something About Mechanical Rubber Goods.

No single treatise or other work hitherto published on the India rubber industry gives an insight into such a variety of uses of this important material as does the new "Descriptive Catalogue and Price List of the N. Y. Belting & Packing Co., L't'd.," a bound volume of 100 pages. This catalogue is a distinct departure from others, in that it combines the artistic with the practical. The commonplace and somewhat monotonous trade catalogue is enlivened by sketches and descriptions that, in a pleasing way, convey an idea of the various uses of rubber, besides containing much information on the methods of manufacture, in which respect it marks a wide difference from the former policy of manufacturers, of keeping secret all facts of this kind.

This catalogue is introduced with some notes on the history of the N. Y. Belting & Packing Co., L't'd. with illustrations and descriptions of their three factories. Some account of their trade-marks follows, after which comes the department of rubber belting, to which thirteen pages are devoted. There is an account of rubber belting in general, followed by detailed descriptions of the belting made by the company for grain elevator use, threshing machines, paper mills, etc.; price lists of leather and rubber belting, and information of value on the use and care of belts, rules for calculating the speed of pulleys, rules for calculating horse power, how to splice belts, and other similar information.

Twenty-four pages are devoted to rubber hose, with an account of its manufacture; steam hose, which is an important product of this company, occupies three pages, with valuable tables and lists; one page is given to air-brake hose, two to fire hose, four to cotton hose and the "Leatherite" treatment of same; three to suction hose; seventeen to mats and matting, including the company's new patented rubber tiling, which they have supplied to the new steamers St. Louis and St. Paul; eight pages are given to packing, gaskets and tubing, and six to emery wheels. Considerable space is devoted to specialties, of which a large variety are illustrated, together with remarks on vulcanization and mold work. Bicycle tires are briefly disposed of, as a separate pamphlet has been published on this subject. A double index, new and convenient in arrangement, gives the pages of both the lists and descriptions of articles. Altogether it is the most complete, comprehensive and artistic rubber goods catalogue that has ever been issued. The Scranton Supply and Machinery Co. of Scranton, Pa., are special representatives in the Anthracite regions for the N. Y. Belting & Packing Co. They will be pleased to send a copy of this catalogue to any mine manager or superintendent.

Coal and Coke Exhibit at Atlanta.

The Tennessee Coal, Iron and R. R. Co. is preparing an extensive exhibit for the Cotton States' Industrial Exposition. It will consist of full sections of the company's coal seams, specimens of coke, samples of pig iron, iron ores, limestones, etc. The most interesting feature of the exhibit will be a relief map of the Birmingham (Ala.) district showing the contiguity of the company's raw materials to the furnace plant. Photographs of the various plants with maps etc. will also be shown. The exhibit will be in the East Wing of the Alabama building just east of the Government building. It will be in charge of Mr. Chas. E. Bowron, mining engineer, whose name is familiar to most of our readers, owing to his contributions to our columns. He extends a hearty invitation to all our readers, to visit the exhibit.

COAL-WASHING.

NOTES ON A SOUTHERN COAL-WASHING PLANT.

A Description of the Coal Treated and of the Machinery Used With a Statement of the Results and Cost of Operation

(By J. J. Ormsbee, Tracy City, Tenn.)

[Transactions of the American Institute of Mining Engineers.]

Attempts at coal-washing have been made in the Southern States during the last twenty years; but it is only within the last four or five years that the practice has become at all general. It might perhaps be claimed as one of the blessings derived from our departed "booms;" for, during their sway, the supply of coal of all qualities, good and bad, could not equal the demand; but with the subsidence of the inflated demand, came imperative calls for fuels of better quality, and washers, previously regarded as luxuries, became necessities.

Among those now in use in this section are representatives of the following types or classes: the trough washer; the jig washer; the percussive table; and those washers, in which a constant upward current of water effects the separation. Without having full statistics, it is safe to say that there are in successful operation in the South more washers of the last class than of any of the others. The purpose of these notes is to present data with regard to the construction, operation, and results of one of these current-washers, based mainly on the plant at No. 2 Slope, Pratt Mines, Alabama.

The coal is mined from the well-known Pratt seam, having here an average thickness of 3 feet 6 inches. It has distinct cleavage-planes; and breaks in cuboidal lumps; is bright black in color, firm in structure, and air-slacks only after considerable exposure. It burns freely, leaving a gray or buff-colored ash. The lump and nut-coals are used for domestic and steam purposes (chiefly, however, for locomotive firing), and the slack for making coke. The specific gravity is 1.272.

The coal from the mines is dumped on an ordinary bar-screen, with spaces 2½ inches in the clear, all going over this screen being shipped as lump. That which passes through is received on a shaking bar-screen, with ¾ inch spaces, which separates the nut from the slack. All the coal going through this screen is sent to the washer. Of an output of 700 to 800 tons per day, about 40 per cent. is shipped as lump and nut, and the remainder is washed for the coke-ovens.

The impurities occurring in the coal are pyrites, mineral charcoal, and slate partings. As delivered at the tip there will be also foreign slate (shale), and dirt from the top and bottom of the seam. The pyrites is found generally in thin sheets or local partings, and not in nodular form. The mineral charcoal also occurs in limited streaks, neither of these impurities forming regular partings of any extent. The slate parting is persistent, varying from a mere trace to a couple of inches in thickness and occupying a constant position about eight inches from the roof. The other impurities mentioned are due entirely to careless mining. The pieces of slate and pyrites in the slack-coal are for the most part thin, and have a length and breadth several times as great as their thickness. The specific gravity of the slate is from 1.8 to 2.

In mining the coal, single entries, with air-courses, are driven, and the workings are opened out by "room-and-pillar." The rooms are made 13 yards wide by 100 to 120 yards in length, the pillar left being 7 yards in breadth. All mining is done by hand, the coal is undercut with the pick and generally brought down by the use of black powder. Sometimes no explosives are needed. The bottom varies, being often a fire-clay, sometimes a soft, and again a very hard, slate. The roof is a sandstone in some parts, a gray slate in others. Between the coal and the roof there is usually, but not always, a thin "muck" parting.

Fig. 1.

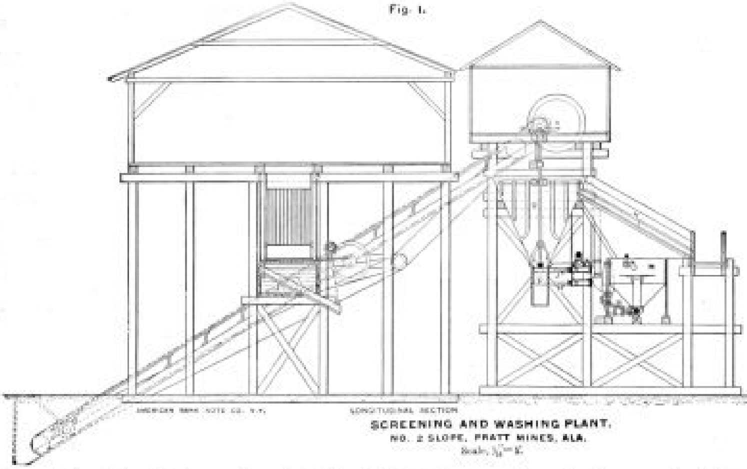

Fig. 2.

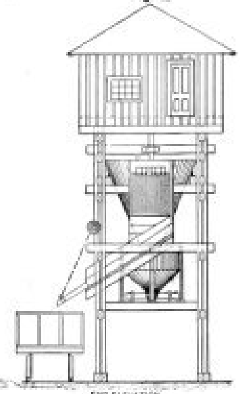

SCREENING AND WASHING PLANT,
NO. 2 SLOPE, PRATT MINES, ALA.
Scale, $\frac{1}{16}$" = 1'.

THE WASHING-PLANT.

This consists of a 400-ton Robinson washer, with the necessary appliances for handling the coal before and after washing. The coal that passes through the nut-screen descends by gravity to a 16-inch screw-conveyor, with a pitch of 18 inches (*A*, Fig. 3). It is horizontal, 19 feet 6 inches long, and has, at a speed of 25 revolutions per minute, an actual capacity of 75 tons per hour. This screw delivers to a flight conveyor (*B*, Fig. 3) with a slope of 32 degrees, the flights being 7½ by 13 inches and set 21 inches apart. As shown in the figures, the lower end of this conveyor is below the railroad-level, that it may take coal from the screw (*C*, Fig. 1), which is used at night, when coal from other mines is brought in by rail. The coal is delivered by this elevator over the central part of the washer-tub (*D*, Fig. 1). This is a cone-shaped tub of iron, 11 feet high, 11 feet 6 inches in diameter at the top and 22 inches at the bottom, the shell being ½-inch in thickness. At the lower end is an annular compartment, connecting with the water-supply, and so perforated as to admit the water to the cone in the form of a number of small upward jets. In the center of the cone is a vertical shaft, reaching nearly to the bottom and carrying four wooden arms, to which are attached iron stirrers. Short stirrers are also attached directly to this shaft near its lower end. Motion is derived by means of gearing from an engine above.

The slack dropped from the conveyor into the washer starts to descend, but is met by the ascending currents of water, and the particles of coal are stopped in their downward career and carried up and over the discharge (*E*, Fig. 2), while the heavier impurities continue to the bottom. This separation is assisted by the continual agitation caused by the stirrers, which make 8 revolutions per minute, and are so arranged that the two sets travel different paths. The refuse material collects in the chamber (*F*, Fig. 1), closed at the bottom by the valve (*H*). When the attendant is satisfied that this chamber is full of slate, the valve (*J*) is to be closed and the lower valve (*H*) opened, discharging the waste into a car without at all interfering with the process of washing. But in practice the waste is allowed to accumulate in the bottom of the cone, and emptied three or four times an hour by working the valves until it is certain that about all the refuse has been taken out. At first the valve-levers were operated by hand, requiring two and sometimes three stout men. But this method has been replaced by an arrangement of steam-pistons, so that the valves are now worked by one man without exertion. At the time when these notes were taken the slate was hauled away by a mule and driver; but it is intended to do away with this arrangement, and run the car by rope, so that one man can do all the work for the washer.

The cleaned coal and water passing the overflow (*E*, Fig. 2) are received on the screen (*K*, Figs. 1 and 3). At first there was but one screen, of steel, with ⅛-inch perforations. It did not drain the coal satisfactorily, and wore out in a very short time. The present arrangement consists of two screens, both of manganese bronze. The upper one is ¼-inch thick, with ⅜-inch perforations, ⅝-inch from center to center. The inclination is 30 degrees, and the screen is 4½ feet wide by 15 feet long, the last three feet, however, being blank. The fine coal and water that pass through this upper screen fall on the screen (*L*, Fig. 1), of No. 20 metal, having $\frac{1}{32}$-inch perforations, the coal from both screens discharging into a chute, which empties into the railroad cars. The water and sludge passing through the lower screen go to the tank (*M*, Fig. 1), from which the pulsometers draw.

In the English and the earlier American plants this tank was merely a "sump" for the pulsometers. But even with $\frac{1}{32}$-inch perforations there is a considerable amount of solid material—fine coal, slate and pyrites—contained in the water. As all the water, except that carried away by the washed coal, is used over again, the effects of the attrition of this material in the pumps and pipes is serious. Valves quickly wear out, and at one plant in the Birmingham district a pulsometer lasted only eighteen months. Again, with the simple tank this fine sediment—and especially the slate and pyrites—settles on the bottom, accumulating until it acquires a considerable height above the level of the discharge-pipe from the tank to the pumps. This, after a while, slips down with a rush and clogs up the pumps to such an extent as to prevent them from working. Daily shoveling was required to overcome this annoyance.

After experience of this sort at the Shaft No. 1 washer, Mr. Erskine Ramsey, Chief Engineer of the Tennessee Coal, Iron and Railroad Company, devised a tank that has been used at the No. 2 Slope plant with gratifying success. As shown in Figs. 5 and 6, it is an iron tank, cylindrical in section at the top, funnel-shaped at the bottom. In this tank is a circular deflecting-plate (*a*, Fig. 5). The water, charged with fine coal and impurities, is delivered into the top and at the center, so that there may be an even distribution over the entire surface of the plate. The flow of the water, on entering the tank, is indicated by the arrows in Fig. 5. With this current of water are carried the fine coal-particles, while the impurities, owing to their greater specific gravity, drop from the current, as indicated in the sketch, into the comparatively still water below the level of the mouth of the pump-supply pipe (*b*, Fig. 5), and collect in the bottom of the tank. From here this refuse is removed by means of a valve (*c*) discharging the sludge into a trough, by which it is carried to the waste-car under the washer-tub. The relation between the diameters of the deflecting-plate and the tank is a

Fig. 3.

Scale, $\frac{1}{16}$" = 1'.

point depending on the amounts of coal and of impurities in the fines and on the difference in specific gravity of these materials. With too small a plate the impurities will go to the pumps with the coal. With too large a diameter the coal will not be carried along with the current, but will be lost with the slate. Once regulated for a given coal, the results are distinctly good, as will be seen from analyses of refuse at the No. 2 Slope washer, given below. In connection with this tank is the valve for supplying the fresh water needed by the washer, automatically regulated by a float (*g*, Fig. 5, and *N*, Fig. 1).

The water, freed from its heavier impurities and augmented by the necessary amount from the fresh-supply pipe, is taken by the pulsometers through the central pipe (*b*, Fig. 5), and the connections (*e*, *e*, Fig. 6), and pumped directly into the washer-tub. This is an innovation on former practice, the old plan being to pump into a tank 40 to 60 feet above the bottom of the washer, with a discharge-pipe from this tank to the washer, in order to maintain a constant head. At this plant the same object is accomplished at less expense. The pipes between the pulsometers and the washer are connected to a stand-pipe (*P*, Fig. 4) 80 feet in height and open at the top. This acts as a balance on the inflowing current, and is of especial advantage when, as sometimes happens after a stoppage, the material in the washer becomes packed. The pumps then force water up the stand-pipe, until a head is developed sufficient to force a way through the obstructing stuff. Seldom has this column-pipe overflowed.

The engine that drives the washer-machinery is single, 10 by 16 inches, with 3-inch steam-supply. It furnishes also the power for operating the two screws, the elevator, and the shaking screen. The steam-plant includes six boilers, each 46 inches in diameter by 26 feet long, with two 15-inch flues, and fired with "run-of-mines" coal. Three boilers are in use, carrying 85 to 90 pounds steam-pressure, and supplying steam for the pair of hoisting-engines at the slope as well as for the washer-engine. One fireman is employed.

One man does all the work at the washer. He must watch the engine and keep it and the other machinery oiled; operate the main slate-valves three or four times an hour, and also the sludge-tank valve, and load the washed coal into the railroad-cars. He is by no means overworked in attending to these duties, and will have ample time to run the refuse-car when the rope-haul for it is introduced. For the same capacity, even the trough-washers can hardly excel, if they can equal, this labor record.

The cost of a Robinson washing-plant must vary with the particular conditions at each locality. Basing the estimate on the records of several plants in Alabama and Tennessee, the total cost of a 400-ton plant complete and ready for washing, including machinery for supplying the coal and disposing of it after washing, and also the royalty to the owners of the patent-rights, may be put at from $5,000 to $8,000. The cost of the washer-tub and its immediate appliances would be about $1,000. The cost of repairs is low; in fact, to the washer proper, there will be almost no repairs needed. But water-valves, pumps, screens, elevators, etc., need attention and renewal from time to time, which are chargeable to the account of the washer.

RESULTS.

Perhaps the first question arising is that of actual working capacity. At this Pratt mines plant the average output has been for many months fully up to the nominal capacity of 400 tons. Occasionally, for several hours at a time, the output has been at the rate of 600 and more tons, per day of ten hours. It is not likely that the quality of the product on these occasions could have been equal to that obtained in treating a normal quantity. From its appearance to the eye this was indeed claimed; but no analyses were made to substantiate it. It may be noted here that the output in clean washed coal may be double the nominal capacity, when nut-coal free from slack is used. On the other hand, if only very fine material be used, for instance, coal from a disintegrator, probably not over 200 tons a day could be cleaned.

TABLE I.—SLACK COAL, BEFORE WASHING.

Sampled 1893.	Volatile and Combustible Material.	Fixed Carbon.	Ash.	Sulphur.
November 1	30.53	63.28	6.19	1.53

Average	29.55	60.26	9.98	1.48

From the analyses of Pratt coal already quoted it will be seen that the average ash is about 3 per cent. These figures were obtained presumably from lump-coal. Table I. gives a series of analyses of the slack used at No. 2 Slope, taken during regular working of the plant and sampled between the last screen and the washer. The spaces between the screen-bars are $\frac{5}{8}$-inch in the clear; and everything that passes through this screen goes to the washer without further treatment.*

Average	3.86		5.22			42.08		15.54

It will be seen that the average ash in the coal has been reduced from 9.98 to 5.78 per cent. In other words, the washed coal contains 42 per cent. less ash than the unwashed. The reduction in sulphur is over 15 per cent., and the gains in volatile material and fixed carbon are about 4 and 5 per cent. respectively. Table III. gives in detail the effects of washing, calculated from the above tables as percentages on the figures for the unwashed coal.

Table IV. gives analyses of the washed coals of larger dimensions only, samples being taken from that part of the product which goes over the screen with $\frac{5}{8}$-inch perforations.

The average of these results, compared with those of Table I., shows a reduction in ash of over 48 per cent., a reduction in sulphur of nearly 15 per cent., and gains in volatile material and fixed carbon of about 5 and 6 per cent. respectively. A detail statement of the results of Table IV. compared with those of Table I. is given in Table V.

It must be remembered that this washer is treating at one operation all sizes of coal from $\frac{5}{8}$-inch in thickness down to fine dust. Many pieces of the thickness named exceed it in their other dimensions, as is natural with a separation by bar-screen only. It could not be expected that a current and speed suitable for the larger dimensions would make as good a separation of the finer materials.

Table VI. gives a series of analyses of the washed coals that pass through the $\frac{5}{8}$-inch holes and over the screen with $\frac{1}{16}$-inch perforations.

TABLE VI.—WASHED COAL, UNDER $\frac{5}{8}$-INCH SCREEN.

Sampled.	Volatile and Combustible Material.	Fixed Carbon.	Ash.	Sulphur.
November 1	29.13	64.05	7.80	1.62
" 2	29.15	66.36	4.49	1.42

A glance at this table and at Table V. shows at once

* These analyses and those in the other tables following were made by Dr. W. B. Phillips.

that the washer, working under existing conditions, is better adapted to the larger-sized coals than to the fines. Yet it is economical to continue as at present, since the amount of product passing through the ⅜-inch screen is small, not over 10 per cent. of the total, and for this amount a secondary treatment would scarcely pay.

With regard to the composition of the refuse, two sets of analyses are presented, the first (Table VIII.) being of coarse material taken from the main washer-tub, the second (Table IX.) of the fine stuff from the sludge-tank.

As the amount of this refuse in a day's run is about 18 tons, and the coal-contents, as shown by the above table, are 12.29 per cent., there will be 2.3 tons of coal lost in the average run. The irregularities in coal contents are due partly to the use of a bar-screen and partly to the work of the attendant. Large lumps of coal are occasionally passed by the screen, and of course descend with the slate. The attendant may sometimes open the the valves too often, and cause a loss of coal.

The value of Mr. Ramsey's tank in getting rid of the worthless material is shown by the following analyses. About 7 tons per day are drawn from it, only 16 per cent. of which, or 1.1 tons is coal. The entire loss in coal then on 425 tons of material treated, is 3.4 tons or

0.8 per cent. of the total. The total refuse material, slate and coal together, is 25 tons or 6 per cent.

The amount of fresh water needed to take the place of that carried off with the refuse and washed coal was found to be 14,050 gallons. On the day of this test 400 tons of washed coal were produced, and the washer was running for 11 hours. The average water per ton of washed coal was 35.1 gallons; average per minute, 21.3 gallons. Hourly measurements were taken, showing from 24 to 51.3 gallons of water per ton of coal. This irregularity was due to the varying coal-supply which, depending on the way coal came out of the mine, was sometimes only 25 tons (washed) in an hour.

The cost of washing per ton of washed coal is low. The daily expenses may be estimated as follows:

For labor at washer..............................	$2.00
For labor at boilers, fuel, etc.,........................	4.00
For repairs and supplies,............................	3.00
Total,....................................	$9.00

This for 400 tons would be 2.25 cents per ton; and it is quite likely that the actual figures are still lower.

THE COKE.

The washed coal is carried in hopper-bottomed railroad cars to the ovens, and there dumped into a series of bins of 5,000 tons' capacity. From these it is loaded into 6-ton larries, hauled in trips of two by small steam

Average..................	0.62	85.70	13.66	1.31

locomotives. The ovens are all of the bee-hive pattern, 12 feet in diameter, and built with a height of 7 feet 9 inches, though the average height now is probably not over 6 feet 9 inches. The outside walls are of sandstone, the oven walls of fire-brick. Of the bottoms, some are of fire-brick; some of 12 by 12 by 3-inch fire-brick tiles; some of common red brick. They were built with the back 6 inches higher than the front, but many have no slope now. With unwashed coal the usual charge was from 4 to 4.5 tons. Since using washed coal this has been increased to about 6 tons, without any increase of of wages to the pullers, as the labor is less than when pulling coke made from unwashed coal. The ovens retain the heat better than before, in spite of the washed coal, being charged damp. Repairs to ovens are less than before using washed coal. All coke is quenched in the ovens.

TABLE XI.—48-HOUR COKE FROM WASHED COAL.

Sampled 1894.	Volatile and Combustible Material.	Fixed Carbon.	Ash.	Sulphur.
January 9..............	0.46	90.00	9.60	0.88
"	0.60	89.06	10.44	1.25
"	0.40	89.40	10.20	1.03
"	0.50	88.40	11.20	1.44
"	0.90	88.35	10.75	1.05
Average..................	0.54	89.04	10.43	1.13

A comparison of Tables X. and XI. shows that there was in the samples taken an increase of 3.9 per cent. in fixed carbon, a decrease of 23.6 per cent. in ash, and a decrease of 13.7 per cent. in sulphur, due to washing. A week's record of washed coke samples from stock house shows:

	1.	2.	3.	4.	5.	6.	7.	Average.
Ash......	10.68	8.80	9.57	10.40	9.93	9.40	9.40	9.73

Coke from the washed coal can be recognized at the door of the oven by the difference in the amount of braize. To determine the improvement in this respect, the weights of the ash-piles in front of a number of ovens were carefully taken, showing the average amount, when coke is made from unwashed coal, to be 521 pounds, and, with washed coal, 238 pounds, or a saving of 283 pounds of coke per oven. If the output from each oven is taken at 2.5 tons (the tests having been made with the same charge as customary when using unwashed coal) the saving is 5.66 per cent. There will also be saved a certain amount of the braize made in forking the coke from the oven-door to the car, in the unloading of the cars, and the loading into furnace-buggies. Weights at the furnaces of braize left in cars after unloading showed 3 per cent. in the case of unwashed coal, and 1 per cent. when washed coal had been used.

This gain in output of marketable coke is sufficient, without charging the furnaces any higher price for their fuel, to compensate the mines for the cost of washing, and for the material formerly put into the ovens but now sent to the waste dump. Assuming a selling-price of $2 per ton, the saving in braize at the ovens is 11.32 cents, in the cars 4 cents, or in both items 15.32 cents per ton of coke. The refuse from washer, formerly coked, is 6 per cent. of the total. To make a ton of coke, 1.67 tons of coal are required. Six per cent. of this, or 0.1 ton, may be called, from the standpoint of the mines, the loss in "coal" per ton of coke. Assuming, as an an average cost of coal, 80 cents per ton, the increase in cost of coal per ton of coke is 8 cents. To this must be added the cost of washing, 2.25 cents per ton of coal, or, 3.75 cents per ton of coke. The total is 11.75 cents, against which there is, as above, a saving of 15.32 cents, or a net saving of 3.5 cents per ton of coke, due to washing.

In the furnace, the washed coke is distinctly advantageous. There is less of that fine stuff from which no valuable service is realized. Comparative tests of crushing strength have not been made; but the "washed coke" undoubtedly will sustain a heavier burden than the unwashed. A few words from a letter of an official of one of the Birmingham companies will show the estimation in which the once despised washers are now held:

"The cost of coke per ton of iron made will be about 50 cents less for the month of March on the furnaces using washed coke. From the present work of the coke in the furnaces it would pay to wash the coal, even though all the waste was coal."

Practical operations in Alabama, Georgia, and Tennessee, during the past four or five years, have proved that this washer is well adapted to such coals as those of the southern field, containing a moderate quantity of impurities. Its advantages may be summed up as follows:

a. Low first cost.
b. Low labor-cost.
c. Compactness of plant.
d. Economy of water.
e. Small waste of coal.
f. Ability to treat with good results materials not closely sized.

NOTE BY THE SECRETARY.—Comments or criticisms upon all papers, whether private corrections of typographical or other errors, or communication for publication as "Discussion" or independent papers on the same or a related subject, are earnestly invited.

The Abendroth & Root Manufacturing Company, 28 Cliff street, New York City, manufacturers of the Improved Root Water Tube Boiler have been awarded the 626 h. p. boiler contract from the Union Car Company of Buffalo, N. Y., and a 500 h. p. contract from the Reading Steam Heat and Power Company of Reading, Pa. They are also erecting in New York City, 300 h. p. in the College of Physicians and Surgeons; 2 boilers in the Baptists Home; 1 boiler in the Farmly Building and 2 boilers for the Sing Sing Electric Lighting Company.

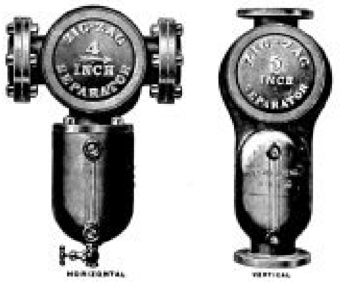
Steam Separators.

The use of steam separators, has, during the past few years, become recognized as a necessity. They enable the engine to work on dry steam, prevent hammering in the cylinder and increase the efficiency of the engine and at the same time reduce the liability to breakage.

Owing to the low cost of fuel at coal mines there is a strong conservatism manifested by the managers, in the trial or adoption of improved ideas in raising and utilizing steam. This conservatism is not so marked at metal mines. It is a trait, that while commendable in some instances, is not commendable in all. The same degree of efficiency and durability in coal mining operations should be and can be secured, as in other industries. Too much conservatism tends to prevent this.

Every expert in steam advocates the use of a good separator. Such a mechanism, known as the "Zig Zag Separator" manufactured by J. S. Stephens, 315 Dearborn St., Chicago, is shown in the accompanying illustrations.

This separator is so constructed that it has a direct, undivided passage for the steam, the distance over which the steam has to travel being not greater than 5 per cent, more than the straight-line distance from face to face of the flanges. The area of the steam passage is 10 per cent. larger than the pipe, thus giving full and free passage to the steam without obstruction or loss of pressure. While this separator has all the advantages that may be obtained by the diaphragm or baffle-plate style, it also combines with this the advantages of the centrifugal form, the centrifugal action or change of direction of the current of steam being shorter, quicker and much more effective than is usual in this construc-



tion, and having the further advantage that the steam is spread out in a thin layer or ribbon-shaped current, giving the greatest facility for separation by centrifugal action. This centrifugal action is combined with serrated separating surfaces, placed at an acute angle to the flow of the steam. The serrations present right angle surfaces to the outer diameter of the ribbon-shaped steam current in each turn it make to obtain separation by centrifugal action, while the turns over these surfaces being reverse curves present each side of the current of steam alternately to the serrated impurity-catching surface. The main current of steam passing over these surfaces at an acute angle has a constant tendency to assist in the separation and removal of any entrained water or foreign substance.

The water and impurities are forced into the receiving chamber by the rapid passage of the current of steam through the separator, while the purified steam passes off at right angles to the direction imparted to the water without the crossing of the two currents.

The vertical Zig-Zag Separator has been designed especially for live steam work, to be placed directly on top of the throttle valve of the engine (where any live steam separator should be, to be most effective and do its duty). This style is tapped for the connection of the lubricator, either right or left handed, as ordered, and fitted with nickel-plated, heavy body gauge cocks and straight-way drain valve.

If the dimensions are given, or a paper template is furnished, the flange will be fitted, drilled and finished, and bolts furnished ready to attach to the flange of the throttle valve.

Culver Valves and Separators.

Those of our readers who have seen the Culver valves and separators, together with those who read the descriptions of those excellent devices, will be pleased to know that Mr. W. B. Culver, the inventor, has turned over the management of the business of the Culver Mfg. Co. to his son Geo. W. Culver, and S. S. Derman. These two young men will give the business that attention which it failed to receive in the past, on account of Mr. W. B. Culver's professional engagements. The new men in the firm are young men who will push the business vigorously. Mr. Geo. W. Culver is a practical machinist, and Mr. Derman is a young business man of hustling proclivities. All letters of inquiry and orders received in the future will receive courteous and prompt replies, and it is safe to say that in a very short time Culver valves and Culver separators will be in use at many prominent steam plants in all parts of the country. The valves and separator are of the simplest possible construction, and the excellent results following their use have made them very popular wherever they have been introduced. The merit of the valves is apparent to every engineer or machinist who has ever seen them, and their apparent merit has been amply proved by practical use at a number of plants. Circulars descriptive of the valves and separator together with prices can be secured promptly by addressing the Culver Mfg. Co., Scranton, Pa.

The Los Angeles Electric Company, Los Angeles, Cal., use "Stevedore" transmission rope for their drive, and have recently ordered 3,000 feet for this purpose from the C. W. Hunt Company, New York City, who are the sole manufacturers.

A NEW TYPE OF BOILER.

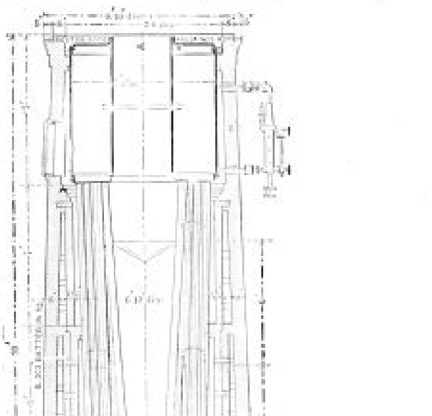
Description of the Cahall Vertical Water Tube Boilers.

Messrs. H. E. Collins & Co. of Pittsburgh, whose advertisement appears in this issue, in reply to our request for a description of the Cahall boiler, send us the following article which is worthy the attention of all boiler users:

"The Cahall Vertical Water Tube Boiler, manufactured by the Aultman and Taylor Machinery Co. of Mansfield, Ohio, for which we are the sole agents in the United States, consists of two drums arranged one above the other, made of best mild, open-hearth flange steel, and connected with 4" lap-welded best charcoal iron tubes. These tubes are vertical, are perfectly straight throughout their entire length, and are expanded into the drums at each end, making lasting and absolutely tight joints.

"The upper or steam drum has an opening through its center for the exit of waste gases. These gases although reduced to a very low temperature in passing through the closely grouped tubes of the boiler, will impart most of their retained surplus heat to the metal sides of the passage through this upper drum, thereby tending to slightly superheat the steam in the chamber above. The water line in the upper drum is about a foot above the bottom of the drum; the drum itself being about six feet high in the clear inside, leaving a space of five feet between the surface of the water and the point at which the steam is drawn off from the boilers, thereby precluding any possibility of the carry-over of water in the steam, either in the form of supersaturation, or mechanical entrainment.

"An external circulating pipe comes out from the upper or steam drum, just below the water level, and is carried downward, outside the brick work, to a point just below the tube sheet of the lower drum, where it enters that drum. There being no steam whatever in this external circulating pipe, and no possibility of making any, and there being in the tubes connecting the two drums, steam in greater or less proportions, the result is (the volume in the external pipe having a considerably greater specific gravity than the mixture of steam and water in the tubes), a very rapid, positive circulation in one direction; the water in the tubes connecting the drums ascending to the steam drum, delivers this mixture of water and steam there, whereupon the steam separating at once from the water, after traveling the space of five feet from the water level to the top of the drum escapes, and the water which is left behind enters the circulating pipe and is carried down to the mud drum and again arises with its mixture of steam. As this mixture of steam and water coming from the upper end of the tube in the boiler, is in about the proportion of half steam and half water in bulk, and as steam at 100 lbs. pressure will occupy about 218 times the space occupied by the water itself, the water in the boiler (being thus delivered in the proportion of 218 parts water to one part steam in weight, at the upper ends of the tubes) will circulate through the boiler 218 times before finally becoming steam. This insures not only a rapid and steady circulation as mentioned, but also insures an absolutely uniform temperature of water in all the tubes, as every particle of fresh feed water being thus circulated 218 times before evaporation must necessarily mingle in such minute parts with the water already present in the boiler, that the water in one ascending tube cannot be different in temperature to that in any others. The boiler is thus relieved from any possibility of destructive strains from unequal expansion.



"The boiler rests upon four iron brackets riveted to the lower, or mud drum, supported upon four piers of the foundation, the entire structure standing without contact with the brick work, thus allowing the boiler every freedom for expansion, without in any way straining the brick setting. In all places where pipe connections are made to the boilers through the walls, they are encased in expansion boxes.

"Owing to the fact that the gases escape through the central opening in the upper drum, the upper tube sheet has a circular opening in its center, leaving a central open space between the tubes, which gradually narrows to the bottom tube sheet. Advantage is taken of this space, which is in the form of an inverted cone, to introduce deflecting plates, which cause the gases to be alternately thrown out and in throughout the whole heating surface, giving them a sweep at nearly right angles to the tubes, thereby extracting from these gases their heat, until they come to very nearly the temperature of the water contained in the boiler.

"This construction presents a form of boiler, which, while from its free direct circulation it gives a capacity per square foot of heating surface unsurpassed by any other boiler heretofore built, at the same time, owing to the direction of the gases over the tubes and the consequent rapid absorption of the heat therefrom, gives an economical performance equaling that of any other boiler ever made.

"The space occupied by each 250 h. p. boiler set in continuous battery is about 9 ft. front for each boiler by 17 ft. long, which is less floor space than occupied by any other boiler built.

"The upper, or steam drum, and the lower, or mud drum, of the boilers are equipped with the Cahall patent swinging man head. By simply taking off the nuts from the man heads (which are on hinges) and swinging them open, a man can place a light in the lower drum of the boiler and get into the upper drum (which is sufficiently large to admit of a man standing upright and walking around in it), and can in five minutes examine the condition of every tube in the boiler; and in case scale or sediment is discovered in any of them, he can in a few minutes run a scraper through the tubes and render them perfectly clean. It will be found in actual practice that the use of the scraper in these boilers will be very seldom necessary, as for instance, boilers in use for about two years have never, up to and including the present time, had a cleaner in a single tube.

"Right here it might be well to mention that very seldom is a tube in a water tube boiler burnt out on account of a general or uniform deposit of scale on its surface. Most tubes failing are burned because a light scale having accumulated in the tubes, patches of it become loose and fall to the bottom of the tube, and remain there, because the tube lies in an approximately horizontal position. There are many instances where boiler tubes were scaled uniformly to the thickness of an inch, without any loss from burning. On the other hand, a single patch of scale less than an inch in diameter and ⅛" thick, on an otherwise clean tube, frequently causes the tube to burn out completely at the point where the scale is deposited. It will be seen that, from the arrangement of the tubes in the Cahall boiler, any scale that might loosen will at once fall to the mud drum at the bottom, and if small enough can be readily blown out through the blow-off pipe; if too large to be blown out, it can be easily removed through the man hole on regular cleaning day. As the entire lower drum is removed from direct contact with the fire, the presence of scale in this drum can act in no way to the detriment of the boiler, the fire not being in contact with the drum, it would not burn, even were the drum allowed to become half filled with scale."

Messrs. Collins & Co. claim for the boiler that, "all materials furnished in and with this boiler are of the very best. The workmanship is of the highest grade known to the boiler-making art. The safety valves are all of the Ashcroft or Ashton Pop type, with nickle seats. The fittings and valves are all specially designed, extra heavy, and the best that money can procure.

"We are determined to make this the world's standard water tube boiler, and no care or expense will be spared to make it such. Our price is lower than that of many other competing makers, but this is not because our workmanship or material is in any way inferior, but because, in the first place, while we use every ounce of metal necessary or desirable in the boilers, we find that it is practicable to make them with a weight of material not much greater than 60 per cent. of that of our competitors, and second, because we are perfectly satisfied with a close manufacturer's profit.

"Owing to the external combustion chamber, roofed with a heavy fire brick arch, which becomes incandescent shortly after the boiler is fired and radiates directly on top of the green coal its intense heat, the Cahall boiler can be operated with less smoke than any other boiler we know of can with the ordinary smoke preventing devices attached. Furthermore, owing to the direct upward passage of all gases and full free openings, we can with a comparatively short stack, obtain in the furnace a draft pressure that is not possible with most other boilers. For instance, in tests made with a stack only 50 feet high, a draft pressure in the furnace of over ½" was attained, which is a result that we doubt could be obtained from any other water tube boiler with a stack 100 feet high. This heavy draft causes a very rapid combustion of fuel per square foot of grate, with the consequent high initial temperature of gases, which all engineers of to-day admit is the primal requisite to either efficiency or economy in boiler practice.

"To sum up, we furnish a boiler equalled by none built, in quality of material, in excellence of workmanship, in surplus capacity per nominal unit, in evaporated efficiency, in small ground space occupied, in ease of examination and cleaning."

PREVENTION OF SCALE AND CORROSION IN BOILERS.

Owing to scarcity of water for steam purposes in many mining fields at this season of the year, a description of a device and resolvent, which when used together permit of the use of such water as is available, is of interest to our readers.

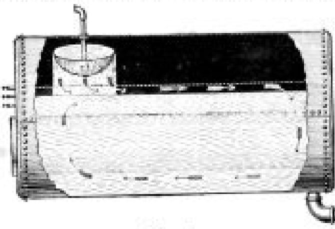


FIG. 1.

FIG. 2.

The Pittsburgh Boiler Scale Resolvent Co. of Pittsburgh, Pa., manufacture a cheap and efficient boiler scale resolvent and acid neutralizer from a product of petroleum that has met with much favor. It is highly endorsed by the officers of the Carnegie works, by the H. C. Frick Coke Co., the New York and Cleveland Gas Coal Co., and many others.

In fact the editor of this journal recently made several inquiries of prominent mining men as to their experience with this product and in every case received an answer that unqualifiedly endorsed it. Mr. Howard Morton, president of the Pittsburgh Boiler Scale Resolvent Co. states that scale and corrosion can be prevented in a 50-H. P. boiler at a cost of ten cents per week.

With a view of making the Resolvent as efficient as possible, and to aid its work in the boiler by the mechanical action of the water itself, Mr. Morton has devised an apparatus for top feed that has proven very successful.

In the above cut Fig. 1 shows a two-flue boiler with the top feed. The arrows show the circulation of the water.

Fig. 2 represents the top feeding device.

A is a brass nipple with threads on each end.

C is a discharge cage of brass.

B is a copper pan which is fastened to the cage *C*, with nut locks, which are not shown in the drawing. *D D* are nut locks to fasten the nipple *A* on either side of the boiler plate through which it passes. A suitable packing is furnished to make it steam tight. The device is so simple as to be readily understood at a glance.

Water parts with its scale forming mineral at the boiling point (212° F.) When the water is fed into the boiler from the rear and bottom, it reaches the boiling point just about the time it is over the hottest part of the boiler.

The mineral thus precipitated fastens onto the fire sheets and soon hardens into scale. Some of it will pass upward through flues and tubes and attach thereto. By the time the water has returned to the bottom and rear of the boiler, it has left the greater part of its scale forming mineral on flues and tubes and sheets, and but a small portion is precipitated within the influence of the mud drum or blow off. Another serious objection to feeding a boiler from the rear and bottom is that water of a comparatively low temperature projected along the upper surface of the fire sheets when the under surface is subjected to a fierce heat of several hundred degrees results in cracking the plates and rupturing the seams. The greatest expense for repairs comes from this source.

Now suppose we feed from the top by means of the device shown in the engraving. The water passing out of the cage *C* fills the copper pan *B* where it becomes heated to a high temperature before it overflows in a thin sheet.

By the time it reaches the surface of the water in the boiler the mineral is separated, but instead of fastening to flues or tubes, is hurried backward along the surface by the rushing current and carried downward to the mud drum or within the influence of the blow off. By using the Boiler Scale Resolvent with this device the mineral is kept in solution and prevented from crystalizing into scale until such time as it can be removed by blowing down or washing out.

An absolute guarantee of the efficiency of the resolvent when used in connection with this device is given to every purchaser. The usual charge for the top feeding device is four dollars, but when a barrel of the resolvent is furnished, one of the feeding devices is furnished free. If a number of boilers are fitted with the device, a charge of four dollars is made for each device furnished except the first one. Then with each subsequent barrel of resolvent purchased, the price of one top feed device is deducted until all the boilers are clear of cost in this particular. The purchaser of the device and the resolvent is the sole judge of its merit. If it does not do as represented, the company will make no charge.

Every man familiar with steam raising knows that petroleum alone is an excellent scale and corrosion preventitive, but that it volatilizes at a very low temperature. The Pittsburgh Boiler Scale Resolvent retains all the desirable properties of petroleum and does not volatilize until a temperature far in excess of that found in boilers is reached.

Written for THE COLLIERY ENGINEER AND METAL MINER.

MINE SURVEYING.*

LATEST AMERICAN IDEAS AND MOST APPROVED PRACTICE.

Rewritten for the use of Mine Officials, Surveyors and Engineers, from Lectures Delivered Before the Students of Columbia School of Mines.

(By Edward B. Durham, E. M.)

CHAPTER VI.

CONNECTING MINE AND SURFACE.

Having considered the ordinary methods of making underground surveys, and the apparatus used, there now remains the problem of connecting the mine survey with the surface, in order to determine the relative positions of points and lines above and below ground. It is the most difficult work in connection with underground surveying, and at the same time, must be done with great accuracy, as the correctness of the orientation of the whole underground survey depends on it.

In the days when the mine surveys were made with the magnetic needle, the meridian was determined underground by means of it, taking the precaution to remove all iron from the vicinity.

With the introduction of the transit into mine work, came the necessity of a more accurate way of orienting the underground survey. The first methods, naturally, used the transit, but, as the mines became deeper, new problems were presented which could not be solved by it with accuracy, and other methods, namely plumbing, had to be employed.

WITH THE TRANSIT.

Flat Inclines.—Where the entrance to a mine is by a tunnel or a slope with less than 40 to 50 degrees of inclination, the survey can be run in the usual way and without special apparatus. If quite flat, the elvations can be determined with a wye level, but if much inclined they must be obtained by the vertical angles and distance. The only difficulty in the work will be the inconvenience in using the instrument, owing to lack of good footing and the awkward positions necessary as the pitch increases.

Steep Inclines.—As the pitch becomes greater than 40 to 50 degrees, the line of sight through the telescope will strike the compass box and shut off the view and special methods must be used.

The eccentric telescopes, already described, throw the line of sight beyond the edge of the plates, and so make it possible to take steep sights downward.

One design is placed on top of the main telescope of the transit, and the other is fastened to one end of the horizontal axis. They are adjusted so as to be in the same plane as the main telescope and parallel to it. If it is placed on top, and is in proper adjustment, the horizontal angles read with it will be the same as if read with the main telescope, but the vertical angles, as read from the vernier will not be correct, unless the signal has been raised, perpendicular to the line of sight, a distance equal to the distance between the two telescopes. The vertical angle might be read with the top telescope, the same as with the main one, without regard to its being incorrect, and, afterward, the amount of error could be calculated and the correction made in the angle, thus: If we let A = a point at the horizontal axis of the transit, B = a point on the top telescope on a perpendicular from the main telescope at A, and C = the signal.

Then AC = distance between horizontal axis of transit and the signal.

AB = distance between telescopes.

BC = line of sight of the top telescope.

ACB = error in vertical angle due to sighting with the top telescope.

Then, since angle $ABC = 90°$,

Sine $ACB = \frac{AB}{AC}$ from which we can find the value of ACB, and subtract it, from the angle read, for negative slopes, and add it for positive slopes.

From this, it follows, that the mean of the vertical angles read with the top telescope at the two ends of a course, will give the true angle, since the correction, applied at one end, must be added to the angle as read, and at the other end it must be subtracted. In taking the second reading the horizontal axis of the transit and the signal must exchange places exactly, as is done with the instruments used for the three tripod method.

This calculation will have to be modified for lines, where the difference of the elevation of the two ends is less than the distance between the telescopes.

If the eccentric telescope is on one end of the horizontal axis, and in adjustment, it will be in the same plane through the horizontal axis as the main one and parallel to it.

The vertical angles as read on the vernier will be the true ones, but the horizontal angles cannot be read correctly unless the signals are offset from the point, a distance, perpendicular to the line of sight, equal to the distance between telescopes. It can be proved† that, the mean of two angles, one read with the side telescope on one side, and the other with it on the other, will give the true angle. This will allow the angle to be read by repetition, by taking the same number of readings with the telescope on one side of the center as with it on the other, and then dividing the final result by the total number of readings taken. The approximate determination of the angle, corresponding to the first angle of an ordinary set, would be found by mesuring the angle, once with the telescope on the left side and once with it on the right, and taking the mean of the two readings.

In setting up the instrument for steep sights care must be taken that none of the legs are in the way of the line of sight. Often it will be more convenient and safer to the man and the instrument, to clamp the transit to a heavy plank nailed across the shaft.

The horizontal angle is read by using the eccentric telescope for both sights. Owing to the many things liable to cause errors it is advisable to read several sets and to read and record every angle of the set, to aid in the detection of any error in observation, which would be apparent, if there was any change in the differences between consecutive readings.

The most likely cause of error in shaft work, with the open lamps, is, that the flames flicker badly, owing to the air currents. In sighting down, one is looking at the top of the wick tube which is not distinct, and in sighting up the body of the lamp is often in the way.

Here the illuminated target is far superior to the open lights, in that the target is at right angles to the line of sight, and the lines at which to sight are sharp and clear.

Having located the point down the slope, the transit is next set up there; if it is necessary to sight still further downward, the eccentric telescope will still be needed, but if the line is to be carried off horizontally, the eccentric telescope can be removed, and the upward sight taken with the prism eye piece, unless the sight happens to be so nearly vertical that one can not get the eye close to the telescope. The work at the bottom is more difficult than at the top, owing to the strained position in sighting upward, and dangerous on account of falling material.

The vertical angles must be read very carefully, as in steep lines they influence the horizontal distances much more than in flat ones.

If without an eccentric telescope, THE COLLIERY ENGINEER AND METAL MINER gives a method by which a line can sometimes be run up a steep slope, thus connecting the mine survey with the surface, by using a prism eye piece and running by foresight only.

To do this, set up the transit at the foot of the slope at a point *A*, when a point *B*, can be located from it, measuring both distance and angle, and in the prolongation of *A B* set a point *C*. Then set the transit at *B* and set a new point *D*, and in the prolongation of *B D* set the point *E*. Then read the angle *C B D* and determine the position of *D*, then move to *D*, and set a new pair of points reading the angle to the nearer one from the line *D E*. Continue in this way to surface, where the transit will be set at the mouth of the slope the signal will be set on the head frame and the angle can be read from it to some point of the surface survey. The angles may be recorded as deflection angles to the right or left, or they may be read by repetition, and then have 180° added to the result, when they will be the same as the ordinary horizontal angles. This scheme does away with all sights down the slope, which could not be made without an eccentric telescope.

The "School of Mines Quarterly" * gives an ingenious method suggested by S. W. Balch of getting a line down a shaft with the ordinary transit, by tilting it so the line of sight will clear the plates. The instrument is adjusted, while in the tilted position so that the centers will be inclined, only in the direction of the line to be thrown downward, then the horizontal axis will be horizontal and the telescope will revolve in a vertical plane. The transit can be set approximately in this position by means of the plate bubble parallel to the axis of the telescope. It can be accurately set with a stride level, or by turning the telescope so it will be exactly 90° from the line to be thrown downward, and then bring the bubble into the center of the tube with the leveling screws the vertical vernier being set at zero. The same result can be obtained, by setting the vernier at zero with the telescope in the plane of the line to be projected, then turn the telescope out so it will be level, and swing it to the right and left through small angles of equal size, and adjust by the leveling screws until the travel of the bubble is equal for equal deflections. The plates must be reset so zero will be in the vertical plane to be projected after each movement of the leveling screws.

When the horizontal axis has been leveled, and the plates are clamped with the telescope in the direction of the line to be projected, it can be swung downward, and one or two points marked in the underground workings. If only one point is set, the surface point will be the backsight but if two, the line between them can be used, as it will be parallel to the surface line. The point over which the instrument is set should be vertically under the center of the horizontal axis when the transit is tilted.

Besides throwing a line down in a vertical plane, a right angle can be turned with the transit in the tilted position without special calculations.

In the original article, the necessary formulas are deduced for turning any angle while the transit is tilted, but the angle could be turned first with the transit level, and the direction of the new line marked out, and then the transit could be tilted and the line projected downward.

Vertical Shafts.—In many of the text books are methods of transferring a surface line underground, by placing the telescope in the direction of the line to be projected, and then to swing the telescope down, marking two points in the mine in the vertical plane thus described, and then connecting the mine survey to the line between these two marks. Or the transit may be placed at the bottom, and a line of the mine survey thrown upward, and marked at the top by a point on each side of the shaft, and later the direction of the line between them can be determined. This could easily be done in large, shallow shafts, but the conditions in practice are not often such as to make it practicable.

This method was used in the Severn Tunnel,† where, owing to the wetness of the shaft and the jar of the pumps, the plumb-bobs were found to be useless. A large transit was set over the shaft, in the vertical plane through the center line of the tunnel, as determined by poles on each side of the Severn river. After the headings had been driven a short distance, in both directions from the shaft, a wire 300 feet long was stretched at the bottom; and carefully placed in line by the transit. This wire was then used as a base, from which the direction for the tunnel was obtained. The headings are said to have met exactly.

The ends of the wire were placed over the *V* threads of horizontal screws and stretched by weights. By turning the screws the position of the whole wire was shifted, as directed by signals from the man at the instrument, until it was in line. About 14 feet of it was visible from the transit, and this was illuminated by an electric light.

If there was no refraction, the errors would all be due to observation.

If the instrument were out of level about an axis perpendicular to the tunnel, the line would still be projected in a vertical plane, and if out about an axis parallel to the tunnel, the telescope would throw an oblique plane and the wire, if it was horizontal, would be placed parallel to the true position, and the error would be constant. This same principle was employed by Mr. E. A. Sperry at Leavenworth, Kansas,* for a connection between two coal mines, each worked by a vertical shaft. He tried plumbing with 5 pound plumb-bobs, but could not keep them steady, even after inserting four wings into each of them to offer more resistance to the water in the tubs. The shafts were about 720 feet deep.

Finally he ran the surface line across the top of the shaft, and marked it by a tack in the collar on each side. After carefully adjusting the side telescope on his transit, he set up his instument on a platform, about 20 feet above the surface and over the center of the shaft, so that the side telescope would revolve in the vertical plane through the tacks. He then swung the line to the bottom of the shaft.

At first he tried to sight at two straight edges, fastened together with a slit about 1/16 inch wide between them, and with lights placed below them. But the lights flared so much that he cut a large hole near each end of the boards, and over each of these placed a plate, with a cross cut in it, and threw a light up through these with a bull's eye lantern. The crosses were then ranged in, and the line between them was used as the base for the underground survey.

The shafts were 5,020 feet apart and he had an error of 3 minutes in angle and of 3 feet laterally, in closing, after the connection was holed through.

In adjusting the instrument, he first made the horizontal axis truly horizontal, by sighting with the main telescope at a long fine wire, adjusting the axis until it followed the wire throughout its length. The wire was suspended from a high trestle and carried a winged bob hung in oil. He then stretched two wires, at a distance apart equal to the distance between telescopes, between the tops of two bu'ldings, and set the instrument directly under one of them, so that the main telescope would travel along it, and then adjusted the side telescope to follow the other wire.

BY PLUMBING.

The transfer of the surface aligument to the mine by plumbing, can only be done where there are vertical shafts. There may be either one shaft or there may be several.

One Shaft.—When there is only one shaft, a line is run across its top, projected to the bottom by plumb-lines, and the line between them there used as a base, from which the underground survey is run. The line across the top is located by the transit, set at some point connected with the surface survey. Planks are fastened across the top of the shaft, and into these two spuds are placed, so that the line from the transit will bisect their eyes. The distance from the transit to the spuds, and the direction of the line through them and the transit, will determine their position. The plumbing wires are now passed through them and lowered by 1 or 2 pound iron bobs to the bottom, where 20 to 30 pound ones are substituted, and hung in tubs. After the wires have stretched all they will, and the bobs have been raised so as not to touch the bottom, the tubs are filled with water to decrease the vibrations, and then a cover with a hole for the wire to swing through, is placed over them to prevent anything from falling in to disturb the water.

Sometimes the water in the tub is covered with oil to quiet the waves and sometimes a thin oil, like signal oil, is used instead of water and at other times thick oil, brine, molasses and even mud and water have been used, according to the fancy of the engineer or to the materials available, the thicker fluids being used to increase the resistance to the swinging of the bob.

The wires must be examined to see that they hang clear throughout the entire depth of the shaft and must be protected from lateral air-currents at the different levels. In plumbing for the Mersey Tunnel they tested the wires with an electric current to see if they touched anywhere. The common method is to have a man at one end of the wire pass a light around it very slowly and have an observer at the other end notice whether he can see it at all times, as he should be able to if the wire does not touch. The distance between the wires should be measured at the bottom to see that it is the same as at the top as an additional check on their hanging freely.

When the wires are all right, the transit is set-up, under-ground, in the prolongation of the line through the two wires. By setting far enough away both wires can be seen without changing the focus. The approximate position for the transit can be determined by passing a light cord just tangent to the two wires, or by ranging a plumb-line in line with them. Several trials will give a mark very nearly right. The transit can then be set over this, and the final setting made by

shifting the tripod head, until the two wires appear directly behind each other on sighting through the telescope. The line can now be transferred to the roof or floor, and marked by permanent points, far enough apart to give a good base line. The direction of the line through them will be the same as the original line carried across the top of the shaft and their distances from the plumb-lines will complete their horizontal location, and the wires may be removed. The elevation of points under-ground are determined by measuring the depth of the shaft.

In sighting at the wires they may be made visible by holding a piece of paper behind them, and illuminating it with a light in front of it or by one behind it.

Where the bobs will not settle on account of air currents or dropping water, it is necessary to bisect the swings of the wires. If the vibrations are small they can be bisected by the eye in sighting at them, but if the wire swings outside the field of the telescope, it can be followed with the telescope to its extreme position, then read the vernier quickly, and follow it to the other extreme, read the vernier again. The center position of the wire will be the mean of the two reading, this should be repeated several times until a good mean position is determined.

As shaft plumbing is only needed occasionally and as the apparatus is simple, the necessary things are usually improvised by the engineer to fit his special conditions. It will therefore be profitable to describe the methods used by different persons, as some combination of them or method suggested by them may aid some engineneer in solving his problem.

There are several schemes for determining the exact central position of the swinging wire.

Prof. Schmidt of the Frieberg School of Mines, determined the middle point of the swings, by means of a finely graduated scale placed behind each wire, and perpendicular to the line of sight. The extremes of the swings were noted, and by bisecting them the central position was found. A number of observations were made and the mean positions were used. The bobs weighed 50 pounds and the wire was 1/25-inch in diameter. The scale was illumined by the ordinary miner's lamp.

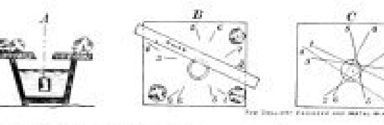

FIG. 14.—TUB FOR SHAFT PLUMBING. *A*, ELEVATION; *B*, PLAN OF TOP; *C*, FINDING THE POINT.

Prof. Schmidt also invented a clamp for holding the wire when its position was to be observed at several levels.

He arranged a cast iron frame, through which the plumb wire hung, and which carried two scales, which could be set so as to be perpendicular to two lines of sight, one from the transit and the other from a second telescope placed at about right angles to the transit. The position of the wire was thus determined in two directions. The bob was then removed, and the wire fastened to a center block, which was shifted by screws in the frame until the wire stood in the central position as determined by the two telescopes. With the wires thus stretched, observations could be made on them at any number of levels.

Another way to get the true position of a swinging plumb wire is to cover the tub in which the bob hangs with a board in which a round hole several inches in diameter is cut conically, Fig. 14—*A*. The cover must be well anchored. Then, as the wire swings to and fro, a rule is placed at right angles to the direction of the swing, Fig. 14—*B*, and kept just ahead of the wire, so that its extreme position can be noted by marks made at each end of the rule, and both numbered alike. This is repeated until a number of marks have been made. The bob is then removed and a plug placed in the hole, Fig. 14—*C*. The lines are now drawn across the top of the plug and a circle drawn tangent to as many of the lines as possible. The center of the circle will be the central position of the wire. Irregularities in the swings will give circles with other centers, but these can be neglected and the point chosen as the central one which has the burden of the proof in its favor. A pin can be placed on the central point when found and used to sight at.

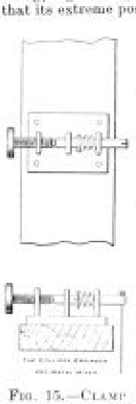

FIG. 15.—CLAMP FOR WIRES.

In plumbing shafts in Montana, from 1,000 to 2,000 feet deep, * Mr. L. Kuhn hung the wires in a single compartment of the shaft. This gave him a base only 3 feet long, but still he checked his surveys within 3 inches. In placing the wires in line at the top, a plumbing board was fastened across the shaft, and the two wires were each attached to a movable support, clamped to it. Each support, Fig. 15, consisted of an iron rod, sliding in two upright pieces. The rod had a groove at the outer end for holding the wire, and the other end was seated against a set screw, and held there by a spring. These allowed the wires to be moved until they were exactly in the desired line. He used No. 22 copper wire, let it down with a one-pound bob, and finally stretched it with a 10-pound one, swinging in a bucket of water covered with an inch of black oil. In communicating with the man at the top, to raise lower or stop, the regular mine signals for hoisting were used.

To facilitate the work of sighting at the bottom, the further wire, from the instrument, was illuminated, while the near one was made to appear, as a dark line on light ground, by placing a light between the two wires and close to the back one, Fig. 16. The light was provided with a reflector, which increased the light on the back wire, and also kept it out of the transit. The base was made two inches wider than the screen and painted white, then by setting it a little to one side, the near wire appeared on this white base as a dark line.

MINE HAULAGE.

Description of a Compressed Air Mine Locomotive.

The Susquehanna Coal Co. has just put at work in No. 6 shaft, at Glen Lyon, Luzerne county Pa., a compressed air mine locomotive built by Messrs. H. K. Porter & Co. of Pittsburg, Pa., and two other leading anthracite mining companies have ordered similar locomotives.

These locomotives are for use in mines where the liability of the presence of explosive gas is such that steam or ordinary electric locomotives might prove dangerous.

Though the current of air forced through the mine workings is large enough to dilute and carry off the gas in a non-explosive state, the managers of the three companies decided to make assurance doubly sure by the use of locomotives that would neither require a fire under the boiler, or a trolley that might emit sparks in case of a sudden accumulation of gas due to some unforseen accident. While this was a potent factor in deciding on the use of the compressed air locomotive, the question of cost and expense of operation was also considered and found to compare very favorably with those of any other system of haulage, and indirectly to be more more favorable than most others.

In the accompanying illustrations Fig. 1 shows a side view of the locomotive, Fig. 2 shows one end view, and Fig. 3 shows the other end view. Naturally, in mine work, the front will as much as possible, be that end shown in Fig. 3.

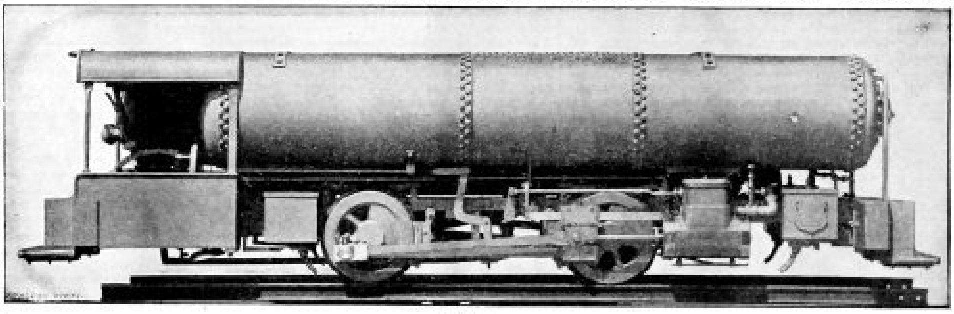

FIG. 1.

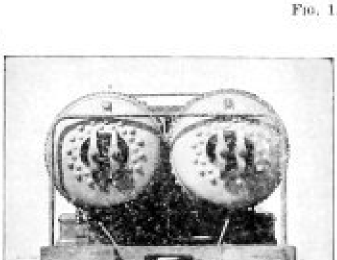

FIG. 2.

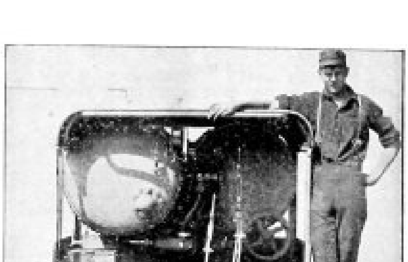

FIG. 3.

A description of the locomotive installed at Glen Lyon is as follows:

It is 17 ft. 6¼ in. long, 5 ft. 2 in. wide and 5 ft. high. It weighs 18,500 lbs. Its working pressure is 600 lbs. The cylinders are 7 in. x 14 in., and there are 4 steel-tired driving wheels each 24 in. in diameter. There are two air-tanks as shown in Figs. 2 and 3. They have a total capacity of 130 cubic feet, with an auxiliary reservoir and reducing valve for delivering the air to the cylinders at 100 to 140 lbs. pressure, which can be varied instantly as desired. The tank heads are convex, and are double riveted with manholes in the end shown in Fig. 2. The horizontal seams of the air-tanks are triple riveted, and an abundant factor of safety has been provided, having been tested tight with 900 lbs. pressure.

The four driving wheels have a powerful hand screw brake attached to each. The tanks, tires, axles, crank pins, rods, cross-heads, guides and links are all made of steel, and there are hardened removable bushings and pins used throughout all valve gear. Sand boxes to sand all the wheels, when running in either direction are provided.

All the operating levers, valves, etc. are in easy reach and under the constant control of the engineer.

The locomotive is specially constructed throughout all its details to secure the best efficiency, utmost convenience and uninterrupted work for long hours under severe conditions. The few repairs necessary can, owing to the construction, be made easily and quickly.

The locomotive in this case runs over a track of 36 in. gauge. There are no excessive grades or very sharp curves, though the machine is designed to overcome such conditions if they did exist.

As was implied before, it is impossible in many mines to use a steam locomotive on account of the danger from fire and sparks and the difficulty of removing smoke from the openings. The compressed air engine, while entirely free from these objections, really aids ventilation to some extent, the exhaust from the cylinders furnishing an appreciable addition to the supply of pure air in the galleries. The advocates of this system claim that it has many advantages also as compared with the electric motor, and these claims may be stated as follows: In the first place, no wires are required, and there are no obstructions overhead or underneath the entry, but the tunnel is left entirely free and clear. In the second place, the power is self-contained, and as long as there is a supply of air in the tanks the engine can move, and is not disabled by any breakage in connecting wires. Thirdly, the engine can be used at will in any entry where a track has been laid, and is not dependent upon wire connections. Again, the only machinery required is the air compressor, with which many coal mines are provided. The operation of filling the tanks is extremely simple, and has to be repeated only at considerable intervals.

While this locomotive is a new feature in the Wyoming region it is by no means an experiment. Two or three years ago we published a description of a similar locomotive built by Messrs. Porter & Co., for use in a mine on the Monongahela river, and it was this description that attracted the attention of Major I. A. Stearns, Gen'l. Supt. of the Susquehanna Coal Co., and the officials of the other two companies, to compressed air locomotives for use in mines where other mechanical haulage devices would not be practicable. Messrs. H. K. Porter and Co., have built a number of these locomotives for mine use, and in every instance they have proven efficient, safe and economical. The same firm has also designed compressed air motors for street cars, which they claim are free from the faults of trolley cars, and are far more reliable than storage battery motors, which so far have only reached the experimental stage.

We note that the Taylor Iron & Steel Company, of High Bridge, N. J., have recently installed the C. W. Hunt Company system of cars and track for handling their material, also that the Otis Company of Ware, Mass., have again added to their already very complete system of Hunt industrial railways.

Correspondence

This department is intended for the use of those who wish to express their views, or ask, or answer, questions on any subject relating to mining. Correspondents need not hesitate to write for supposed want of ability. If the ideas are expressed, we will cheerfully make any correction in composition that may be required. Communications should not be too lengthy, and personal reflections should be carefully avoided.

All communications should be accompanied with the proper name and address of the writer—not necessarily for publication, but as a guarantee of good faith.

The Editor is not responsible for views expressed in this Department.

☞ Correspondence should be in as simple language, and as free of technical terms and formulæ as possible, consistent with clear solution.

Questions on subjects not directly connected with mining will not be published.

Ventilation.

Editor Colliery Engineer and Metal Miner:

SIR:—Please insert the following question for solution in your next issue.

I have a pair of parallel entries between which I have seven break-throughs and my entries are driven in 35 yards past the inside break-through. Break-throughs No. 6 and No. 7 are so that you can close them in a minutes notice. Now, there is a shot fired in my return entry. What I want to know is this: Will the smoke leave quicker by closing No. 6 break-through and leaving No. 7 open, or will it leave quicker by closing No. 7 for five minutes and opening No. 6, then, closing No. 6 and opening No. 7, changing continuously until the smoke has gone.

Yours etc.,
Elco, Wash. Co., Pa. HUGH CAIRNS.

Expansion and Contraction of Air.

Editor Colliery Engineer and Metal Miner:

SIR:—Please insert the following question in your valuable paper for some of the readers to answer.

As air expands $\frac{1}{491}$ for every degree of heat and shrinks or contracts $\frac{1}{459}$ for every degree below zero. Now, suppose the law of contraction holds and we fix the temperature at 459° below zero, what will become of the air and its weight?

Yours etc.,
E. Palestine, O. R. T. DAVIS.

Ventilation and Arithmetic.

Editor Colliery Engineer and Metal Miner:

SIR:—Please insert the following in your valuable paper in answer to query given by A. McDonald, Port Morien, in your August, 1895 issue.

(1.) What would be the area of an airway to pass 50,000 cubic feet of air per minute if 20,000 cubic feet is passing through one 5′ x 4′ or 20 feet area.

We will suppose the pressure and also the form of the airway to remain the same, then, by the following rule: Take $\frac{2}{5}$ root of the ratio of the quantities of air and multiply this by the given height, which will give the height of required airway, then multiply the $\frac{2}{5}$ root of the ratio of the quantities by the given breadth, which will give the breadth of airway required. The ratio of the quantities will be $\frac{50,000}{20,000} = 2.5$ then $(2.5)^{\frac{2}{5}} = 1.4427$ and $1.4427 \times 4 = 5.77$ feet, the height of airway required. Then $1.4427 \times 5 = 7.21$ feet, the breadth of airway required, and $7.21 \times 5.77 = 41.6$ sq. ft. the area of airway required for 50,000 cu. ft. per minute.

(2.) What is understood by the formula $(3)^{\frac{2}{5}}$? Work out and explain.

The formula $(3)^{\frac{2}{5}}$ means to extract the $\frac{2}{5}$ root of 3 and can be easily solved by logarithms as follows. You will find in a table of logarithms the log. of 3 to be .477121 and to obtain the $\frac{2}{5}$ root of any number, multiply the log. of the member by 2 and divide by 5 thus: log. 3 = .477121 and $\frac{.477121 \times 2}{5} = .190848$. The number corresponding to log. .190848 is 1.5518 +.

Yours etc.,
Scammon, Kans. J. G. WILLIAMSON.

ANS. 1. We will assume that the pressure is the same for both airways.

For small airway $p = \frac{k\,l\,p\,a\,v^2}{a}$ (1).

Now, as the ratio of the dimensions of the large airway, is not given, we will suppose it to be square.

Let x = length of one side of large airway.
Then $4x$ = perimeter.
And x^2 = area.

Whence $p = \dfrac{k\,l\,4\,x\left(\frac{q}{x^2}\right)^2}{x^2}$ (2).

From (1) and (2) $\dfrac{k\,l\,o\,v^2}{a} = \dfrac{k\,l\,4\,x\left(\frac{q}{x^2}\right)^2}{x^2}$ (3).

Now, dividing (3) by k l, and substituting known values, it becomes

$$\frac{18 \times (1{,}000)^2}{20} = \frac{4x\left(\frac{50{,}000}{x^2}\right)^2}{x^2}$$

Simplifying and transposing

$$x^5 = \frac{10{,}000{,}000{,}000}{900{,}000} = \frac{100{,}000}{9} = 11{,}111.11.$$

Therefore $x = \sqrt[5]{11{,}111.11} = 6.444$
$x^2 = 41.525$ = area required.

Yours etc.,
Houtzdale, Pa., Aug. 6, 1895. ADOLPHE COOK.

1. ANS. $\frac{50{,}000}{20{,}000} = 2.5$.

$\sqrt[5]{2.5^2} = 1.4427$.

$(1.4427 \times 5) \times (1.4427 \times 4) = 41.627$ + area of airway required.

Assume length of airway as 1,000 feet and the well-known formula $p = \frac{k\,s\,v^2}{a}$ will prove p equal in each airway.

2. ANS. $(3)^{\frac{2}{5}}$ equals $\sqrt[5]{3^2}$ or the fifth root of 3 squared. $3^2 = 9$ $\sqrt[5]{9}$ is found by logarithmic tables.

Thus, Log. 9 = .9542425.

$\frac{.9542425}{5} = .1908485$.

.1908485 = Log. of 1.55184.

Therefore $\sqrt[5]{3^2} = 1.55184$.

Yours etc.,
Victoria Mines, C. B., Aug. 8, 1895. T. J. B.

(2). What is understood by the formula $(3)^{\frac{2}{5}}$? This means that 3 is to be raised to the $\frac{2}{5}$, or what is the same, to the .4 power. This will require the application of logarithms, and the following is the rule.

(1). Find the logarithm of the number and multiply it by the exponent of the power, and the product will be the logarithm of the power.

(2). Find the number corresponding which will be the power. Consulting a table of logarithms we find:

Log. 3 = 0.47712. $0.47712 \times .4$ = Log. 0.19085.
Number corresponding to Log. 0.19085 = 1.5518 +.

Yours, etc.,
Rock, W. Va., Aug. 15, 1895. E. W. BAILEY.

To Extract the 5th Root by Arithmetic.

Editor Colliery Engineer and Metal Miner:

SIR:—Please insert the following in answer to A. McDonald, of Port Morien.

QUES. What is understood by the formula $(3)^{\frac{2}{5}}$? Work out and explain.

ANS. It is a mathematical expression, meaning the 5th root of the square of 3, sometimes written thus $\sqrt[5]{(3)^2} = \sqrt[5]{9}$. The extraction of roots by logarithms is easy, but there are no helps (*and rightly too*) at examinations. By the following method any root may be extracted. You will observe there are four columns. There is always one column less than the root to be extracted. The operation is as follows:

Col. 1.	Col. 2.	Col. 3.	Col. 4.	
1 1	1 2	1 3	1 4	$\sqrt[5]{9} = 1.55184$ 1
2 1	3 3	4 6	50000 81875	800000 679375
3 1	6 4	10000 6375	131875 121250	14062500000 13528[illegible]875
4 1	1000 275	16375 7875	2531250000 174469375	533901[illegible]0000 28887294012751

7752 1	24040503 7753	37349[illegible]7648 19250700672		
7753 1	24048256 7754	37368[illegible]20000 963245710464		
7754 1	2405601000 620464	3739[illegible]464		
77558 8	2406221464 620528			
77566 8	2406841992 62[illegible]592			
77574 8	240746[illegible]84 62[illegible]6			
77582 8	240808[illegible]000 3103[illegible]			
775901	24081142701[illegible]			

Point off the given number into periods of five figures each. The first period may contain from one to five figures. Find root figure of first period, place it to the right as a quotient in division, also place it in first column. Multiply it by root and place in 2nd column, multiply it by root and place in 3rd column, multiply by same figure, place in 4th column, multiplying by same root figure, place product under first period and subtract it from same. Bring down next period, next add root figure to figure in first column, multiply this sum by root figure just found, add to second column, multiply sum by root figure, place in third column, multiply sum of third column by root figure, place in fourth column. Now annex four ciphers to fourth column and again add root figure to first column; continue as above, then annex three ciphers to third column, add root figure again to first column, multiply it again, add to second column and annex two ciphers to second column, add root figure to first column. The figure in first column will now be five times root figure, find next root figure from column four and place in quotient, also place it in first column to the right of figure or figures there, thus increasing the number ten times, the new root figure being in units place to right of that already there. Proceed in same way throughout. The example will help explain.

Yours, etc.,
ROBERT HINNING,
Carterville, Ill.

Magnetic Attraction of Iron Ores.

Editor Colliery Engineer and Metal Miner:

SIR:—In the July number I read some considerations on the magnetic power of iron ores.

To complete the knowledge on the matter I can tell you that it is true that many iron ores have no action on the magnetic needle, but this is not a sufficient proof of its diamagnetism.

To ascertain the magnetic power of iron ore, it is necessary to reduce it to a very thin powder and put it in a little pipe of paper 4 inches long and ¼″ in diameter. The ore must be compressed in the pipe as much as possible.

When this pipe is suspended with a thin thread, if you approach a strong magnet with it, the extremity of the pipe is attracted.

I have made such an experiment with the ores of our mine which have no practical influence on the compass when in place, but are very little magnetic if experimented as described.

Yours etc.,
Orbetello, Italy, July 28th, 1895. UGO BAGNOLI.

Mischievous Mine Legislation.

Editor Colliery Engineer and Metal Miner:

SIR:—In the May issue of this Journal I was allowed the privilege of commenting on an undeniable case of Mischievous Mine Legislation, viz: the recent alteration of Section 2, Article 15 of the bituminous mine law of Western Pennsylvania.

As a victim of this particular clause, I claimed the right to protest against it, and only asked an opportunity to attempt to confute whatever arguments had been advanced in its favor, and to prove the evil influence exerted by a few apparently harmless words. In order to test the validity of the arguments that had been used to effect this change, I offered to discuss the subject with the gentleman who had introduced it, but he has not deigned to reply. Had he accepted my offer and been able to demonstrate that it was essential to the welfare of the coal diggers and ordinary mine workers, or a benefit to the coal operators subject to its jurisdiction, if he could successfully combat any of the comprehensive articles that occasionally appear in this paper against similar cases of illconsidered laws, or if he could have shown any of the arguments I proposed to bring against it to be erroneous, I would have been forced to admit that my objection was groundless.

Owing to the silence of the aforesaid gentleman, I can only appeal to the gentlemen who inadvertently supported this measure to reconstruct this clause so that any reputable American citizen having the requisite experience in bituminous mines—either at home or abroad—may be legally entitled to compete at any examination for a certificate as a mine official.

The clause in question virtually declares that a miner is incompetent to manage a coal mine in this State unless he has had five years' local experience. This is not only a harsh and unwarranted commentary against the capability of every miner outside of Pennsylvania, but it is unjust, seeing that experienced miners from Pennsylvania are eligible as mine foremen in almost every part of the United States, whereas this ridiculous clause effectually prevents Pennsylvania from granting similar privileges to American miners from other coal fields, thereby gaining the questionable distinction of being one of the few states in the Union where a certain section of the American people are treated as foreigners.

Will this prohibition of competent miners from other mining districts increase the efficiency of Pennsylvania mine officials? Is it likely that a better class of mine foremen can be selected from a comparatively small area (Pennsylvania) than from a large one (the United States) or is it assumed that there are no capable miners except those having five or more years' experience in the mines of Pennsylvania?

As a direct result of this clause in its present form, an American miner from any other state, who, by force of circumstances, is induced to follow his occupation here, must surrender for a term five years, the rights and privileges of American citizenship that are generally supposed to be inalienable. Surely it is not a criminal act for a workman to move from one state to another, yet if the immigrant is a coal miner with a laudable desire to improve his condition, and Western Pennsylvania is his objective point, this mischievous clause determines the penalty for such an act to be disfranchisement. If this law had been in operation a few years ago, some of the leading mine officials of this State—men who have given undeniable evidence of their ability to succeed in any position connected with this industry—would most certainly have been kept out of the State. If the mining authorities of other states were foolish enough to adopt a law similar to this one, American miners could not be truthfully classed as American citizens, they would become citizens of Ohio, Indiana, or any other coal mining state, but not citizens of the United States, not American citizens.

By a slight contraction of the "Scientific Frontier," defined by this clause, a miner qualified to act as a mine foreman in the Pittsburgh district, would be prevented from holding a like position in the Connellsville district, and vice versa, men who would be considered competent officials in one county could not lawfully perform similar duties in an adjacent county. Contract it again and it might eventually be illegal for a mine foreman in Mansfield to be engaged for, or to accept a position as mine foreman at "Saw Mill Run," or a man might be considered a trusty official in the vicinity of Dunbar, yet it would be unlawful to employ him as an official in the neighborhood of Uniontown, the only difference between the assumed and the actual line of demarkation being a question of extent.

Amend the mine laws by all means, raise the intellectual standard of mine formen either by making periodical examination compulsory—similar to the mine inspectors—or by any other method that will offer an incentive to them to study the theory of mining, and thus enable them to cope with unexpected dangers, but in the name of common sense and justice, do not make laws, nor allow those already made to remain on the statute books of Pennsylvania, that will boycott experienced miners, and American citizens, because they may have had the misfortune (?) to be trained in other coal mining districts, and probably under conditions more difficult and dangerous than are usually found in the coal mines of Western Pennsylvania.

Yours etc.,

Allegheny, Pa., Aug. 7th 1895. EDWARD HALPIN.

Why Theory has a bad repute among many Practica Men.

Editor Colliery Engineer and Metal Miner:

SIR:—I noticed in your issue of December, 1894, page 109, this sentence. "There is mistaken idea among many miners that theory is a bugbear that they must avoid at all hazards." As a miner I would like to give a few reasons why this idea exists. In the past, and until quite recently, nearly all mining literature was written in language that was unintelligible to the average miner and some of it was written by men with limited practical experience, which often resulted in giving the miner a sort of a "Gullivers Travels," description of his every day occupation. I recently read a book written and published in Pennsylvania about forty years ago; the author after complimenting the miners as being the most ignorant class of workingmen, devotes several pages to describing a mattock, a tool used to cut clay with and finishes with a rather positive statement that the gold discoveries which had been and were being made in California at that time would soon be exhausted, and that Georgia was about the only State which might be expected to furnish a regular and permanent supply of gold. About fourteen years ago one of the most prominent of M. E's., C. E's., E. E's. and all other E's. combined, wrote a series of articles to the *Mining Journal*, London, Eng., from San Francisco, informing us miners that we need not expect to find much gold outside of California or Australia, still later a theoretical M. E. asserted that the Anaconda of this place was no mine but simply a hole in the ground. This mine is one of the largest and richest that was ever known, it is down 1000 feet with good ore on the bottom, and the ore body in some places is over one hundred feet wide.

A theorist who had charge of some very important operations connected with copper mining in Montana, ridiculed the statement made by miners that some of our copper ores carried large quantities of silver.

Such incidents as these tend to destroy all respect that a miner might have for theory as it is written.

Further, miners as a class are great travelers, they know of different methods used at different places to accomplish the same object, they tell each other of the different methods, argue vigorously in favor of their own local custom, but generally adopt the method or modification which is really the best, they have a good deal of theory of their own which, perhaps, is not as scientific as it might be, but most of them can apply it practically as they understand it. By the term miner I mean those men who have worked underground from childhood, who would rather work there than on surface, many of them are fond of collecting specimens of some of those beautiful fern fronds, and other fossil impressions so frequently to be found in some strata in and about the minerals in which they are working, and some have formed opinions of their own respecting the manner of deposition of veins etc. I exclude the ice cream and banana peddlers found working in the easten coal mines, and also the railroaders, woodchoppers, rfarmers and teamsters that are very numerous in the western mines, with their established rate of wages, which makes all underground workers, miners.

Yours etc.,

Butte, Montana. STEPHEN H. NORTHEY.

The C. W. Hunt Co's. new catalogue entitled "Industrial Railways" is a beautiful production, and contains many useful hints for users of industrial or mine tracks. It is sent free on application to the C. W. Hunt Co., 45 Broadway, N. Y.

PRIZE CONTEST.

PRIZES GIVEN FOR THE BEST ANSWERS TO QUESTIONS RELATING TO MINING.

For the best answer to each of the following questions, the value of $1.00 in any of the books in our book catalogue, or six months' subscription to THE COLLIERY ENGINEER AND METAL MINER.

For the second best answer to each question, the value of 50 cents in any of the books in our book catalogue, or three months' subscription to THE COLLIERY ENGINEER AND METAL MINER.

Both prizes for answers to the same question will not be awarded to any one person.

Conditions.

First—Competitors must be subscribers to THE COLLIERY ENGINEER AND METAL MINER.

Second—The name and address in full of the contestant must be signed to each answer, and each answer must be on a separate paper.

Third—Answers must be written in ink on one side of the paper only.

Fourth—"Competition Contest" must be written on the envelope in which the answers are sent to us.

Fifth—One person may compete in all the questions.

Sixth—Our decision as to the merits of the answers shall be final.

Seventh—Answers must be mailed us not later than one month after publication.

Eighth—The publication of the answers and names of persons to whom the prizes are awarded shall be considered sufficient notification. Successful competitors are requested to notify us as soon as possible as to what disposal they wish to make of their prizes.

Competition Questions for September.

QUES. 175. There is at present a ready market and a good price for fire-bricks; flooring tiles for fire-proof buildings; common bricks for filling and backing; glazed and unglazed facing bricks; sewer pipes and drain traps.

Our Coal Mining Company wish to share in this manufacture and trade, and have desired me to make sample bricks out of the underclays of five different coal seams we are working. I have done so with the following results: Clay of seam *A* makes a hard strong red brick coarse in the grain; Clay of seam *B* contains iron balls, but the dressed clay makes a soft white brick that is very porous; clay of seam *C* makes a soft white brick that is very porous and speckled with blackish brown spots; clay of seam *D* makes a hard coarse grained brick, and of a black and bluish color; clay of seam *E* makes a white brick that is very strong and fine in the grain. Now I desire to know two things to enable me to make a satisfactory report to the company.

First. What classes of goods are each of the clays best adapted for making?

Second. What are the constituents in the clays that give to the bricks their different characteristics?

QUES. 176. Here are two samples of bituminous coals, and in chemical composition they are both alike, and even make cokes that are alike, after they have been ground small and steeped in hot water. Hot water disolves out of sample *A*, nitre, and out of sample *B*, common salt, and what I want to know is this, what effect will nitre have on the coking of sample *A*, and what effect will common salt have on the coking of sample *B*.

QUES. 177. We have a bituminous seam of coal at a depth of 400 feet and lying nearly level, and we are going to work it by the system of longwall retreating. The floor is a soft shale and the roof is a slate. We will be obliged if you will give us a map of the best plan of working, together with all the necessary explanation.

QUES. 178. We find the roof of a coal seam we are working is an argillaceous lime stone, and what our neighbors call the same seam in the surrounding collieries has in some cases a slate roof, in others a sandstone roof and in others an arenaceous limestone roof. Do you think it is the same seam of coal in all the cases, and if it is, under which kind of roof will the coal be thickest?

QUES. 179. I am now a fire-boss but I am promised promotion if I can learn to level, will you therefore show me with a sketch and an explanation how to level upgrade for 25 yards? Make the surface very uneven, and after setting up the instrument read the staff every five yards.

QUES. 180. The action of one of our mine pumps is very peculiar, and it will startle you when I tell you, that any increase above a certain speed of the piston reduces the lifting power of the pump, and at another increase of speed the pump looses the water altogether. Now as I would like you to explain the tricks of this peculiar pump I will give some particulars. When the pump piston is at the bottom of its stroke, it is 12 feet above the level of the supply water, and as the force to lift the keep valve and overcome the friction of the water moving through the tail of the pump is equal to a two-feet column of water, we may reckon the mean lift to be 14 feet. Will you then tell me two things.

First. What is the highest speed at which this pump can be run to obtain a maximum effect?

Second. At what piston speed does the pump loose the water altogether.

Solutions to Questions which Appeared in the July Number, and for which Prizes Have Been Awarded.

152. There is a shell-fish that is commonly found on the sea beach near the mouths of rivers and it is best known as "the *mussel*." This fish is a bi-valve, and strange to say, a bi-valve exactly like it is frequently found in great numbers, and closely compacted in masses, in the blue or black shales that overlie some of the coal seams, and stranger still, the miners often call the fossils "stone mussels."

There can be no doubt that the bi-valve of the Carboniferous period belonged to a family closely allied to the representatives of the mussel families that live in our seas to-day. Will you then be good enough to let me know the period during which this bi-valve made its first appearance, and also the different names it is known by in all the succeeding formations up to the most recent, including those now living on the ocean shore.

ANS. Representatives of the Mytilidae are first encountered in the Tremadoc slates (British classification), and in the Trenton period of the Silurian (U. S.).

Mytilus is found from the Silurian to the present time. This genus is represented by 100 fossil and 65 existing species.

Myalina is found from the Carboniferous to the Permian—there becoming extinct.

Modiola is found from the Silurian to the present time—and the same may be said of the sub-genus Modiolopsis.

The following are some of the species found as we ascend the paleontological scale.

Modiolopsis carinata—Trenton period, M. Subrhomboidea—Niagara period.

Mytilarca occidentalis—Chemung period.

Modiola metella—Chemung—Catskill period.

M. Augusta—Catskill period.

Myalina recurvirostris—Coal measures.

The following are some of the modern representatives of this family:—

Mytilus edulis, M. latus, M. canaliculatus, M. magellanicus; Modiola modiolus, M. capensis, M. pelagica, M. viator, etc.

WILLIAM R. EVANS,
133 So. Lincoln ave.,
Scranton, P.

Second Prize, JOS. VIRGIN, Hollsopple, Pa.

QUES. 163. The underclay of a coal seam we are working is four feet thick, and the company have requested me to find out if it is good fire-clay, or if it will make good sanitary pipes. I am told that the best way to test it as a fire-clay, is to make three or four bricks and burn them in a furnace of high temperature, when if the bricks contain iron or lime in *excess*, they fuse and "run," and therefore such clay will not make fire-bricks, but the best sanitary pipes can be made of it. Now I would like to make a show in my report and to do so, will you explain to me?

First. Why clay containing an excess of iron or lime fuses?

Second. What is an excess of lime or iron?

Third. Why good fire-clay will not make good sanitary pipes?

ANS. First. When the underclay of a coal seam contains 2 or more per cent. of iron, and 1 or more per cent. of lime or magnesia, at a high temperature, 2,500° F., the silica fuses with the iron and lime of the clay, and vitrifies.

With higher percentages of iron or lime, the fluidity of the glassy fusion increases.

Second. Clay containing an excess of oxide of iron or lime, at a high temperature fuses into true glass, for many oxides of metals, mixed in equal parts by weight with silica, fuse and produce a perfect glass.

Third. A good fire-clay that makes refractory bricks that withstand the temperatures of the hottest furnaces, is too porous and too brittle for the manufacture of sanitary pipes, that ought to have a relatively high tensile and compressive strength.

P. H. CARROLL,
Vivian, W. Va.

Second Prize, S. U. PHILLIPS, Leechburg, Pa.

QUES. 164. We have a coal seam 12 feet thick, with a shale band in the middle of it, 30 inches thick. All the coal is of first rate merchantable quality. The seam is pitching 5 degrees to the east, and the thickness of the cover is 1,200 feet. The roof consists of 5 feet of shale which falls. The floor is very strong. Say how you would work this coal and secure the face, and give good reasons for your conclusions.

ANS. I would drive the entries in the lower seam, and to prevent a jam in obtaining the top seam, I would take down the 30 inches of shale and have the top coal for the roof in the first working. I would advance my rooms to the west, upgrade, and leave good stumps between the rooms which I would make 7 yards wide, and advance them 65 or 70 yards in length.

If possible I would keep up the 5 feet of top slate in the rooms. While coming back with the rib; I would take down the top coal the full width of the room and rib and secure the face of the rib by 1, 2, or 3 rows of posts kept under the top seam, and while drawing the room and entry stumps the top seam could be got as before. This system of working would be the safest for the the miners, and be the most profitable for the operators.

Each pair of entries should be driven in line, before the rooms are turned off.

HUGH CAIRNS,
Eleo, Washington Co., Pa.

Second Prize, THOMAS WEST, Sherrodsville, Carroll Co., O.

QUES. 165. We have got the creep in one of our seams and we have extended it by trying to stop it. An old experienced miner says "that the quickest, cheapest, and surest way to stop the creep is to help it by drawing out all supports, and by weakening the pillars of coal that interfere most with it. Is the old man right or wrong? Please let me know at once, and explain, if you agree with him, why his mode of proceeding is the best.

ANS. The old man is right, and to support his conclusion it is a fact that all seams are subject to creep, that have a strong cover and a soft floor, and without a soft floor the coal may be nipped, but the floor will not lift and creep.

When the floor is soft and the covering rocks are strong, the pillars ought to be large and no coal stumps or undrawn timber ought to be left in the gob. To stop the creep, first proceed to examine a map of the workings, and you will invariably find, that small pillars are not so much the cause of creep, as groups of pillars belonging to unfinished workings, and jutting right out into the gob and preventing the breaking of the covering rocks, these should be worked out as quick as possible, and in the meantime, the pillars skirting along the outside of the locality of the creep should be strengthened by cribbing.

L. A. Garany,
Brookwood, Ala.

Second Prize, Jos. Quigley, Westville, Pictou Co., N. S.

Ques. 166. For an extension of the haulage in a coal seam we are about to make a branch road going due east from the main entry going due north from the shafts. Now the junction of the branch road with the main road has to be done with a curve of 24 feet radius, and as I would like show off a bit with this curve, will you give me a plan showing how to set up the centre lines with chords, and the fewest angular measurements required for a complete quadrant, the curved road being 12 feet wide.

Ans. We are sorry to say that we have not been able to select out of many papers sent in, a satisfactory *practical* answer to this question. No competitor has even attempted to show how to *set up* the center lines.

Editor.

Ques. 167. Show that the flora of the Devonian period was similar, and therefore just antedated the flora of the Carboniferous period, and further show, that the fauna of the Carboniferous period was characterized by the introduction of a class of vertebrates, higher in the life scale than fishes.

Ans. Vascular cryptogams such as equisetinae and lycopodinea are first found in the Silurian formation. Some genera of ferns and conifers, sigillaria and lepidodendrons are first found in the Devonian series, and are found to have continued through the Carboniferous period, but we find each of these examples having their distinguishing characteristic more sharply defined, and more highly developed, in the latter formation. The placoid fishes of the Old Red sandstone or Devonian times, became true saurians in the Carboniferous seas, and are found as the fish lizards of the type enalrosaurs.

R. Evans,
133 So. Lincoln Ave.,
Scranton, Pa.

Second Prize, Jos. Virgin, Hollsopple, Pa.

Ques. 168. We have bought a good second-hand double engine with 20 inch pistons and 3 feet stroke. Our hoisting shaft is 750 feet deep, and we intend to hoist 600 tons in 10 hours, and make the old engine do the work, and for that purpose we are going to set it on the first motion. The mean velocity of the hoisting rope when doing coal-work, has to be 1,600 feet per minute. Will you then oblige me by giving two values. *First.* The steam pressure required.
Second. The weight of coals for each hoist.

Ans. Make the winding drum 12 ft. in diameter, then the revolutions per minute will be $\frac{1600}{12 \times 3.1416} = 42.5$ nearly. Allow for time of running 5 hours, then the weight of coals per hoist will be $\frac{600 \times 750}{5 \times 60 \times 1600} = .94$ tons or 2085.6 pounds.

Let the winding rope weigh 1120 pounds, then add the weight of coal to the weight of rope and we have 3205.5 pounds, and the units of useful work done by the engine per minute will be $3205.5 \times 1600 = 5128800$ Allow the modulus of the machinery to be .8, then $5128800 \div .8 = 6411000$ units of gross work to be done. The pressure of the steam then is

$$\frac{6411000}{20 \times 20 \times 2 \times .7854 \times 3 \times 2 \times 42.5} = 40 \text{ pounds.}$$

First; Steam pressure 40 pound per square inch.

Second; Weight of coals per lift .94 ton or 2085.6 pounds.

Joseph Quigley,
Westville,
Pictou Co., N. S.

Written for The Colliery Engineer and Metal Miner.

A "PRISON" MINE.

A Sketch of Prison Life at an Alabama Mine Worked by Convicts.

Without going into a discussion of the question of the right or wrong in the case of the employment of convict labor in mines, a description of a large mine operated wholly by convict labor may be of some interest to the readers of The Colliery Engineer and Metal Miner, such a mine having recently been visited by one of our representatives.

The mine in question is one of a group of coal mines known as the Pratt Mines, operated by the Tennessee Coal, Iron and Railroad Co., at Pratt City, a few miles from Birmingham, Ala., this particular one being locally known as the "Prison Mine."

The reader who has had his sympathies played upon by would-be philanthropists who in the columns of various so-called *newspapers* have set forth what have seemed to their imaginations to be the wrongs inflicted upon those individuals who have transgressed the rules laid down by society for its protection, commonly called "law," would hardly be prepared in mind for such a state of things as he would find on a visit to this penal institution, and he would probably lose a good deal of sickly sentiment concerning the treatment of prisoners.

The "prison" proper at this mine consists of a collection of frame structures within a stockade comprising dormitories, mess-hall, warden's residence, and hospital. All these are but one story in height, raised two to four feet above the ground, and thoroughly whitewashed within and without. Except for gratings at the windows the buildings might pass for whitewashed barns rather than for places for the confinement of criminals.

No cells for isolation of prisoners from each other are used. The men sleep in four large dormitories, 100 to 150 in each, in comfortable beds, and none of the ordinary prison discipline compelling non-intercourse between the men is seen.

The rooms are well aired and ventilated. There are ample though not the most lavishly appointed water-closet accommodations, and the sanitary condition of these is good. No odors come from these closets and they are regularly and thoroughly flushed by ample flow of water.

The hospital accommodations, while not necessarily large, owing to the excellent situation of the place, are ample for the needs of the convicts and a surgeon and physician is in regular attendance.

So much for the quarters of the men. Their "accommodations" in the mine proper will now be described.

The workings proper do not differ materially from others of their class, other than in the provision for bathing accommodations for the prisoners presently to be described. In a big room near the foot of the shaft are a large number of wooden tubs amply supplied with hot and cold waters and soap. In an adjacent room are racks with numbers which serve the purpose of lockers. This part of the equipment is not furnished as a privilege to the miners, but its use is imposed upon them as a necessity every day before they leave the mine.

Each man on entering his term of service at the mine, if his work is to be underground, is furnished a suit of coarse white duck, consisting of a blouse and pair of trousers, in addition to his regulation suit of prison "stripes." The latter is not worn at his work, nor can the former be worn above ground in the prison proper. On entering the mine in the morning each convict wears his "stripes" until he reaches the locker room, above referred to, where he exchanges this suit for his duck suit left there the previous night, and goes to work in the latter named clothing. On leaving the mine at night he first goes to the bathroom described, where, after a thorough wash in hot water he dons his "stripes" to go above ground, leaving, as just noted, his working suit in the locker room. By this system the sanitary condition of the convicts clothing is kept much better than it could be were the same to be worn in the mine and out.

At the time of our visit some 600 names were on the prison register. Of these nearly all were negroes, very few white men being sent to the mines to work. Such whites as were there were all working on the surface, it evidently not being conducive to good feeling on the part of either party to work white men and negroes side by side.

Many of the prisoners who are known as "trustys" are worked above ground as teamsters, tipplemen, gate tenders, cooks, and in whatever positions they can fill. These men, of course, all wear the regulation prison garb of "stripes."

As noted above, no attempt is made to prevent communication between prisoners. In fact, it may be said that sociability and entertainment of each other is the rule of the place, for at intervals regular jollifications are had. The large space with the iron floor at the foot of the shaft is utilized as a dancing pavilion, and various sorts of pleasure gatherings are had here. The natural musical proclivities of the negro stand him in good stead at these times, and the affairs are not infrequently considerably on the minstrel show order, furnishing amusement and entertainment to all present.

These little social affairs do much to brighten the lives of the convicts. One of the officials related how one versatile and genial negro who had been sentenced to a long term of service for stealing a pair of pantaloons, used to put everybody within hearing of his voice in a good humor by his keen wit and entertaining songs.

The labor imposed upon the convicts is not severe. The men are classified, according to their physical condition and experience, into four grades, and to each is assigned a certain "stint" per day. These grades and their respective allotment of work are as follows:

Able-bodied, experienced men, 4 tons of coal per day; a second grade, 3 tons; a third class of 2 tons; and a fourth class of less than 2 tons each. Once a month State officials of the prison department visit the place and make a thorough examination to see that the convicts are being properly cared for in every way.

It takes but a little reflection to discern that it is no less to the interest of the company operating the mine with this class of labor to keep the men in good physical condition than to the State itself. It is a matter of honor and humanity with the State; it is both of these and the further matter of business with the company. For, if the men are not kept in good health and physical vigor, the work per man is correspondingly lessened, while the cost of keeping is increased. Hospital treatment and special diet for convicts with cessation of work is not conducive to profit from the mine.

It should be stated here, perhaps, that no men who can be termed old, or physically infirm, are sent to the mines at all.

Owing to lack of skill and to the natural disposition of convict labor, as a class, to shirk if it can, there is little direct profit in the use of this class of labor, it is asserted by the company officials. In fact, they go so far as to say that with skilled "free" miners they could operate the mine at less cost than it is done now. There is an indirect advantage, however, in the employment of this class of labor, that it is not affected by labor agitation, going on without interruption from strikes, thereby ensuring shipments of coal when other mines may be shut down.

There is some incentive held out to the men to become skilled miners, for to all those who mine over the highest quantity above named as a day's work, 4 tons, the same pay per ton is given in cash to the miner as is paid the free miner in the adjoining mines, though this is something few make any effort to accomplish.

The mine is operated by a shaft. It communicate with an adjoining mine, so ample egress is afforded in case of accident to the shaft or hoisting equipment. This shaft is without the prison enclosure proper, but communicates with it by means of a narrow lane between two high fences well protected by guards stationed at intervals. This will soon be changed, however, as a slope is now being driven directly from a central point in the mine to the prison yard. The slope when completed will effect three important objects; it will give another means of egress from the mine, it will avoid any long exposure of the men in stormy or cold weather, and it will materially lessen the chances of escape of prisoners.

In closing, acknowledgement must be made of the courtesies shown by the Tennessee Coal, Iron and Railroad Co., through its officials, Chief Engineer Ramsay, Asst. Engineer Riley, Mine-Boss Haley, and the Warden of the prison. The trip through the mine was made with State Mine Inspector Hillhouse and a small party of Birmingham friends and every facility was accorded to gain information concerning the system of working with convict labor. Nothing was hidden, nor did there appear to be any occasion for withholding information. The trip concluded with a lunch and refreshment at the warden's house which were appreciated by all.

Coal Mining in the Transvaal, South Africa.

The *South African Mining Journal* gives the following account of the mines of the Transvaal Coal Trust, located 16 miles east from Johannesburg. The mine is developed by the "Old" and "New" main shafts: "The old main shaft is no longer used for development purposes, but the pumping and electrical plant is placed there, and the workings are drained to a large reservoir excavated in the neighborhood of the shaft. This has a capacity of about 1,000,000 gal. The mine makes about 85,000 gal. a day. A Cameron steam pump, with a capacity of 24,000 gal. per hour, is in use and can easily cope with the water made, even in wet seasons. An Evans' Cornish pump of 16,000 gal. is kept in reserve, and a Tangye pump of 3,000 gal. per hour is used for pumping clean water for the use of the natives. The lighting plant consists of an Ellwell-Parker dynamo with 50 lamps of 16 candle power, and a small Tangye engine. The new shaft is placed close to the line of railway, with which the loading floors are connected. The shaft is 13 ft. by 9 ft. with two hoisting ways and a pump way, each 4 ft. by 9 ft. Cages carry two 20 cubic feet trucks, equal to about 18 cwt. of merchantable coal. The shaft is 131 ft. deep (156 ft. to the delivery platform).

The present output from the shaft is 1,000 tons a shift of 10 hours, but this can be increased to 1,500 tons without any extra pressure upon the facilities. The hoisting is done by a coupled 15x20 Daglish engine, with 8 ft. 6 in. drums. The delivery platform on the headgear is very large, being 75 ft. x 50 ft. To obtain the necessary fall to the screen it has been built 25 ft. above the ground and its timbers covered with a flooring of sheet iron.

The steam for the surface engines and that under ground is drawn from three Babcock and Wilcox boilers. The water used is very impure, owing to the sulphides in the coals. Magnesia and lime compounds are also present.

The coal bed is practically horizontal, 12 ft. to 14 ft. thick. The roads are 10 ft. wide and 7 ft. or 9 ft. high, and lighted by electricity. Endless cables are in use in some of the roads, and this system will soon be much extended. The principal road has a cable for 1,800 ft., with a cable of 900 ft. at right angles driven off it by means of double pulleys. In the side roads mules are employed. The mining is all done by natives under the superintendence of Europeans.

The usual pillar and stall system has been adopted, the pillars being about one-fourth of the total quantity developed. An excellent roof of shale is found almost throughout. Only three boys have been killed during the last two years. The coal is almost free from shale bands and it is the practice to mine everything and sort out the small proportion of shale at the belts. The deposit differs from European fields in the absence of cleavage lines. This has the effect of making the mining costs higher, for the coal appears as a solid and unbroken mass and no advantage can be taken of the usual natural divisions. The probable recent character of the deposit and the absence of any weight of superincumbent rocks and corresponding pressure, are doubtless, the reasons for this absence of cleavage.

Dynamite is used. The drilling is all done by native miners, but Mr. Williams declares in favor of coal cutters, preferring the percussive type driven by compressed air as being lighter and more easily handled. The cheap labor of the native miner has assisted to prevent their adoption, but it is the question of initial cost which is the principal objection urged against them.

The total quantity of the clean coal, round and nut, produced to date is 859,459 tons; the proportion of waste has not been less than 20 per cent., and 25 per cent. of the total quantity developed is still in the pillars. The monthly tonnage is increasing, and the output of this year will probably considerably exceed 300,000 tons.

Utilization of Water Power.

The new mills of the Grand Rapids Pulp & Paper Co., at Bearin, on the Wisconsin River, are being rapidly pushed forward. The company is constructing a dam, excavating a large mill pit from solid rock, and erecting large substantial brick buildings. They have contracted with James Leffel & Co., of Springfield, Ohio, for 15 of their large Samson Turbine Water Wheels, which will be in position in November. All the work is being done upon the most approved plan, and is of the most substantial character.

The Colliery Engineer
AND
METAL MINER.

ESTABLISHED 1881, INCORPORATED 1889.
PUBLISHED MONTHLY AT SCRANTON, PA.
WITH WHICH IS COMBINED THE MINING HERALD.
Entered at the Post-Office at Scranton, Pa., as second-class matter.

Advertising Rates on application to Main Office, Scranton Pa., or Chicago Office, No. 509 Pontiac Building.

TERMS.

Subscription, (*Postage in the U.S., Canada, or Mexico, prepaid.*) **$2.00 a Year**

TO FOREIGN COUNTRIES IN THE UNIVERSAL POSTAL UNION $2.50.

Remit by P. O. Order, Express Money Order, Bank Check or Draft or Registered Letter.

P. O. Orders.—You can buy a Money Order at your Post-Office, payable at the Scranton Post-Office.

Express Money Orders can be obtained at any office of the American Express Company, the United States Express Company, and the Wells, Fargo & Co.'s Express Company.

Registered Letters.—If a Money-Order Post-Office or an Express Office is not within your reach, your Postmaster will register the letter you wish to send us on payment of eight cents.

We Cannot Be Responsible for money sent in letters in any other way than by one of the four ways mentioned above.

EXPIRATION OF SUBSCRIPTION.

The date after your name on the wrapper of THE COLLIERY ENGINEER AND METAL MINER shows to what time your subscription has been paid.

RENEWALS, ETC.

If you do not want THE COLLIERY ENGINEER AND METAL MINER continued for another year after your subscription has run out, you should notify us by postal card to discontinue it. The courts have decided that subscribers to newspapers who do not order their paper discontinued at the expiration of the time for which it has been paid, are held liable for the payment of their subscriptions up to the date when they order the paper discontinued.

NOTICE OF DISCONTINUANCE.

THE COLLIERY ENGINEER AND METAL MINER is sent to subscribers until an explicit order for its discontinuance is received by us, and all payment of arrearages is made, as required by law. *Papers returned are no notice of discontinuance, as we cannot tell where they are from.*

CHANGE OF ADDRESS.

A Subscriber wishing to have his address changed should be careful to give his *former* as well as his present address; otherwise we cannot find his name on our mailing list.

All communications should be addressed,

ILLINOIS COAL MINES.

THE Thirteenth Annual Report of Mining, issued by the State Bureau of Illinois is at hand, and like its fore-runners, it is full of that class of facts that are required in the construction of history, in the gauging of the resources of the commonwealth, in stimulating the progress and development of trade, in finding the advantages or otherwise of new mechanical appliances and modes of working, and above all in finding what we should, and what we should not do to reduce the loss of human life, and more, and more curtail the causes of accidents in mines.

Historically this report records the great depression in the coal trade in Illinois, and throughout the United States and the world in 1894, and the occurrence of the common accompaniment of bad sales, and low prices, namely, a strike with all its attendant misery, vexations, and blighted hopes.

The mines were closed for 61, and the miners were idle for 73 days. So great are the national resources, that notwithstanding the slackness of trade and a strike combined, the output of coal in the State of Illinois for the year of 1894 was 17,113,576 tons against 19,949,564 for 1893; and thus it appears that had no strike occurred the output in 1894, would at any rate have been equal to that of 1893.

The number of miners in the State of Illinois is 32,046, but that number is increased by 6,431 the number of persons employed above ground, thus making the grand total of employes 38,477.

There is an increase in the percentage of fatal and non-fatal accidents in the mines of the State, and we hope this will be reversed in the Bureau report of 1895. While expressing this wish we are not unmindful of the fact that every strike is a fruitful source of accidents, for during the cessation of work, the roof settles and becomes traversed with unseen cracks and joints, while the floor is broken and tends to rise, and thus the pillars are shattered and made unstable, and the result is, in this and other ways, unseen and unexpected causes of danger arise.

Perhaps no greater cause of danger ever arises than that of the new environment of the miners themselves, for they are "stiff" and awkward after a strike, and as their employment is then often at unknown mines, they are reckless and venturesome, and it is only after painful experience that they begin to practise prudence.

Machine mining has become an important item in the Bureau reports, and deserves close and careful attention. The writer has long believed as a practical man that there were conditions of the roof and floor in some coal-seams that made the use of coal cutters impossible, and he has frequently expressed as his opinion that machines may be made to cut under a longwall face where the roof would stand without timber. This has been accomplished and we must not forget that machines may yet be made to work in a "forest" of timber, or if our own conversatism is subdued, the timbering may be done to suit the machine. At any rate we have now to confront an established fact, not only that machines can cut coal, but that they can so cut the coal as so to obtain a larger percentage of "lump;" and further, in the Bureau report of Illinois for 1894 we have among other tabulated statements, tables of "Mines in which Machines are used exclusively," and of "Mines in which Machines are used, but not exclusively." We cannot do otherwise than commend the steady progress of machine mining.

Twenty-five years ago, much was expected and little of a practical character was accomplished by the machines in England, but with improved modes of transmitting energy, and increased experience of the requirements of the machines, the results commercially are better and better, and we cannot even yet speak of finality in machine development, especially in this country.

Although ten additional fans have been introduced in 1894 for improved ventilation in the mines of Illinois, yet still more than double of the present number are required before the primitive modes of ventilation are entirely displaced. Still although there are 296 mines ventilated with fans, 176 with furnaces, 21 with steam jets, and 301 with natural ventilation, if we consider the fan in relation to the number of men employed it is very far in the ascendant. Fan ventilation is provided for 33,470 men; while furnace, steam jet, and natural ventilation is provided for 4,859 men, or nearly 7 out of every 8 miners in the State are provided with fan ventilation.

When we consider that many of the so-called mines are only small workings for an exclusively local supply, we need not wonder that 301 "mines" have natural ventilation. But as the coal trade of the State increases and extends, in the future the small mines will become large ones furnished with all progressive improvements, and the furnace and natural ventilation will disappear.

AUSTRIAN EFFORTS TO PREVENT ACCIDENTS IN MINES.

THE Prevention of accidents in mines is the constant care of the Austrian government, and nothing that legislation can do has been left undone to enforce a practice that is good or prevent one that is bad.

With the use of flameless explosives, miners are beset with two dangers that these very "safety" compounds introduce, namely, strong *flaming* detonators and shots that *deflagrate* instead of explode. The dangers due to the use of strong detonators are evident enough, but when a shot deflagrates or vomits a stream of hissing fiery sparks like a rocket, the most certain mode of igniting coal-dust or fire-damp is present.

Nitrate of ammonia, or other like nitrates are used to chill the flame of combustion in explosives of the flameless class, because the nitrogen of these compounds absorbs the heat in a latent form, but the consequent reduction of temperature or tendency thereto renders the charge difficult to ignite, hence powerful detonators *must* be used, and when an excess of the nitrate dilutes the heat of combustion too much, instantaneous firing is prevented, and the shot burns slowly or deflagrates.

This is not true of all the flameless explosives, but it is true of many. In Austria all fuses of the fire kind have been found to be dangerous, and therefore, firing by electricity is preferred, but above and over all, they find that the dangers due to shot firing are, regardless of the class of fuses, detonators, or explosives used, most surely reduced and almost removed, by employing intelligent men that have received a befitting education for the work of examining for gas, and firing the shots. Experience has fully demonstrated that neither life nor property is safe when in the keeping of densely ignorant men.

In Austria, to secure the safety lamps against the interference of the miners who use them, a magnetic lock was introduced, but ignorance and stupidity if not constructive are always destructive and here is the proof. "From October 20, 1894, when a serious colliery accident occurred at Anina, to November 20, in the same district, no less than three cases of opening Wolf's benzene lamps were detected, and in two the magnetic locks were uninjured, for the miners found that by swinging their lamps violently against the ground with both their hands, they could make the inert force of the lock bolt overcome its magnetic force, and thus open the lamp, and further the miners actually have been found to force out of the fountain of the lamp a small portion of flaming benzene to light their cigarettes in the mines. What then in the face of all this must be done? Surely state enactments, scientific experiments, and mechanical and constructive improvements are no security against the force of ignorance.

To make mines safe and profitable, we must encourage the younger men in them to obtain such instruction as will brighten and elevate them, and fit them to be our protectors.

Francis Joseph, the Emperor of Austria, has done much to obtain a flameless explosive, but he cannot cure ignorance that is a greater danger than flaming explosives.

ADVANTAGES OF A LIBERAL MINING EDUCATION.

THE great desideratum at present in the mining world is a combination of surveyor and scientific expert in the most comprehensive sense of the term. To be able to survey and level, and plot maps and sections should only be a small portion of what he can do, for in addition he must be a geologist, a chemist, a mineralogist, a metallurgist, an assayer, and a good prospector.

Any man furnished by industry and education with the fitness here outlined cannot fail to make a success either as an agent for a company, or operating for himself individually.

A mine owner from the mining regions of South Africa, told the writer that it was only through the practice of great diplomatic skill that anybody could make any money, because it required such a staff of opposing elements among the employes to determine the values that justified speculation and enterprise. Surely then when men discover they have character and brains, and aim at making life a success, they ought to qualify for a profession that is full of adventure and cash, and especially is this the case when we have a whole profession with but a few practitioners. Such an expert would take high rank in the confidence of a company and secure that kind of stability that is necessary for success. He would be well informed in the theory and practice of ore dressing, and along with a first-class mine captain would make a mine successful where the mine captain alone would fail, because the expert would not only be able to correctly gauge the yield of the matrix, but he would know what particular class of dressing machinery would be best adapted for the ore to be treated.

The practical miner is very good within the boundary lines of his experience, but a lead miner from a limestone region would fail as a tin miner in the granite, and so it is, many good miners have condemned good ground, because they could not associate it with the ground of their experience, thus proving the small compass of their mining resources.

Geological, mineralogical, and chemical tests cannot deceive us, therefore, they must take the fore-front. The reader will now suppose that the mine superintendent must take a back seat, but that can never permanently happen, for who is so likely to acquire and practice the necessary education as he, especially if he aspires to do so?

It does not pay to stand back and see others advance. The watchword should be forward. Mr. Nicol Brown, F. G. S., England said before a meeting of the Geologists Association, that "Mining operations should be under the control of an educated and experienced mining superintendent. He must be a practical miner, and should have had experience in mining various ores in different parts of the world. It is a great disadvantage to employ a miner whose prejudices have been developed by long experience in one particular series of rocks or of the physical structure of one country.

"Such a man, however capable otherwise, has no resources when he comes to deal with new geological conditions. A vast industry of the first importance is needed to gather out the infinitely small scattered portions of gold as they exist in nature. The directors of the Bank of England may hold the key of the Bank's gold, but the geologist holds the golden key of knowledge to the earth's store house of the kingly metal."

WE congratulate our contemporary *Engineering News* in securing the services of Mr. Wm. Kent, as one of its associate editors. He will prove a valuable addition to the able staff of the journal. He will have especial charge of all matters relating to mechanical and metallurgical engineering. Mr. Kent has been a member of the American Society of Mechanical Engineers since its establishment, in 1880, and has held the offices of Manager and Vice-President. He has been for nineteen years a member of the American Institute of Mining Engineers, and is the present Chairman of the Section of Mechanical Science and Engineering in the American Association for the Advancement of Science. His valuable contributions to engineering literature, in the transactions of these societies and elsewhere, with his wide professional experience, have made him well known throughout the engineering profession.

LEGAL DECISIONS ON MINING QUESTIONS.

Reported for THE COLLIERY ENGINEER AND METAL MINER.

Effect of Vein Crossing Side Lines.—Where the course of a vein or lode is across the claim, instead of in the direction of its length, the sides of the location become the end lines, and the end lines the side lines. It is a question, whether, in a case in which a vein or lode passes through one end line and one side line of a mining location, the owner of the claim has any right to follow the dip beyond the vertical plane of his side lines within the limits of some equitably created new end lines, or is limited to the common-law rights of an owner of real estate, and nothing more; and whether, in case the location is amended so as to cut off one end of the claim, and thus make the vein pass through both end lines, assuming that such amended location is valid, the rights acquired under it are to be regarded as relating back to the date of the original location, so as to give a right to follow the dip underneath an intermediate location, or as arising simply at the time of amendment, in which case the intermediate location would have the prior right.

Last Chance Min. Co. v. Tyler Min. Co. 15 U. S. Sup. Ct. Rep. 733.

Insufficiency of Complaint.—A complaint in an action for injuries to an employe caused by failure of a mining company to make safe the roof of its mine, and which fails to allege the company's knowledge, or the employe's want of knowledge, of the condition of the roof, is bad on demurrer, though it alleges generally negligence on the company's part, and want of negligence on the employe's part. The sufficiency of the general allegations of negligence and want of negligence in ordinary cases, where negligence is sought to be put in issue, cannot be controverted. It is the duty of the master to exercise reasonable care to provide safe working places, appliances, and machinery for his servants. Where a recovery is sought for the master's neglect of his duty with reference to safe place or appliances, knowledge of the defect by the master, and want of knowledge by the servant, must be affirmatively shown by the complaint. The servant's knowledge or want of knowledge must be specially alleged, because upon this it depends whether or not he is to be held to have assumed the risk of the defect, assumption of the risk and contributory negligence being separate and independent factors. It is also established by the authorities that the allegation as to knowledge includes not only actual, but constructive knowledge.

New Kentucky Coal Co. v. Albain. (Appellate Court of Indiana.) 40 N. E. Rep. 702.

Sale of Portion of Mining Claim.—If the locator of a mining claim should convey a portion of his claim, without any reservation in his deed of conveyance, his grantee would be entitled to all the gold that might be found within the ground conveyed, in any vein whose apex was within the surface lines of his deed. So if a locator should convey to A. the east half of his claim, and afterwards should convey the west half to B., each of his grantees would, in the same manner, be entitled to all of the gold found in any vein which was entirely within the surface lines of his conveyance; and, on the same principle, if the proprietor of a tract of mining ground which has been derived through several locations should dispose of the same in parcels, irrespective of the lines of such locations, the rights of his grantees would be measured by the terms of their deeds. In such cases section 2,336 of the Revised Statutes of the United States has no application. That statute was not intended to limit or define the rights of a person in mere possession of a tract of mining ground, where there is more than one vein, or to prescribe the effect of a conveyance by the locator of a claim of a portion of his location containing one of such veins. The object of the statute was to supplement the provisions of section 2,332, and to prescribe rules under which different locations by different proprietors should be held, and to determine the rights of such proprietors in case of intersecting veins. The position of the proprietor of a mining claim, who conveys a portion, and retains the remainder, is analogous to the position of the United States after it has issued its patent for a location.

As the United States, as well as a subsequent locator, holds the unpatented claim subject to the prior rights of the patentee, as prescribed by section 2,336, so the grantor of a portion of his claim, in the absence of any reservation in his deed, or proof of mining customs, holds the ungranted portion subordinate to the rights of his grantee in the ground conveyed. When mining ground is conveyed by deed without express limitation, the grantee takes subject to the characteristics of mining property given to it by prevailing customs and laws, and not with the absolute dominion which flows from a conveyance in fee of ordinary land. The mining land thus granted is still subject to all mining laws and customs which are applicable, but the provision of section 2,336 that, when two veins intersect, "priority of title shall govern, and such prior location shall be entitled to all ore or mineral contained within the space of intersection," cannot possibly be applied to the case where A. conveys part of his mining claim to B., for in such a case there is no "prior location." Therefore in such a case the ordinary rules which govern grants of land must, of necessity, apply, and if the intersection takes place on part of the claim conveyed the grantee takes all the mineral within the space of intersection.

Stinchfield v. Gillis, (Supreme Court of California,) 40 Pac. Rep. 98.

Right To Follow Dip In Overlapping Locations.—A controversy arising from overlapping locations, after being carried on both before the land office and the courts, was compromised by allowing one of the locations to patent most of the disputed land. A company was then organized, representing both parties to the dispute, and the land was conveyed to it. It was held, that this company could not refer its title to either or both of the contending locations, at its election, so as to give the right to follow the dip within the end lines of either location at will, but, on the contrary, it must derive its rights in this respect solely from the location under which the patent was obtained. The fact that the apex of a vein, on its strike, passes through one end line and one side line of the location, does not cause both of these lines to be regarded as end lines, so as to destroy the parallelism, without which there is no right to follow the dip laterally beyond the boundaries of the claim. On the contrary, the owner of such a claim will have a right to follow the dip, within his original end lines, so far as he holds the outcrop within his location.

Del Monte Mining & Milling Co. v. New York & L. C. Min. Co. (Circuit Court, D. Colorado.) 66 Fed. Rep. 212.

Construction of Contract.—A provision, in a bond for title to an undivided interest in a mining claim, that the vendees are to pay the vendor one-sixth of the net proceeds of all shipments of ore, to be applied on the agreed price, is unambiguous; and parol evidence is inadmissible to prove that, according to a custom of miners, the expenses of mining as well as of shipping the ore should be deducted before such payments.

Keefe v. Doreland, (Supreme Court of Montana.) 39 Pac. Rep. 916.

Liability for Injuries to Miner.—In an action by a miner against the owner of a coal mine for damages for an injury sustained by the falling of an overhanging part of the roof of the mine. It was contended that the injury was occasioned by the failure of the mine boss, a fellow servant, to do his duty in keeping the roof of the mine safe. "If it were conceded that the mine boss was the fellow servant of the miner, and not the representative of the employer, still his negligence would not absolve the employer, although it may have concurred with the negligence of the latter in producing the injury. Where the master is negligent, he is responsible, although the negligence of a fellow servant may have concurred in bringing injury upon the employe. An employer must answer for his own breach of duty to his employes, even though one of his employes was also guilty of negligence which contributed to the wrong done to the injured employes. This rule rests on solid principle. It is no more than bare justice to compel a wrongdoer to answer for the proximate consequences of his own negligence, and it must be to the last degree unjust to permit him to escape responsibility upon the ground that some one else was also guilty of culpable negligence. The duty of the master to exercise ordinary care and skill concerning the place in which the servant is required to work is a continuing duty, and the master cannot escape responsibility for failure to keep such place safe by delegating the performance of the duty to another; and the servant may rely upon the master to perform this duty. It is well established that where negligence of the master combined with the negligence of his servant produces injury to a fellow servant, the injured servant may recover damages of the master. That the mine boss was acting for the master when he gave directions to the miner to enter the room, and that the miner was justified in obeying the directions, is not seriously questioned, but shows such negligence as will hold the mine owner liable, whether the mining boss was a fellow servant or a vice principal, when he negligently failed to maintain the roof of the mine in a safe condition for the employes to work in.

Island Coal Co. v. Rischer, (Appellate Court of Indiana,) 40 N. E. Rep. 158.

BOOK REVIEW.

A HANDBOOK FOR SURVEYORS, by Mansfield Merriman, Professor of Civil Engineering in Lehigh University and John P. Brooks, Instructor in Civil Engineering in the same institution. 16 mo. 242 pages. Bound in morocco with flap. Price $2.00 published by John Wiley and Sons, New York. As usual with publications written and compiled by Prof. Merriman, this is an exceedingly practical book. It is designed for the use of classes in technical schools and also as a field book for surveyors. It covers the subject in 4 chapters and 14 sets of convenient tables. Chapter I, is devoted to Fundamental Principles, Chapter II, to Land Surveying, Chapter III, to Levelling and Triangulation, and Chapter IV, to Topographical Surveying. The tables are in convenient form and cover every class used in field and office work.

REPORTS RECEIVED.—Coal Report of Bureau of Labor Statistics of Illinois for 1894. Fourth Report of the Bureau of Mines of Ontario. Report on the Use of Metal Railroad Ties, and on Preservative Processes and Metal Tie Plates for Wooden Ties, by E. E. Russell Tratman, A. M., prepared under the direction of B. E. Fernow, Chief of Div. of Forestry, U. S. Dept. of Agriculture. Report of the Canal Commission of Phila. to Select and Common Councils, on the most feasible route for a ship canal between the Delaware River and Atlantic Ocean.

Catalogues Received.

We have received from the C. W. Hunt Co., of 45 Broadway, New York, an exceedingly handsome catalogue of machinery for coal handling for steam generation. Like all the other catalogues of the C. W. Hunt Co., it is well illustrated and interesting.

The Phila. Engineering Co. send us three catalogues designated as "L", "M" and "N." Catalogue "L" describes fly wheels in a thoroughly technical manner and shows that the company's engineers devote as much care to designing and proportioning fly wheels as they do to other pieces of machinery.

Catalogue "M" contains rules and tables for the equalization of power developed in the cylinders of compound engines.

Catalogue "N" is devoted to condensing and non-condensing engines for rolling mill work.

Compressed Air and The Clayton Air Compressors is the title of an excellent publication of 86 pages devoted to the various uses of compressed air, and to descriptions of the Clayton air compressors, etc.

Work Placer Mines Carefully.

The object which has hitherto guided the operations of the placer miner has almost always been to take the cream, if one may use such an expression, and to leave the skimmed milk; to hurry through the ground, taking out the bulk of the gold with the greatest possible economy of time and labor, and to let the rest go. This is one great reason why the patient Chinese can make a living out of ground that has been abandoned by white miners. The evils of such a practice are self-evident. Very much of what is left is so disseminated, and the ground is rendered so unworkable, that it is doubtful whether it can ever be recovered. Placer miners are now, however, beginning to realize the importance of taking a little more care to save as much as possible of the precious metal, and the various improvements in machinery, etc., which have been brought into more general use, for saving the fine gold, is attracting more attention to placer mining each succeeding season.—*Ex.*

PERSONALS

Mr. F. P. Gridley formerly with the Union Pacific Coal Co., at Scofield, Utah, has resigned and accepted the superintendency of the Diamond Coal and Coke Co., at Diamondville, Uintah Co., Wyoming.

The Lidgerwood Manufacturing Company of New York City have in the press a pamphlet entitled "Travelling Cableways and Some Other Devices Employed by the Contractors on the Chicago Drainage Canal." This book will be one of their well known sketch book series, same size as the previous issue, and will contain 72 pages, 36 full page illustrations and is intended particularly to illustrate the multiplicity of uses to which the Lidgerwood hoisting engines can be placed. The Travelling Cableways, twenty of which have been sold and used on the Chicago Drainage Canal, occupy the larger part of the book. It will be free upon application and those desiring a copy should apply at the New York headquarters of the Lidgerwood company, 96 Liberty street.

The Abendroth & Root Manufacturing Company, has of late filed a number of notable orders for their improved Root water tube boilers, principally in New York City and vicinity.

It may be mentioned in this connection that Arthur Loretz, Jr., formerly New York manager for the National Water Tube Boiler Co., is now representing the "Root" boiler at 28 Cliff street, New York City.

THE PROGRESS IN MINING.

ABSTRACTS FROM THE PROCEEDINGS OF THE MINING SOCIETIES

And Journals of Europe and America, Illustrating the More Modern Developments in all Branches of the Mining Industry.

Mesozoic Reptiles.—The following is taken from the *Black Diamond*. One of the most remarkable finds made in our time was the discovery in 1878, of a herd of twenty-five gigantic land reptiles, called "iguanodon" which had been accidentally drowned in an ancient river gorge, cut by a stream through several hundred feet of coal measure strata, forming in jurassic times, one of the lesser valleys of Belgium, which was at that remote time a land surface, as it is to-day, but covered then with cycads and tree-ferns and other semi-tropical plants of the Wealden period.

The river was well stocked with fish having bony enamelled scales, like the American bony-pike, whilst the banks of the river formed the home of lizards, crocodiles, water tortoises and hugh iguanodons.

Thick vegetation of ferns and other plants clothed the marshy margins of the stream, and in times of floods, which were not infrequent, the giant iguanodons with the plants they fed on, together with many reptiles and fishes of the stream, were all entombed in a common grave and covered up with deposits of fine mud left by the river. In process of time the valley was quite filled up with sediment, and in modern days, when coal pits had been sunk at Bernissart, between Mons and Tournay, near the French frontier, the old Wealden or jurassic valley, was re-discovered at more than 1000 feet beneath the present surface of the ground.

At one spot instead of workable coal, the mine galleries traversed for 400 feet only barren ground, composed of chalk and green sand; here in the black Wealden shale the miners met with the remarkable series of skeletons of the iguanodons which were with great difficulty extracted in many pieces and brought to bank by M. Depauw and the engineers of the mine. They have since, with infinite labor, been put together by M. Depauw, and five of them have been set up in the Royal Museum of Natural History in Brussels. Through the kindness of M. E. Dupont, the director of the Brussels Museum, a cast of the entire skeleton has been acquired for the British Museum, and it has been set up in the reptile gallery of the geological department, where it forms one of the most striking objects ever presented to the gaze of the British public. The beast stands 15 feet high, and measures 30 feet along the vertebral column and covers about 156 square feet of gallery.

The Remuneration of Mine Surveyors in Germany.—From the *Colliery Guardian*. Throughout Germany mine surveys are conducted by a corps of highly-trained surveyors appointed by the Government and the amount of remuneration to which they are entitled is clearly specified by the Prussian Board of Trade. It has however, been found that the scale of fees fixed in June, 1876, is in many respects inapplicable at the present time, and a new scale has been drawn up by the Baron von Berlepsch, the Prussian Minister of Trade. This enactment comes into force this year, and the provisions it contains cannot fail to be of interest to mine surveyors in this country.

The remuneration, it is stated, may consist either of a fixed daily fee or of variable fees based upon the amount of work performed. The daily fee is $3.60 and this sum is payable for days spent in work or for days devoted to travelling on survey business, as well as for the Sundays and legal holidays which are necessarily spent away from home. A working day consist of eight hours, and a travelling day comprises a journey of at least four hours. For surveys that do not occupy a full day, the remuneration is computed at 48 cents per hour. If the mine surveyor is obliged to carry out his measurements between 8 P. M. and 4 A. M.; or on Sundays or legal holidays, he is always entitled to make a supplementary charge of 24 cents per hour.

As travelling expenses, mine surveyors receive for railway or steamboat journeys 5 cents per mile, inclusive of porterage of instruments and plans, and for the journey to and from the railway station 72 cents each way. For journeys not by rail or steamer, the rate is 7 cents per mile. If the residence of the surveyor is less than a mile and a half from the mine to be surveyed, no expenses are allowed beyond the cost of porterage of the instruments. Distances of 2 to 5 kiloms. (1.2 to 3 miles) are reckoned as 5 kiloms (3 miles). If on one trip the surveyor makes surveys for several mines, his travelling expenses must be borne by the various mines in proportion to the time spent at each. In lieu of the charge per mile, the surveyor is always at liberty to charge the sum actually disbursed on production of vouchers.

The fees based on the work done are somewhat complicated. The following are some of the principal details:—For surveys with the dial, vertical angles being observed, the charge allowed per 10 yards is 12 cents underground and 8 cents at the surface. When vertical angles are not taken, the charge is 10 cents underground and 5 cents at the surface. When back and fore sights are taken with a view to eliminate local deviation of the magnetic needle, the charge is 22 cents underground and 11 cents at the surface. For tacheometer surveys the charge is 14 cents for each point determined; for plumbing shafts, 24 cents for every 10 yards; for levelling, for each setting of the staff, 10 cents underground and 5 cents at the surface; for traversing with the theodolite, including measuring the angles, permanently marking the station, recording the observation, and plotting the point on the plan, for each station 72 cents underground and 48 cents at the surface; and for triangulation 48 cents for each angle of the triangle.

In fiery mines where it is necessary to work with safety lamps, a small supplementary charge is allowed. This is also the case in very wet or very hot (above 77 degs. Fahr.) mines or in workings less than 4 ft. in height.

The copying of plans of all kinds is to be charged for at a rate per 100 square yards of the area plotted, inclusive of lettering, which varies, according to the scale adopted from 4 cents (scale $\frac{1}{250}$ to $\frac{1}{500}$) up to 48 cents (scale $\frac{1}{2500}$ to $\frac{1}{10000}$). For copies in which the scale is greater or less than the original, this rate is increased one and a half to two and a half times, according to the amount of change of scale. Copying on tracing paper or on tracing cloth is reckoned at half the rate for copying on drawing paper. When the plans have to be colored the rate is increased a third. In all cases in place of these fees, the daily or hourly charge for the time actually occupied may be made.

The drawing paper, tracing paper, or tracing cloth, of the best quality, is charged for at a given rate, and the cost of field-books, etc., is reimbursed on the production of vouchers.

If the mine surveyor engages the workmen required to assist in the survey, he may enter in his account the wages he has to pay them. The wages must, however, be at most 25 per cent. above the mean wage of a coalgetter in the district in question.

A Competitive Trial of Flue-Heated Coke Ovens.—The report of this trial has been extensively published in the foreign mining journals and from which we extracted for "Progress in Mining" in our August issue, the particulars then given. In this synopsis occurs the statment that "The trials were conducted under the in-pection of controllers appointed by the competing companies" and as this statement is called in question by the Otto Coke and Chemical Company of Pittsburgh, Pa., the American representatives of Dr. Otto, we hasten to give their denial full publicity.

Pittsburgh, Pa., August 7th, 1895.

Editor of the COLLIERY ENGINEER AND METAL MINER,
Scranton, Pa.,

DEAR SIR:—In your August issue you publish a resume of a "Competive Trial of Flue heated Coke Ovens." The original report of this alleged trial appeared in full in "Stahl und Eisen" Dec. 15th, 1894, accompanied by the following very pertinent foot note by the Editor.

"We entertained some doubts in regard to publishing the above paper without having informed the firm of Dr. Otto & Co., at Dahlhausen a. d. Ruhr, as to the contents of same:—Our desire however, which was repeatedly made known to Mr. Huessener, has been declined by him. We believe that in such cases a referee or arbitrator would have been indispensable. Nevertheless, the publication has been decided upon, because the comparative trials and their results are undoubtedly of great interest to the majority of our readers, and the discussions that will most probably follow from coal distillers, may lead to valuable communications relating to this important branch of industry.

"In this case, another of our reasons against publication may be waived, *i. e.*, the rules laid down for the competitive coking test were agreed to by the representative of the Huessener system alone, while on the other hand, the Otto-Hoffman system had no representative, the owners of the ovens alone being a participant to the tests.

"The responsibility for the contents of the above article will remain with the author, Mr. A. Huessener."

THE EDITOR.

From this you will note that an important misstatement has been made in your article viz "The trials were conducted under the inspection of controllers appointed by the competing companies."

"Stahl und Eisen" Jan. 1st, 1895, publishes a criticism of the so called test, over the signature of Dr. C. Otto & Co. (for your convenience we append a translation in full of this answer). As an index as to the impression this so called test makes upon one of the leading German iron masters, we refer to an article in "Stahl und Eisen" Jan. 15th, 1895, (page 79) by Herr Pizak.

Resp'y. yours
OTTO COKE & CHEMICAL CO.,
JNO. F. WILCOX, G. M.

Translation from "Stahl und Eisen," January 1st, 1895.

The competitive coking test Bulmke vers. Germania.

In No. 24 of this journal Mr. A. Huessener, Manager of the "Actiengesellschaft fuer Kohlendestillation" at Bulmke near Gelsenkirchen, published a report accompanied by extensive data on "The competitive coking test between the Otto Hoffmann and Huessener Oven Systems."

We feel obliged to make a few statements regarding this report, but we do not need to go into details. Our statements will pertain to the subject matter and its origin. It is necessary to comment only upon a few essential points of the report which covers more than 20 pages of your journal, in order to characterize it.

According to Mr. Huessener's statements the following percentages of water were contained in the coke samples produced from the same coal at Germania Colliery and the "Kohlendestillation" at Bulmke:

PER CENT. WATER IN COKE.

Date.	Bulmke.		Germania.	
1893, August 7th	.706	.296	6.948	7.868
" " 8th	.336	.374	6.485	5.396
" " 9th	.875	1.475	5.396	2.485
" " 10th	.435	.205	8.526	4.666
" " 11th	.356	.285	4.315	7.445
" " 12th	.356	1.005	6.526	12.085
" " 13th	.996	1.235	4.065	5.375
" " 14th	1.134	.654	6.126	6.066
" " 15th	1.165	.805	7.595	7.055
Average	.63		6.55	

The comparison of these figures shows evidently that the coke at Germania has been most recklessly and cruelly abused, (the water having been determined in the large coke exclusively).

This "deplorable coke," which was forced to absorb up to 12% *of water* showed "a somewhat darker, not quite as silvery gray color and its appearance was not so uniform," as the Bulmke coke which had been properly quenched, even while very hot, and which did not contain on the average more than .63% water. It was not necessary to go to the Siegerland* to ascertain this.

Furthermore, it is thus easily understood that of this blackened coke a larger percentage was thrown on the pile of "half burned or waste coke" especially as the classification on *either* side was performed by employes of Mr. Huessener. We therefore could hardly expect anything else than a decreased coke yield at Germania, of 3½% (71.610% against 75.145%, according to the statements.)

It seems that equal amounts of quenching water of equal quality would be a very necessary proviso in a competitive coking test.

In the report it is furthermore stated that the *total* yield of coke, free of water, from Germania coal has been:

At Germania	80.656
At Bulmke	80.108

We are familiar with the said coking coal for many years, up to the present day, and know that it yields 76-77% coke in the crucible. Until to-day we have been unable to obtain in our Otto-Hoffman ovens, a yield in excess of this figure, and have never claimed it. We must therefore refuse, with thanks, to accept the increased yield of eventually 4%, attributed to us by Mr. Huessener. Whether the ovens at Bulmke actually performed such miracle, we cannot decide. The annual business report of the "Actiengesellschaft fuer Kohlendestillation," for 1893-4 does not confirm it, as it showed a yield from this coal of 69.63% coke and only .973% sulphate of ammonia.

We are unable to determine where to look for this discrepancy. It seems also that it would have been proper in a competitive coking test, to ascertain right along how much coke *could have been produced* from the charged coal. †

In a competitive coking test it must be considered as most important and indispensable that the rules laid down are to be strictly adhered to; for instance, if it is provided that the percentage of ash shall be determined day and night. Mr. Huessener's rules, which are published on pages 1110-1112 mention this, especially in article No. 5. This rule, however, has not been observed.

So much for to-day, to characterize the extensive publication. Regarding the origin of the test, the following may be stated:

At the close of the year 1892, our engineer, Mr. Meyn, was informed by Director Randebrock that the "Actiengesellschaft fuer Kohlendestillation" desired a competitive coking test, to which, of course, nothing could be objected. According to later advice, (Dec. 13th, 1892) the competitive coking was to commence about the middle of January and was to last for about 12 days. Inevitable repairs and a strike, however, made a postponement necessary. It was not before August 3d, 1893, that we were informed that the intended competitive coking test was to commence on Monday, August 7th, and it was not before August 10th that we received the rules, which were laid down by Mr. Huessener alone, and *which, up to that date, we had not even seen.* For this reason, and especially on account of already evident partialities in the carrying out, which were also characteristic of Mr. Huessener's report and which we could still further corroborate in a very efficient way, we could not accept the "rules." We actually did not accept them and entered our protest against such procedure.

(Signed) DR. C. OTTO & CO.

Dahlhausen on the Ruhr, Dec., 1894.

Non-Sparking or Polyphase or Alternating Electric Currents, for Mine Haulage and Pumping—This installation of electric hauling plant sets at rest the doubt concerning the safety of electric motors in fiery mines.

1.—*Installation on the Alternating Current System in the Erzherzog Albrecht Pit at Peterswald.*—As it was necessary to commence the extraction of the coal at this mine from a lower level than had before been customary, a new engine was required, and later on it was decided that the wagons should be drawn up and down the shaft by means of a traction cable. The transmission of power by electricity is well adapted to this sort of work; but as this particular colliery is subject to explosions from fire-damp, it was necessary to prevent the engines and electrical apparatus from sparking, which led to the adoption of an alternating current three-phase installation allowing motors without brushes to be employed.

The installation for the production of the electric current was situated on the ground level in the fan engine shed, and comprised a twin steam and condensing engine of old type belonging to the mine. It had been furnished with regulating valves in order that it should work as smoothly as possible. The power of this engine is 80 horse power at eighty revolutions per minute, and its flywheel drives, by the help of a transmitter fixed in the top of the shed, both an alternating and a continuous current dynamo. The alternating current dynamo is of the Siemens and Halske type R$\frac{4}{44}$; it furnishes an output of 44,000 watts, when the *outer resistance does not give place to induction*, but where the machine is driven by the motor, self-induction is inevitable and the power is reduced to 33,000 watts. In order to obtain this force a power equal to 50 horse power has to be expended, including that of excitation. The dynamo is so constructed that the continuous exciting current is conducted by two brushes and two collecting rings into the part excited by a rotatory movement, while the alternating current is received within the three boundaries of the fixed inductor. The alternating current dynamo is constructed so as to give a difference in potential of 500 volts, and therefore requires, at 750 revolutions, 1,200 watts furnished by the continuous current for the excitation of the field magnets. By increasing the power of the continuous current, the voltage of the dynamo may be easily carried to 600, and its power be proportionately increased.

The dynamo exciting with continuous current is of the H 6a type. Performing 1,050 revolutions, it produces an intensity of 50 amperes at 110 volts; it serves for the excitation of the alternating current dynamo and also for the lighting of the pit. This installation for the production of the electric current comprises, of course, all the necessary apparatus and instruments for the measuring, controlling and regulating of the two dynamos; the apparatus and instruments in question are placed on a

* Where the coke was tested in the blast furnace.

† Crucible tests of coal should have been made during the test.

table behind the platform where the engineer stands. Three cables are *detached* from the commutator for the transmission of power, each of them having a sectional area of copper of 35 mm. (1 mm. = $\frac{1}{25}$ in.). In the engine house and the mine the cables are covered with india rubber and *covered* by porcelain insulators, then they are continued by insulated copper conductors, wrapped in silk, on *oiled* insulators, and after running along a distance of 205 m. (224·19207 yards), reach that part of the pit where the wagons commence their movement and are continued for 20 m. (21·9872 yards) above the loading place. The conductors are entirely cased in wooden boards. Twenty-two yards above the loading place is a box connected with the cable as well as a *commutator*. From this box the conductor is formed of a cable encased in lead, and with triphase current, having iron bands and presenting a sectional area of copper 3 × 25 square millimeters in size. This cable is so placed as to be proof against all danger of deterioration and is continued as far as the receiver, placed 240 m. (262·4 yards) from the loading place, where it again comes into *contact* with a junction box, and is prolonged as far as the motor by a cable covered with india rubber.

The three-phase current motor is of direct derivation—that is to say, that the part excited by a rotatory *movement* has no brush nor friction ring, and consequently does not directly receive the current, which is conducted into the fixed induction coil. This motor developes a force of 25 horse power, at 736 revolutions and 475 volts.

Onyx Marbles.—A paper on the above subject will be read before the Atlanta meeting in October, 1895, of "The Institute of Mining Engineers," by Prof. Courtenay De Kalb, School of Mines of the University of Missouri, Rolla, Mo.

From the paper we learn that the word onyx is only applied in this case to distinguish a variety of beautiful and ornamental calcite, and is neither an onyx or a marble, for, says the writer, "In the beginning a sharp distinction must be drawn between the precious onyx, which is a cryptocrystalline variety of quartz, and the ordinary commercial "onyx" which is a deposit of carbonate of lime from aqueous solution."

It appears there are many varieties of the onyx marbles and the origin of the mineral may be detected by noticing the fact that some varieties are called the cave onyxes, and consist of cemented masses of stalactites and stalagmites, consequently it is interesting to know that the onyx marbles have their birth in the vicinity of limestone rocks. Further, true calcite, or dog-tooth spar, or crystalline masses of the true carbonate of lime do not constitute onyx marble, for says Prof. De Kalb:

"The requisite qualities for a commercial onyx marble are: First, perfect, or nearly perfect, homogeneity of texture; second, absence of subcrystalline structure, so that no tendency to crystallization may be observable by the eye; third, freedom from porosity and cracks." The natural conditions favorable to the formation of that variety of travertine called onyx marble, are engrossingly interesting to the student of mining, because through them we see how to explain much we meet with in the "filling" of veins and lodes. The conditions are: First, carbonic acid in solution; second, hot springs containing bicarbonate of lime in solution; third, limestone rocks in juxtaposition; fourth, the contiguity of volcanic hot springs."

Prof. De Kalb says: "From the foregoing summary it appears that the deposits furnishing the superior onyx marble of commerce are found in regions which have been subjected to volcanic disturbance; that they are superficial deposits or vein like inclosures, not connected in any manner with caves; that they are so frequently associated with active hot springs, or with other deposits manifestly resulting from hot springs, as to lead to a clear presumption that there must be a genetic relation between them and such hot springs; and finally, that they occur associated with limestone rocks, or with rocks yielding large percentages of lime." At present the most important deposits of onyx marble appear to be found in the Republic of Mexico, although some fine examples of the stone are found in many parts of the United States.

Improvements in Miner's Lamps.—A self-lighting miners' lamp has been invented by Herr Koch, manager of the Karolinengluck Colliery, near Bochum, in which no spare parts are required. The igniting strip is contained in an annular space, formed by pressing, without solder joint, in a metal ring underneath the cylindrical glass; and this space is sufficiently large to permit the strip to take from three to five turns according to the size of the lamp, thus accommodating a large number—up to 150—fulminate igniters. An advantage of this arrangement is that the heat radiated by the lamp flame keeps the strip and its chamber dry, and therefore the fulminate igniters in a good condition for performing their office. The igniting strip is made with a wire running through it, so that it can be drawn out of its chamber by being wound up on a small spindle, notwithstanding the combustion which takes place on ignition being effected as each fulminate igniter is drawn across a rubbing surface.

An igniting band which does not dim the glasses of miners' lamps and is not liable to miss-fire has been devised by Herr Heinrich Freise, of Hamme-Bochum, being prepared in the following manner, so as to burn without producing a sooty flame. A web, traversed at fixed intervals by a stronger thread, is coated with strips of igniting substance, sulphur and lycopodium mixed with a cementing medium, on one side while the other receives a coating of lycopodium, both sides of the web being afterwards varnished with collodion in order to ensure the continuance of combustion.

The arrangement of another saftey lamp has been patented by Herr C. Dalmann, of Herne, Westphalia, the special feature of which is that, by the side of the metal chimney and main gauze, a smaller and supplementary gauze cylinder is arranged, extending downwards from the level of the top of the chimney to near the flame, and the lower end being beveled off, for introducing the air necessary for combustion quite near the flame. The top and bottom ends of this supplementary gauze cylinder are closed by gauze caps, with the object of increasing the counter pressure when explosions occur in the inside of the lamp, and thus bringing about extinction of the flame. It is also recommended to protect the supplementary gauze by a fixed or removable shield, in order to still further increase the counter pressure on explosion occurring inside the lamp, and, if required, to regulate or shut off the air admission.

The Effects of Different Explosives on Fire-Damp and Coal Dust.—A paper on the above subject by Bergassessor Winkhouse, was read before The North of England Institute of Mining Engineers, and gave in detail the nature and results of some experiments in Westphalia, Germany, with different explosives fired in the presence of explosive gases and coal-dust.

Blasting powder was altogether excluded from the experiments, because the earlier investigations of the Prussian Firedamp Commission had shown that it was highly dangerous in all fiery and dusty mines and should therefore be no longer used in such mines. The substances which came into purview were:

I.—Among the non-safety explosives:

1. Gelatine-dynamit.
2. Kieselguhr-dynamit.
3. Stonite (Gesteins-carbonit.)

II.—As safety explosives:

1. Wetter-dynamit, from the Schlebusch dynamite factory, consisting of trinitro-glycerine, 52·9 per cent.; sulphate of magnesia (bitter salt, $MgSO_4 + 7 H_2 O$), 32·7 per cent.; kieselguhr, 14.4 per cent.

2. Carbonit (coal) which (according to the manager of the Schlebusch carbonite factory) consists of nitro-glycerine, 25.0 per cent.; nitrate of potassium, 34.0 per cent.; rye-meal, 38.5 per cent.; wood-meal, 1.0 per cent.; nitrate of barium, 1.0 per cent.; bicarbonate of sodium, 0.5 per cent. The chemical analysis of a sample showed that the proportion of nitro-glycerine was 29.5 per cent.

3. Sekurit from the Koln-Rottweil powder factories, consisting of ammonium dinitro-benzol, 29 per cent.; nitrate of ammonium, 37 per cent.; nitrate of potassium, 34 per cent.

4. Roburit from the roburit factory of Witten on the Ruhr, consisting of dinitro-benzol, 17.8 per cent.; nitrate of ammonium, 79.2 per cent.; ammonium chloride and ammonium sulphate, 0.3 per cent.; water (damp through long storage of the sample), 2.7 per cent.

In order to investigate as accurately as possible the properties of the various explosives, and in particular their behavior in presence of fire damp and coaldust, each alone or mixed together, every explosive was subjected to the following series of experiments:

1. Firing a shot from the upper cannon in the absence of firedamp and coaldust, so as to observe the breadth and length of the flame.

2. Firing of a series of shots with varying weights of explosive in order to determine the smallest amount which can, under the following conditions, ignite the explosive gaseous mixture, it being previously settled that such ignition can be brought about by the heaviest charges which it is possible to introduce into the cannon, say 16 to 20 oz. (500 to 600 grammes.)

(*a.*) In presence of coaldust strewed in the gallery and suspended in the air, without any firedamp being present.

(*b.*) In the midst of an explosive mixture containing 6 to 7 per cent. of firedamp, without any coaldust being present.

(*c.*) In the midst of a mixture containing firedamp, coaldust being at the same time strewed in the gallery and in suspension in the air.

(*aa.*) In presence of a gaseous mixture, such that the proportion of marsh gas present is just recognizable with a safety lamp, say about 2½ per cent. of firedamp.

(*bb.*) In presence of an explosive gaseous mixture containing 6 to 7 per cent. of firedamp.

With those explosives which, in presence of 2½ per cent. of firedamp, did not, even with heavy charges of as much as 17 oz. (500 grammes), ignite the coaldust, further experiments were made in presence of gaseous mixtures richer in firedamp (say 5 per cent. of marsh gas), yet not in themselves explosive, coaldust being strewed and in suspension as before.

Preliminary experiments were made to test the uniformity of the gaseous mixtures containing firedamp. The electric detonators were also subjected to test as to whether they would ignite firedamp, but no ignition ever took place.

As variable results were obtained according as the charge of explosive reached to the aperture of the borehole or lay at the bottom of the cannon, and also according to the length of free space left in front of the cartridge, a series of experiments was first carried out, in which the cartridges were so set within the cannon that they exactly coincided with the foremost edge of the borehole, and precisely identical conditions were arranged for each explosive. Another series of experiments was undertaken, wherein the explosive charges were simply placed on the bottom of the borehole, leaving in front of them a free space of about 5.91 in. (150 mm.) in length. No stemming was used in these experiments, as in the previous series. The study of the effects of stemming was reserved for a special set of experiments.

First Series of Experiments.—With regard to the first series of experiments (with the explosive in the foremost portion of the cannon) the following observations are given:—

1. That flame phenomena, more or less considerable, were observable in the case of every explosive. Those of greater intensity were noticed with stonite, kieselguhr-dynamit and gelatine-dynamit. The safety explosives gave rise only to short flames, and with coal carbonit only a feeble flash of light was observed.

2. From the point of view of their behavior in presence of coaldust without firedamp, gelatine-dynamit, securit, kieselguhr-dynamit, and stonite are to be regarded as by far the most dangerous. Charges of about 3·53 to 4·41 oz. (100 to 125 grammes) almost invariably sufficed to ignite a dusty atmosphere. Roburit and wetter-dynamit proved much more reliable. With these explosives the coaldust was ignited only by a charge of 10·58 to 12·34 oz. (300 to 350 grammes). The explosives westfalit and dahmenit, the cartridge cases of which had been strongly steeped in resin, paraffin, or ceresin, to protect them against damp, and were used, still in the original coverings, in ordinary working, ignited coaldust as soon as the charge reached about 9·88 oz. (250 grammes). But if the explosive, instead of being enclosed in a paraffined covering, was simply wrapped in an ordinary paper one, ignition of coaldust did not take place, even with charges as heavy as 17·59 oz. (495 grammes). With progressit the dangerous influence of the paraffined cartridge cases was not at first noticed. The biggest charges which could be set in the cannon in the original cases (that is, 15·87 oz., or 450 grammes) failed to ignite coal-dust. The same observation applies to coal-carbonit.

3. In the presence of gaseous mixtures containing small percentages of firedamp (say about 2½ per cent. of marsh gas) the safety of the greater number of explosives was found to diminish in a very remarkable degree. The accompanying table shows the smallest quantity of the several explosives which would produce ignition. Progressit and coal-carbonit proved in this case to be safe in charges of 14·11 to 15·87 oz. (400 to 450 grammes):—

Name of explosive.	Weight of explosive. Ounces.	Grammes.
Gelatine dynamit	2·64	75
Kieselguhr dynamit	2·64	75
Stonite	3·92	111
Securit	1·76	50
Roburit	5·37	152
Wetter-dynamit	7·06	200
Westfalit	10·58	300
Dahmenit	10·58	300

4. In explosive gaseous mixtures containing high percentages of firedamp (say 6¼ to 7 per cent. of marsh gas) the following minimum charges of the various explosives sufficed to bring about ignition. No essential difference in regard to ignition was noticed when coaldust was strewed at the same time, and such differences as were observable may be attributed to purely accidental circumstances:—

Name of explosive.	Weight of explosive. Oz.	Grms.	Pit gas without coaldust. Percentage of marsh gas.	Weight of explosive. Oz.	Grms.	Pit gas with coaldust. Percentage of marsh gas.
Gelatine-dynamit	1·76	50	6·20	1·59	45	6·50
Kieselguhr-dynamit	2·05	58	6·50	1·05	30	6·80
Stonite	2·86	81	7·00	—	—	—
Securit	5·29	150	6·40	—	—	—
Wetter-dynamit	2·40	68	6·30	1·80	51	6·60
Roburit	5·44	154	6·10	4·59	130	5·80
Westfalit *	8·97	254	7·10	8·82	250	6·30
Dahmenit *	8·97	254	7·30	8·82	250	6·20
Progressit *	19·42	550	6·75	19·77	560	7·25

Coal-carbonit, even in charges of 21·18 oz. (600 grammes), and in the presence of 7·3 per cent. of marsh gas, did not produce any explosion of firedamp.

Folds and Faults in Pennsylvania Anthracite Beds.—A paper on the above subject will be read in October, 1895, at the Atlanta meeting of "The American Institute of Mining Engineers," by B. Smith Lyman, of Philadelphia, Pa.

The paper is illustrated by 33 page-plates containing 177 sections copied from the State Geological Survey.

The writer has only one aim and that is to disprove the conclusions of Prof. H. D. Rogers concerning the prevailing abruptness of the incurvation of the northwest slopes of the anticlinal waves in Pennsylvania.

To make the object of the paper clear let us first quote the contention of Professor Rogers.

"There exists among undulations of the strata in Pennsylvania a few—they are very few—exceptions to the almost universal law of a superior degree of abruptness of incurvation upon the northwest slopes of the anticlinal waves.

"There are a few examples of unusual steepness of the southwest dips in the primary class of flexures; but nearly every one of these exceptions applies to only a local portion of the wave, and will be found connected either with a fault in the strata, or with an oblique interference of the end of an anticlinal of another group."

Mr. Lyman's views are expressed in the following paragraph: "We may conclude, then, that steep northerly dips in the Pennsylvania anthracite region are much less prevalent than was formerly supposed; that nearly half the basins and saddles are about symmetrical; and that nearly three-fourths of the subordinate ones are so in the Western Middle field, but that less than a quarter of the main ones are so in the Southern field." Mr. Lyman gives the following table of what he calls "Percentages of Equal and Steeper Dips" or what Professor Rogers would call equal and more abrupt incurvations.

Anthracite Fields	Main Folds. Equal.	North.	South.	Subordinate Folds. Equal.	North.	South.
Northern	38½	27¼	34½	40½	38½	21
Eastern Middle	33½	53	13½	37¾	51½	10¾
Western Middle	45	40½	14½	71	20½	8⅝
Southern Middle	21	60	19	60	37½	12⅝
All the Fields	37½	48	14½	48	38	14

The columns "Equal" mean the incurvation is equal on each side of the wave, and North or South means that the abrupt incurvation is greater on the North or South side of the anticlinal wave.

Strange to say both the Professor and Mr. Lyman are right from their own points of view, for it is clear that the rock waves were produced by lines of force acting at right angles to the axes of the anticlines, and as the axes of the waves run from the southwest to the northeast and the crumpling force acted from the southeast to the northwest, the inception of the force was greatest at the southeast, as is proved by the high percentage of abrupt incurvatures on the northwest sides of the anticlines, namely, 48 per cent. by Mr. Lyman's figures. We are obliged to admit that Professor Rogers is somewhat right, and not even ignorant of Mr. Lyman's own conclusions for he says, that the exceptions "will be found connected either with a fault in the strata or with an oblique interference at the end of an anticlinal of another group." Again Mr. Lyman is right, because all the abrupt incurvatures are not on the northwest sides of the anticlinals but the observations of both Mr. Lyman and the Professor are in harmony with the results of the direction and mode of action of the force that produced the great rock waves of Eastern Pennsylvania.

FIRE-RESISTING PAINT.

A Paint That Has Stood Severe Tests and Will Prove Effective in Protecting Mine Buildings From Fire.

Some remarkable results are reported from the use of the Jamieson fire-resisting paints and kalsomine. Recent severe tests have shown that a wooden building protected by only two coats of this product will effectually resist ignition. In a large fire at Carteret, N. J., last year the value of this paint as a check on the spread of flames was illustrated. The cut presented herewith gives a veiw taken three days after the fire.

The three buildings standing in the background were protected by Jamieson fire-resisting paints; the ruins represent several acres of buildings painted with ordinary paint. Every building painted with ordinary paint, we are informed, was totally destroyed, while none of the buildings painted with the Jamieson fire-resisting paint were sufficiently injured to require repairing.

The burned blocks of buildings were only about sixty feet removed from the buildings painted with the Jamieson fire-resisting paint, and extended lengthwise beyond them on either end. The direction of the wind during the fire was directly from the burning buildings toward the unburned block, and although the covering boards were badly scorched in several places, they did not ignite. Owing to the almost entire absence of fire appliances, it was considered certain that had these buildings once caught fire in any one spot they also would have been totally destroyed, and that they did not catch fire was undoubtedly due to their protective coating of Jamieson fire-resisting paint.

A practical test like this on a large scale is in some respects of more value than prepared tests on a small scale, no matter how carefully the details may be arranged. In one of such tests lately held some very satisfactory facts, however, were brought out. This test was made in the presence of the representatives of the New York fire department, building department, dock department, board of fire underwriters and of several large railroad and manufacturing companies. The following description of this test is given:

"The ordinary course of these events is that the conflagrations start in some light, quickly-burning and very inflammable substance; for example, paper, shavings, oil waste, etc. From these any adjacent heavier combustibles are ignited. The wooden portions of a building, as a rule, furnish the readiest fuel, and are the best means of spreading the fire. To imitate the regular course of events, therefore, a large cask of hardwood was placed in the building, filled with shavings and the whole soaked with kerosene oil. The match was then applied, and immediately the oil-soaked shavings burst into flames, completely filling the building. At the same time the outside of the building was surrounded with similar fuel (shavings and hard wood barrel staves), and the attack started from the outside as well as the inside.

"After several minutes, the shavings and oil having burned out and the barrel staves having caught, the flames became less in volume, but of greater intensity, and the spectators retired to a distance, and, shielding their faces from the intense heat, expected the destruction of the building. Matters were stimulated by throwing on a few gallons of oil at intervals. Then the fuel was allowed to burn itself out, and as soon as the flames from the barrels died down and the building was cool enough to approach, it was seen that the boards had not caught fire at all, and the only damage was a charring of the surface.

"The process of firing was then repeated and continued for a period of one hour and twenty minutes, the only intermissions being a few seconds at a time to see whether the building had taken fire. The intense heat gradually charred the wood away until holes were burned completely through the side and roof, but still the building did not take fire, the nearest approach to it being at the edges of the boards, where little flickering flames appeared, which, however, made no headway, but died out when the fuel ceased to burn. Finally the building was upset over a mass of burning barrel staves, but still refused to break into flames.

"The total time of test was one hour and twenty minutes, and the actual time of exposure to intense fire (deducting the time of stoppages for examination) was one hour and ten minutes.

"The results of the test satisfied those present that a building of ordinary pine lumber can be protected from fire by a simple and necessary operation without any increased cost of construction, viz, by painting with the Jamieson fire-resisting paint or kalsomine. It was further shown that light and inflammable pine, if coated with the Jamieson fire-resisting paint or kalsomine will not actively burn, but must be slowly charred away by the heat from some external fuel." The manufacturer of this compound is the Jamieson Fire-Resisting Paint Co., 62 and 64 William St., New York.

THE MOORE DIFFERENTIAL PULLEY BLOCK.

In the installing of new machinery about mines, or in making the ever recurring repairs, if the work is to be done with celerity and ease, some convenient means of handling heavy weights, better than the devices usually found in such places, can be used to advantage. The simple block and fall needs contant attention to prevents its running back when hoisting, to say nothing of the need of frequent renewal of ropes, and some of the older types of the differential pulley block have excessive friction, making the work of hoisting slow and difficult.

One form of differential pulley block recently brought out by the Moore M'f'g. & Foundry Co. of Milwaukee, Wis. possesses, it is claimed several points of superiority over any other form of this device. From a circular issued by the manufacturers we adapt the following description of the peculiar advantages and construction of the device.

The leverage in this new Moore Block is obtained by a gear and pinion movement. As shown in Fig. 1, the pinion is double, that is, two sizes in one casting. Referring to Fig. 1, and noting the point "A" in the center of the eccentric, the point "B" directly below it on the pitch line of the smaller pinion, and the point "C" below and in line with the other two points on the pitch line of the larger pinion—the line on which are these three points is the lever. The fulcrum is an imaginary point "F" on the line of the lever, midway between the pitch lines of the small and large pinions.

Fig. 1.

Fig. 2.

The annulars, Fig. 2, or internal gears, are in mesh with the two pinions (or double pinion) at points "B" and "C" on the above named lever. The lever operates on the annulars at these points; and, since the lift chain hangs from opposite sides of these annular wheels, they are pulling in opposite directions, one on each side of the imaginary fulcrum, point "F." Now, turn the eccentric slightly, the lower part to the right, imagine the fulcrum point "F," stationary, the point "A" of the lever moves to the right, the point "B" of the lever will move in the same direction, but the point "C," being on the other side of the fulcrum, will move in an opposite direction; the two points, "B" and "C," necessarily carrying with them the annular, or lift chain wheels, in opposite directions.

Fig. 3.

It will readily be seen that whatever the position of the eccentric and pinion, the relative position of this imaginary line, or lever, is always the same.

It is rather an infinite series of levers, corresponding in number with the number of points on the pitch line of the annular wheels.

It is apparent that the load on the block exerts through this leverage a constant pressure on the side of the eccentric, and that the block will "run down" unless there is sufficient friction to prevent it. Such friction is secured by means of the automatic brake, illustrated in Fig. 3

A friction plate "F" of slightly less diameter than the hand wheel is mounted upon an extension of the hub of the hand wheel and between it and the block frame "A."

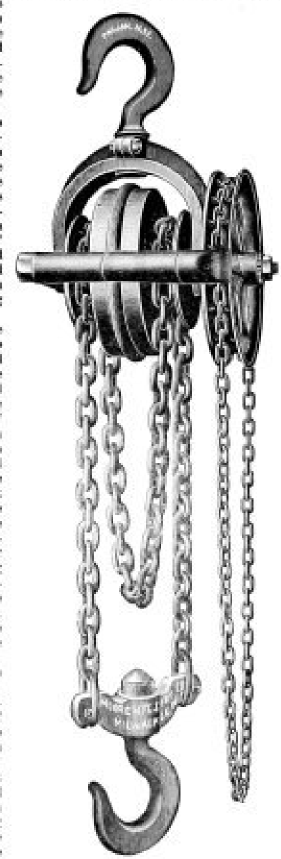

Fig. 4.

The friction plate has a wedging contact with the block frame at "B," and the hand wheel has a reverse wedging contact with the clutch "D," which is keyed to the shaft and held in position by the adjusting nut "E."

A pull on the hand chain to raise the load loosens the wedge "B" and tightens the wedge "D," while a pull on the hand chain to lower the load tightens the wedge "B" but loosens the wedge "D," one wedge counteracting the other and producing no friction between the plate and the frictional surface of the wheel at the point "F."

But when the hand wheel "G" is in a state of inertia, the pull of the load on the shaft tightens the wedge "D," carrying with it the hand wheel and friction plate, tightening also the wedge "B," and the two wedges acting together set the frictional surfaces into contact and effectually lock the block. A pull on the hand chain in either direction releases one of the wedges, but as soon as the pull ceases the load instantly catches up and locks both of them. The lock is positive and smooth working, since the friction surfaces are really never out of contact, and heavy loads may be lowered by a pull on the chain of a very few pounds.

The block with all parts assembled and ready for use is clearly shown in Fig. 4.

By the construction shown friction is almost wholly obviated, and a smooth working, serviceable device has been produced. The block is made in various sizes, ranging from ½ ton to 10 tons capacity. The manufacturers will be pleased to furnish to mine operators and managers any further information as to prices and sizes desired.

EASY LESSONS ON MINING.

This Department contains articles to assist ambitious Miners to educate themselves, and obtain Certificates of Competency as Mine Foremen, or to become Mine Superintendents.

The articles are written to be understood by the unlearned and the learned alike. Plain language is used, no obscure terms are employed, and each subject treated, is made as clear and easy to understand as possible.

Further: The Questions asked at the different Examinations for Mine Foremen and Mine Inspectors, are printed and answered.

☞ The Series of Articles "Geology of Coal," "Chemistry of Mining," "Mining Methods" and "Mining Machinery" was commenced in the issue of March 1894. Back numbers can be obtained at twenty-five cents per single copy, $1.00 for six copies, and $2.00 for twelve copies.

MINING MACHINERY.

Gyration and Percussion.—Mean Effective Radius of a Fan.—The Calculations for Efficiency.—Radius of Gyration of Discs and Rims.

61. Gyration and Percussion.—The mode of action of the centrifugal variety of fans is full of interest to the student of mining, and in the fore-front of the investigation there are certain elementary principles in mechanics that must be known, or otherwise progress is impossible; first then let us determine the radii of gyration and the centers of percussion that will have to be sought for and found in the solutions of fan problems.

First then what is meant by the term "radius of gyration"? To make the matter clear let us take for an example a straight bar of uniform section, and find out what will occur if it is made to revolve or turn on one of its ends. With the aid of Fig. 107 the bar in question is supposed to be in the act of turning on one of its ends as at O, while the end P, describes an arc of a circle. It will be further seen, that points all along the bar from O to P, move at different velocities, and these velocities are directly proportionate to the distances of the points from O; or beginning at O, and travelling along the bar to P, the velocities for the uniformly increasing distances are 1, 2, 3, 4, 5, 6, 7, 8, 9, 10. Each of the equal divisions of this bar of uniform section will be equal in weight, to each and all of the other divisions, therefore we will call the weight of one division 1. Again although the divisions are equal in weight, the energy stored up in each is different the moment the bar begins to turn on O; for we are confronted again with that principle in mechanics that is met with so very frequently in mining, namely, the energy stored up in moving bodies "varies as the squares of the velocities," consequently all along the bar from O to P the energy in each point is as follows, the top line of figures representing the velocities and the under line the energies, as

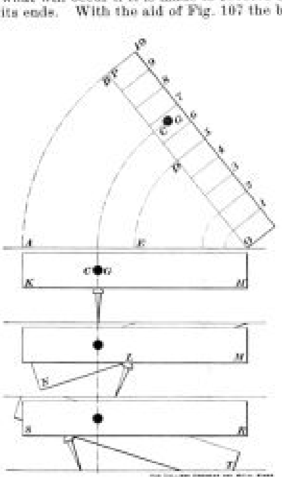

FIG. 107.

1, 2, 3, 4, 5, 6, 7, 8, 9, 10.
1, 4, 9, 16, 25, 36, 49, 64, 81, 100.

For example, the point 10 moves through a distance equal to the arc AB, while the point 5 moves through an arc of half the length as ED. The energy stored up in the particle 10 will then be 4 times that stored up in 5, because $\frac{10^2}{5^2} = \frac{100}{25} = 4$. Taking the energy of the particle 1, for unity of measure, then the sum of the energy stored up in all the particles as a whole will be in the proportion of the sum of the squares of the distances of the particles from the center of motion: and let us here notice that the distances 1, 2, etc. are not so exactly proportionate to such distances as would correctly represent the value required; for example, the first divisional piece is 1, but one end of that piece has no velocity, because it touches the center of motion; the mean velocity then of the center of gravity of that piece is .5 and the mean velocity of the piece 10 is therefore 9.5, but for the present, to avoid fractions that would becloud the explanation, let us take the remote distances 1, 2, 3, etc. The velocities can then be represented by the distances along the radius, because the linear velocity varies directly as the distances of the particles from the center of motion, and the energy stored up in each particle varies directly as the squares of the distances from the center of motion; and to still further make the matter clear, let us repeat the relationship of motion to energy by two lines of figures which in the first case represent the distance of the particles from the center of motion as before, and in the second case, the energy due to the velocities generated by the distances 1, 2, 3, 4, 5, 6, 7, 8, 9, 10 from O in the figure.

Energy stored up as the result of the different velocities of the particles 1, 4, 9, 16, 25, 36, 49, 64, 81, 100.

The total energy or the sum of the energy in the particles is

$(1 + 4 + 9 + 16 + 25 + 36 + 49 + 64 + 81 + 100) = 385.$

This sum is, as we have already shown, too large, because the distances were extreme, but the number 385 can be corrected by a constant number .891288 as $385 \times .891288 = 343.14588$.

We are now in a position to find the radius of gyration, so important in fan calculations; that is the length of a radius whose revolving end or extremity would move with such a velocity, that if all the matter in a bar of uniform section could lie in the point just named, and the bar continued to have the same angular velocity as before, the units of energy would continue to be equal to 343.14588. To find the radius of gyration in this case we must first find the mean energy per unit as $343.14588 \div 10 = 34.314588$. Now we saw by the explanation that the energy in each particle along the bar was proportionate to the square of the distance from the center of motion, therefore the length of the radius of gyration in this case must be $\sqrt{34.314588} = 5.8578$. That is to say if a uniform bar 10 inches, 10 feet or 10 yards long, was made to turn on one end, the energy stored up in it would be the same, as would be stored up in the same weight of matter, all gathered together in one point situated at 5.8578 inches, feet, yard, miles, etc., from the center of revolution. From the radius of gyration we can determine the position of the center of percussion another point of great importance in fan calculations. This point divides the energy stored up in a uniform bar turning on one end, into two equal forces, and as we now know that the energy in the particles of this bar are different, we conclude, that the center of percussion will be nearer the rapid moving end; and taking the length of such a bar to be 1 inch, 1 foot or 1 yard, or one any other unit of length in length, we find the center of percussion to be one-third of the length of the bar from its rapid moving end. Now the terminus of the radius of gyration is .58578 of the length of the bar, from its center of motion, and therefore the complement of the length of the bar is $1 - .58578 = .41422$. Now the square of the radius of gyration is twice the square of its complement, and therefore these squares are exactly proportionate to the short and long ends of the bar, as measured from the center of percussion. The number 12 may be taken to illustrate what all this means. Now let a 12 inch bar turn on one end, then the center of gyration would occur at 7 inches from the center of motion, because $12 \times .58578 = 7.02936$ but leaving out the small decimal part, 7 inches is a very near result, and therefore, 5 is the complement, or the number to be added to the radius of gyration to make up the length of the bar. The two portions of the bar that lie in opposite sides of the center of percussion are to each other as,

$$.41422^2 : .58578^2 :: 1 : 2 \text{ or } \frac{.58578^2}{.41422^2} = 2.$$

Again you only have to remember that the center of percussion is situated at a distance of one-third the length of the bar from its fast moving end to find the equivalent of the radius of gyration or the number .58578, because this radius and its complement are to each other, as the square roots of the two distances from the center of percussion. Now the axial lengths from the center of percussion, can be used as factors to determine the value of the fractional multiplier for finding the length of the radius of gyration in any given case as

$$\frac{\sqrt{2}}{(\sqrt{2} + \sqrt{1})} = .58578,$$

the relative length of the radius of gyration.

In the figure before us is given an illustration of the importance of this point called the center of percussion; for example, if a bar turning on one end, strikes a nail head immediately under the center of percussion, the nail will advance plumb into the wood, as in the case $K H$, where CG is the center of percussion; should however, as in the case NM, a point L within the center of percussion strike the nail head, the excess of energy at the N side of the nail head, will cause the bar to advance and drop as shown at N, and in spite of care, the nail will incline in towards the center of motion. Again in the case of $S R$, if the bar strikes the nail head without the center of percussion as at S, the excess of energy within the center of percussion will cause the bar to drop as at T, consequently the nail head is thrown off as at S.

Sometimes the mass revolves about the center of motion without reaching to it, as illustrated by Fig. 108, and here we see that the center of motion is situated at O, and from O to a measures 6 feet, and that a to m measures 6 feet say. The velocities are proportionate to the radial distances as ab, cd, ef, gh, ij, kl, and mn and to find the radius of gyration in a simple and easily understandable manner, let us find the mechanical moments with the mean distances 6.5, 7.5, 8.5, 9.5, 10.5, 11.5; then $(6.5^2 + 7.5^2 + 8.5^2 + 9.5^2 + 10.5^2 + 11.5^2 = 503.5$. Now the mean number of mechanical moments can be found by dividing the sum by the number of particles as

$$\frac{503.5}{6} = 83.916,$$

and as before the radius of gyration will be equal to the square root of the mean number of mechanical moments as $\sqrt{83.916} = 9.16$.

62. Mean Effective Radius of a Fan.—The lower portion of the figure is to show that the energy within a fan due to the centrifugal force is confined to the annular space whose radial depth is equal to $r p$, or $q s$.

By the arrows on the outer circle the fan is seen to revolve, left about, and by the radial arrows it is intended to be shown, that the air passing through a fan flows along the front of the advancing blades, and the result is the energy must be determined by the mean radius of gyration situated between r and p or q and s.

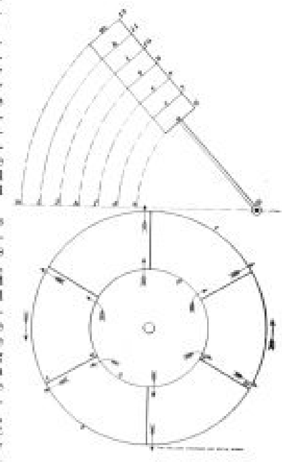

FIG. 108.

63. The Calculations for Efficiency.—It will require several lessons to explain the mode of action, and how to determine the work done by a fan, but if the reader will take care to secure these introductory facts and explanations, it will make the work in the final calculations easy, indeed it is our aim to so explain the fundamental principles, that the reader can antedate the conclusions.

64. Radius of Gyration of Discs and Rims.—Fig. 109 is given to show that the radius of gyration for

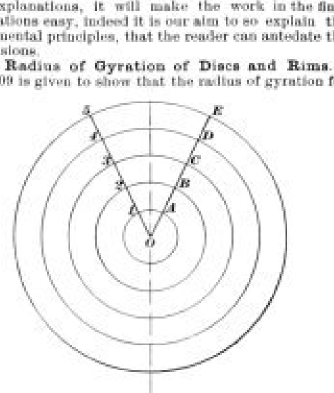

FIG. 109.

a solid discoid wheel, or for the rim of a fly wheel is found not by the squares, but by the cubes of the radial distances, and the reason of this is clear, when you consider that the mass in each annular division along the radius increases directly as the radius; for example, the matter in the ring 2 B, is twice that in the ring 1 A, or the matter in the ring 4 D is twice that in the ring 2 B. Consequently for annular masses such as the rim of a fly wheel, we proceed to find the area of gyration as follows: Taking the figure of a wheel A B D as an example, here the radius of the inside of the rim is 8, and the radius of the the outside of the rim is 9, then

$$\sqrt[3]{\frac{(8.5^3 + 9.5^3)}{2}} = \sqrt[3]{\frac{(614.125 + 857.375)}{2}} =$$

9.08 = the radius of gyration.

Fig. 110 illustrates first the angular velocities of the points A, B, E and F and this sketch is further intended to show that the motive column in a fan supplies force for a three fold purpose;

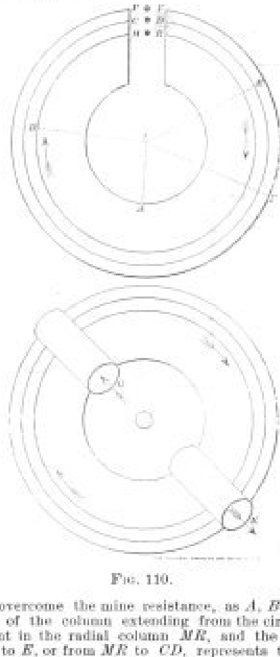

Fig. 110.

first to overcome the mine resistance, as A, B, or that portion of the column extending from the circle A to the point in the radial column MR, and the column from B to E, or from MR to CD, represents the proportion of the column that gives motion to the air blowing into the fan, and the depth of the column from E to F, or from CD to PV, represent that portion of the motive column that is expended in blowing the air out of the fan: the distances require however to be qualified by the differences in the linear velocities in the proportions LA, LB, LE, and LF. At G and K the figure draws attention to a matter that will still further engage our attention, namely, that the orifice of inlet into a fan should be equal to the orifice of outflow, and that the area of K should never exceed the area of G. Fig. 111 illustrates the characteristics

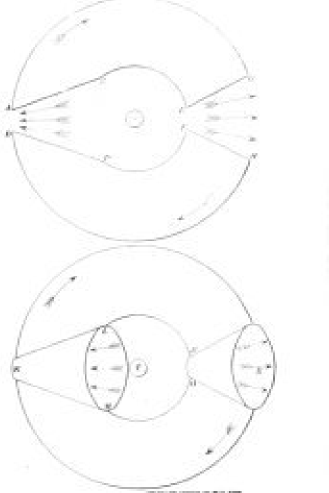

Fig. 111.

of the two classes into which fans are divided, namely the low and high pressure varieties. The orifice of entry at CD and LM is so large in proportion to the orifice of outflow, that the conical constriction causes no acceleration of the air at discharge and thus wastes the energy of the fan, unless the mine resistance is high as in the typical encased fan. In the case of the open running fans the diffusion as indicated by the arrows at G, H and R will be shown to be a mistake. The Figs. 110 and 111 are given for frequent reference in the future articles explaining the processes involved in fan calculations.

CHEMISTRY OF MINING.

The Action of Commutators.—Electric Impulse.

60. **The Action of Commutators.**—We saw in our last lesson that the magneto-electric currents, or the electricity induced by magnetic action, was alternate in direction; that is, it was alternately positive and negative during the revolution of the armature, and we repeat again that magnets can only be used to generate alternate currents, for at make and break the electric pulsations are positive and negative in direction as all our previous lessons have shown.

Where, however, a continuous current is required a commutator is made to give continuity to the external portion of the circuit: and to make the use of this current director understandable Fig. 102 is

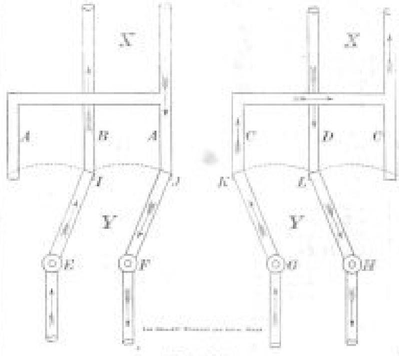

Fig. 102.

introduced. The internal portion of the circuit that constitutes the solenoids of the magnets, or the coils of wire on the magnets, is always the path for alternating or polyphase currents; then let us suppose that X, X is the internal or solenoid portion of the circuit that is alternate through the cables C D or A B and that G H and E F are the terminals of the external circuit that convey the current for lighting or motive energy as Y and Y. It will be seen by looking at the cables C D and A B, that they are just two examples of the same cables, and that the directions of the outgoing currents H and F are alike, and also those of the return currents G and E; this continuity of the currents in the same direction is secured by the action of a commutator. There really are no commutators applied to magneto electric machines or dynamos, like the one before us, but this example furnishes the best illustration of what a commutator is, and enables us afterwards to understand the more complex arrangement.

Now it will be seen that branch connections from C and A are marked like their stem A and C, and it is further seen that two contactors L H and K G, or J F and I E, turn on hinges E, F, G and H, and when the the current from the coils of the dynamo has adirection such as D and C, the contactors are turned over to make contact at K and L, and when the induced *alternate* current, has the outgoing and return directions of B and A, the contactors are moved over to I and J, and thus by the alternate movements of the contactors, first to the right and next to the left, the external current outgoing at F and H and returning at E and G

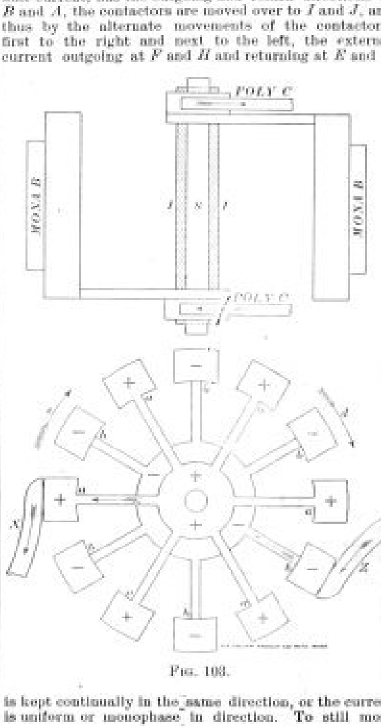

Fig. 103.

is kept continually in the same direction, or the current is uniform or monophase in direction. To still more clearly explain the commutation on a dynamo, Fig. 103 has been designed.

The shaft S being a metallic conductor, it is necessary that the commutator be insulated where the boss carrying the opposite sections is keyed over the shaft, a sheave is also keyed over the shaft as a fixed portion of each boss. The wood insulation is seen in section at I I and the shaft at S. A spring connection rests on each sheave, and these are intended to contact for the outgoing and return ends of the wires from the generator coils; the result is, they are polyphase, or they are the channels for the passage of alternating currents as Poly C, and Poly C. The lower portion of the figure is not a drawing of a commutator, but a design to explain its use, and if the reader can comprehend the principle of the construction and mode of action of this figure, he will never fail to understand the commutator in its completeness; and let us notice that this instrument is one of the marvelous productions of human genius, and its function is that of a regulator or director of the continuity of the electric current, and is therefore allied to the continuity regulators, such as the intake and delivery valves of a pump, or the steam and exhaust valves of a steam engine. We have already shown how the two sets of contactors are insulated from each other, and now to make the illustration unmistakably clear, the insulated contactors are seen to be attached to or to spring from different discs at the center of the wheel, the large one is marked — — and the small wheel is marked + +. All the contactors connected with the small disc are lettered a, and all the contactors connected to the large disc are lettered b. As we now know the current is produced in impulses at the moments when the polarity of the magnets is greatest and least, and these opposite conditions of induction generate alternately positive and negative impulses in regular order and succession, and this being so the commutator is made to sychronize these impulses in such a way that at the precise moments when the magnets induce a positive electric wave in the coils of the armatures, the contactor touching X is positive, and the one touching Z is negative, and all the b contactors become a or positive on reaching X and all the contactors marked a become b or negative on reaching Z. Or in rapid succession the a's are changing to b's, and the b's to a's, or every twelfth of a revolution the contactors are changing from positive to negative, or from negative to positive, but the change takes place in such order, that as each contactor arrives at X it is a or + and as each arrives at Z it is b or —. The brushes on a commutator as X and Y or Mona B and Mona B in the upper portion of the figure, are for sweeping off the positive electricity and returning the negative of the circuit, hence the continuity of the current.

61. **Electric Impulse.**—Fig. 104 is an illustration of electric impulse; here a rocking lever d, turning on the axis c, and moving rapidly with the hand on the

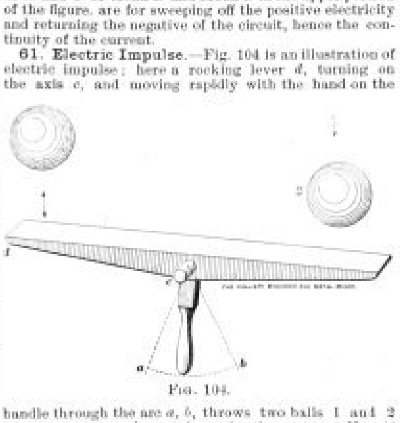

Fig. 104.

handle through the arc a, b, throws two balls 1 and 2 alternately upwards as shown by the arrows. Now if after every toss of a ball, the lever was turned in a horizontal plane through half a circle, the same end of the lever could be made to knock both the balls upward, and in that case we would have the the exact analogue of the commutator in so far as the mode of action is concerned, but this lever and balls also illustrate another characteristic of electricity that will just now concern us, and that is electrical pressure, tension, or voltage: for example, the higher the velocity with which the balls are thrown off the ends of the lever the greater is the elevation to which they will rise, and as the energy stored up in each ascending ball will vary

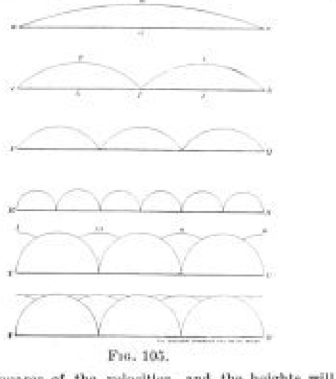

Fig. 105.

as the squares of the velocities, and the heights will vary directly as the work, these balls furnish an illustration of the pressure of an electric wave as illustrated by Fig. 105, and here the height or voltage of the wave is shown at *b d*, but the breadth of the wave *a c*, indicates a low progressive velocity, or the armature is running at a low speed. At *e k*, the voltage has increased as at *g h*, or *i j*, because the speed of the armature has been doubled as shown by two waves, *P Q* is an illustration of intermitting impulses at long intervals, and *R S* shows distinct impulses at shorter ones, but at *T U* an approach to uniformity in the pressure or voltage of the current is made by overlap waves, and at *V W*, the electrical swell of tension or voltage, is made to approximate a continuous level, by a double series of intermissions, and by this means a mere pulse or succession of outbursts, is converted into a steady even flowing electric stream.

[TO BE CONTINUED.]

GEOLOGY OF COAL.

Life of Silurian Times.—Carboniferous Fossils.

49. **Life of Silurian Times.**—The fossil records of the Silurian period, in so far as the imprints of marine life are concerned, show that it was as prodigious and varied as the life in our seas to-day, and yet these protozoic organisms were only prototypes of the higher organisms of the higher environments of all the succeeding periods.

The Silurian period is noted for its immense fauna and its almost unwritten page of examples of its flora. Nearly all that we know of its plant life relates to thallogens, or the most lowly vascular cryptogams and fucoids, or weeds of the sea.

We can hardly entertain the conclusion that the dry land of the period was a lifeless waste, because the plant forms that we have found imprints of, con-

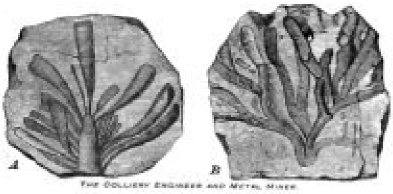

Fig. 80.

tinued into the succeeding Devonian period, where we find them along with the highly organized coniferous trees, that have continued with little alteration through all the mighty ages and changes, until they are our pine trees of to-day. Why then are so few evidences of a profuse flora found in the lamina of the Silurian rocks? An answer to this question we cannot give, but we rest assured that the childhood of the coniferous tree, even antedated the Silurian period. Fig. 80 furnishes two examples of fucoids, or sea weeds. Now this may furnish a cue to knock the ball along, for we know that the animal life of the sea could not exist without the prime source of his nourishment. In the order of nature, plants alone appropriate inorganic matter, and build up out of it organic tissue, animal life cannot be nourished by inorganic matter, and therefore a vast number of animals derive their life supplies from the consumption of organized vegetable tissue, and the vegetable eaters in

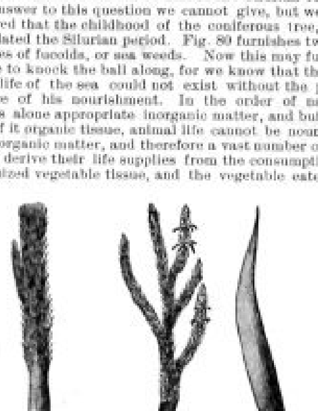

Fig. 81.

their turn become the food of the carnivora, but the great fact remains, namely, that plant life is the prime source of the sustenance of all animal life; if then evidences of animals on the dry land can be found, other than fish eating examples, we may be sure that a supply of vegetable food was accessible. Now in the upper Silurian a fossil scorpion has been found, and this carnivorous insect could only obtain its food by devouring other insects, that obtained their food from the fruits, leaves, bulbs, and roots of relatively highly organized plants.

From all this we learn that the positive indications of Silurian strata are the primitive life forms, such as graptolites among zoophites, brachiopods among mollusce, and that the negative evidence is of a decisive kind, namely the almost entire absence of plant remains. So much is this the case that the prospector for coal can at all times determine with precision the presence of Silurian rocks.

The Devonian that succeeds the Silurian, is teeming with evidences of a stupendous advance both in variety and development of a highly developed fauna and flora, for plants now furnish positive instead of negative indications of the presence of the Devonian strata; and strange as it may appear, the Devonian flora was not only the immediate precursor of the Carboniferous flora, but of the horsetails and conifers of to-day.

The ferns and other aerogens of the Devonian period are however of a more lowly type than those of the Carboniferous period. Fig. 81 furnishes examples of the sigillaria of the Devonian period, and but for the immature organic development which the imprints indicate, they might be mi-taken for Carboniferous fossils. In the figure at *A* and *B* we have the sigillaria as a tree and at *C* an enlarged view of one or its bracts or leaves, at *D* we have a fossil imprint of a portion of the stem of this primitive tree that contained the embryo of the conifers or pines. Fig. 82 furnishes at *A*, *D* and

Fig. 82.

E some examples of Devonian ferns, and it will be seen that their fronds or leaves have a structure and variation characteristic of the period, but far short of the higher development of the fronds of the ferns, that characterize the Carboniferious period. At *B* and *C* are examples of embryonic, lepidodendra.

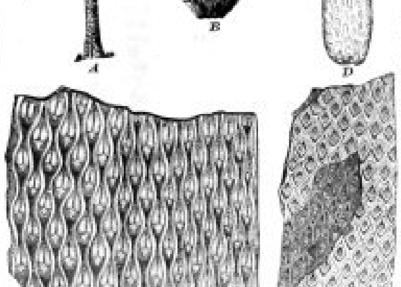

Fig. 83.

50. **Carboniferous Fossils.**—Figure 83 shows lepidodendra of the Carboniferous period, at *A*, a restoration, and at *B*, *C*, and *D* the seed or spore cases of the plant. It is only in Australia and in tropical countries in Asia, that tree plants allied to the sigillaria and lepidodendra are now found, and stranger still, a small acrogen grows in Europe that is a dwarf example of these singular trees. The lepidodendron is the forerunner of the sigillaria and the sigillaria is the immature pine, or the forerunner of the conifers. At *E* and *F* we have fossil imprints of the stem of the lepidodendron.

Figure 84 is an illustration of the horse-tails or true rush trees of the Carboniferous period and known under the general name of calamites. These peculiar plants

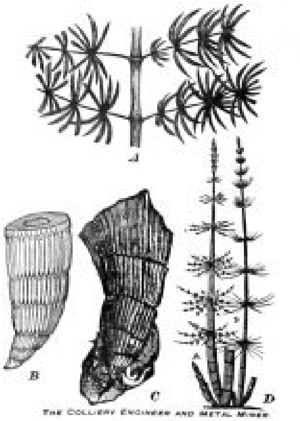

Fig. 84.

are the forerunners of the endogens or the grasslike plants of our day, as common grass, wheat, oats, barley and many such like plants, along with canes and bamboos. How interesting then must be the study of economic mining geology, when we discover that all the plants that distinctively characterize the Carboniferous formation had in embryo, the germs out of which the highest types of their successors have been developed. At *B* and *C* we have fossil examples of the root end of the stem of the calamites, and at *A* we have a piece of a stem of the plant, showing the nodes or knots from which the bracts spring. At *D* is a view of the plant while living and growing. All the fossils of this plant found are flattened and lying horizontally on the beds of the strata, just as a large hollow reed growing in water would do at the period of decay.

MINING METHODS.

The Velocities of Air Currents—Measurement of Current Pressure.—Water Gauges in Action.—The Advantages of Tube Gauges—Improved Types of the Water Gauge.—False Reading of Water Gauges.

56. **The Velocities of Air Currents.**—The volume of air circulating in a mine, or the measure of the ventilating current in cubic feet per minute, was first determined by finding the time required for a cloud of black smoke to ascend the upcast or furnace shaft of a bituminous mine in England and the mode of proceeding was as follows: Two observers with their watches set exactly alike were stationed so that one was beside the furnace in the mine to note the second of time at which "small" coals were thrown on the furnace fire, and the other was stationed at the surface to note the exact time at which the cloud of black smoke arrived.

The difference of the times of the two observers, was the time of the ascent of the smoke in the shaft. The depth of the shaft and the diameter being known, it was easy to determine the cubic feet of air per minute in the ventilation of the mine; and to make the matter clear let us suppose the diameter of the circular shaft was 10 feet, and the depth to the furnace 600 feet, and the time of the ascent of the smoke 40 seconds, then the velocity of the air current in the shaft, in feet per minute is

$$\frac{600 \times 60}{40} = 900.$$

The area of the circular section of the shaft is $10 \times 10 \times .7854 = 78.54$ square feet, and the volume of the ventilation in cubic feet is $78.54 \times 900 = 70686$.

57. **Measu ement of Current Pressure.**—At the time under notice the current pressure was not measured, but when the current was moving quick the miners used to speak of the "force of the wind" and at last the inquiry was, what can that force be? and then attempts were made to measure it. The so-called water gauge was first used by the engineers of gas companies to measure the super-atmospheric pressure of the coal gas in the "mains." The pressure in gas mains is various according to the extent of the distribution and the grades on which the pipes are deposited, and the elevation of the supply tanks. As the distribution of coal gas through pipes brings before us the operation of many natural laws that concern us in mining, just let us notice some of them, first then, when the gas tank is situated at an elevation of 450 feet above the level of distribution, it requires a pressure of 3 inches of water gauge to sink it to the low level of the city, for if a cubic foot of air weighs .077 of a pound, a cubic foot of coal gas will weigh .03465 and $.03465 \times 450 = 15.5925 = \frac{15.6}{5.2} = 3$ inches of w. g. Second, as the area of the transverse section of the pipes is small, the current friction is considerable, and would be so great

as to require a high pressure to send the gas through many miles of pipes, but for the splitting that takes place. First we have the splits of the first degree in the great mains, and then the district mains, or splits of the second degree, and next the street mains, and then the splitting, and splitting, and splitting until the splits are of hundreds of degrees before the gas reaches the burners, the result is the current friction is very much reduced, and yet the pressure to force gas through the pipes ranges from 5 to 25 inches of w. g. *miners measure*.

The gas engineers do not reckon the pressure per square *foot*, but per square *inch*, and they coined the term water gauge, and the miners have followed suite.

58. Water Gauges in Action.—Figure 105 is an illustration in vertical section of the earliest miners water gauges. The instrument consisted of two parts, the tank *T*, and the vertical glass tube *G*. This tube was bent at the top to allow the instrument to be connected with the low pressed air, on the negative or *M* side of the stopping or door, as *M* on the left hand side of *XY*. The lower end of the tube entered the bottom of one side of the tank *T* on the positive or current pressure side of *XY*, as *P* +. The gauge was used to measure the inches and tenths of an inch in the elevation of the water column in the glass tube, or the height of *a b* above the level *c d*.

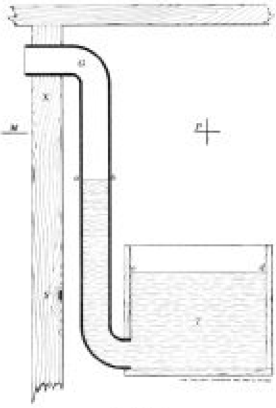

Fig. 105.

This variety of the water gauge was considered inconvenient and unsightly, and was therefore substituted with bent glass tubes as in Fig. 106.

59. The advantages of Tube Gauges.—These tubes are convenient and portable, and can be carried in a side-pocket, and if the bent ends are fixed in a cork, they can be tried on a door or stopping without the waste of much time. If you desire to make a gauge, 18 inches of glass tubing about an eighth of an inch in the bore, and of the variety easily softened in the flame of a gas-jet, can be purchased for 10 cents, and the bending is easily done by a novice, the result is, no mine foreman need be without a gauge for determining the current pressure. Two gauges are fixed on opposite sides of a wood stopping, with the view of illustrating, how the water column in one leg of the gauge is depressed, while that in the other is raised, and let us notice that the limb on the super-pressure side is always depressed as *K* and *G*, because they are on the *P*, or + side. The two figures furnish a good illustration of the square inch, and square foot modes of measuring current pressure, for let the cistern or tank *T*, Fig. 58, have a top surface as extended as the surface of the ocean, or let it measure a square inch or a square yard, the same difference in pressure between the *P* and *M* sides of the diaphragm *XY* would produce the same difference in the levels *a b* and *c d*. It will be seen by the figure that the leg of the gauge on the low pressure side of the stopping contains the highest water column as at *H* and *E*. The difference of the levels *a b* and *c d* means that a slab of water one foot square in the base, and 2 inches deep, say, is equal in weight to the pressure that is producing ventilation. Now such a slab of water will weigh 10.4 pounds because if a cubic foot of water weighs 62.5 pounds, that is if a slab of water 1 square foot in the base and 12 inches deep weighs 62.5 pounds, then 2 inches must weigh one-sixth of that and $62.5 \times \frac{1}{6} = 10.4$ pounds. The pressure producing ventilation is reckoned per square foot, the pressure however is not altered by the unit of measure because it might be represented as pressure per square inch after the custom of the engineers of gas works, now the unit in mining is found by dividing a cubic foot of water into 12 slabs, each an inch *thick*, that is $\frac{62.5}{12}$

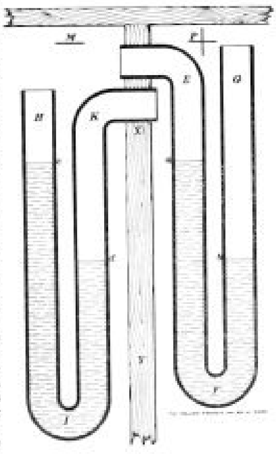

Fig. 106.

$= 5.2$. The gas engineer takes for his unit of weight 1 inch in depth, and 1 square inch for his base, or in short the weight of a cubic inch of water which is equal to $\frac{5.2}{144}$ or $\frac{62.5}{1728} = .03611$ or .036.

60. Improved Types of the Water Gauge.—Fig. 107 introduces to us the improvements that experience rendered necessary in the construction of the water gauge.

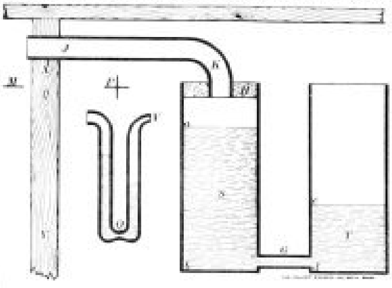

Fig. 107.

When Cook's rotary pump and Nixon and Strauve's reciprocating pumps were introduced as mine ventilators, it was found that the water gauges in use could not be used to find the pressure of the ventilating currents, for at every throw of Cook's eccentric drums, and every stroke of Nixon and Strauve's pistons, the water columns in the legs of the gauge oscillated so much, that no reading could be taken, and therefore special gauges had to be made. The chief improvement secured by the Daglish patent was the contraction or reduced orifice at the *U* bend of the tube, as that shown at *Q*, for when the current pressure was rapidly fluctuating, the water could not flow responsively through the contraction, and the result was a mean reading.

But for ventilating pumps, the gauge shown at *S T*, is the best in practice. Here large square glass chambers are connected as *S* and *T*, by the small connecting tube *G*, and the result is, the pulsating or throbbing current, does not prevent a correct reading of the ventilating pressure.

The differences in the head levels of the water columns in the large tubes are as a matter of course, the same as those that would be indicated by small ones. At *V*, the *open* leg of the gauge is contracted to prevent evaporation and the entry of dust. At *H*, the branch tube *J K* passes through an air tight cork at the *K* end, while the *J* end is fixed in the stopping *X Y*. The gauge may be read as in all other cases by the height between the levels *a* and *c*, or the difference of the heights, *a b* and *c d*.

61. False Readings of Water Gauges.—Fig. 108 is given to show how inaccurate indications of the mean current pressure arise. The variations in the gauge that produce false readings, are the result of the manifestation of inertia arising from deflections and displacements in the path of the current. To prove this, partly fill a bottle with water, and introduce through the cork a T pipe as *d*, *m*, *j*, *q*, the connection of *j q* with *d m* is made with a small contracted orifice at *j*, and a contracted mouth piece at *m*. Now the cork must not fit air tight into the bottle neck. If you blow a good blast through the mouth-piece *m*, the current in the tube *d m*, sweeps over the orifice at *j* and produces at that opening a partial vacuum by displacement, the result is, the water rises up the leg of the tube *j q*, and when it reaches *j*, the blast of air cuts off the head of the uprising water, and intensifies in this way the vacuum. The same mode of action sometimes seriously effects the reading of water gauges; for example, this is explained by a study of the entering tubes *A*, *B* and *C*, which are connected with water gauges through the side of a fan drift, and the current is blowing right onto the open orifice of *A* at *K*, here the false reading is a greater pressure or falsely increased pressure, as the result of the inertia of the arrested particles of moving air. At *B* the air is seen to sweep past the open orifice at *G* and thus produce a depression as in the case of the pipette on the bottle. At *C*, the air is seen to blow from the orifice at *D*, and thus make a partial vacuum and consequent depression of the gauge. To correct all this, the connection of the gauge with the drift has to be wisely made. Fig. 109 shows two examples of false readings arising from deflections of the air currents. The first drift has a right angle elbow, and the reading of a gauge connected at *A* is too small, as the result of the inertia of the impinging air striking the reflecting side of the drift. A gauge connecting at *B* is not reliable, and strange to say a gauge connected at *C* gives a higher than the true reading and is most unreliable, because the deflected air not only produces a depression at *C*, but the wave impulse of the agitated air makes the *C* reading very unsteady.

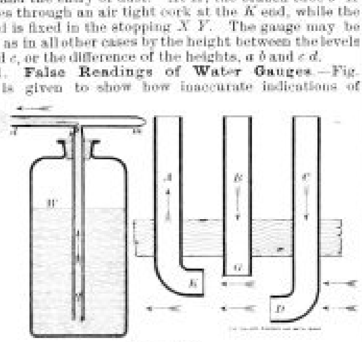

Fig. 108.

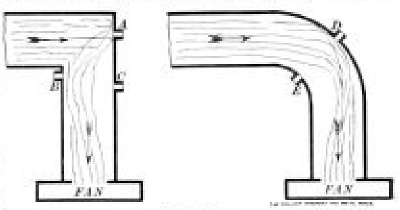

Fig. 109.

In the same way the depression at *E* will be greater than at *D*.

(TO BE CONTINUED.)

LONG DISTANCE POWER TRANSMISSION.

The Utilization of a Splendid Water Power by Aid of Electricity.

An interesting long distance power transmission plant is in course of construction at Fresno, Cal., which is unique in more than one particular. The head of water to be used is 1,410 feet and the distance of transmission about thirty-five miles. The natural conditions surrounding the installation are extraordinary in themselves. The water for supplying the power is taken from the North Fork of the San Joaquin river. The stream of the North fork runs for several miles down a rocky canyon, forming rapids and cataracts as it runs between the steep mountains. At the head of the rapids a canal will take the water out upon the summit of a high ridge, which it will follow for six miles to a point nearly fifteen hundred feet above the San Joaquin river. Here a reservoir has been constructed with an average depth of ten feet. It covers about eight acres and can be made both larger and deeper, should the demand for power require an extension. Into this reservoir, the water brought along the ridge by the canal will be stored, but it will be used solely as an emergency store. It is calculated that it will hold enough water to drive the machinery for several days, so that should a break occur between the reservoir and the source of supply, the electrical work could continue until the repair was effected.

A pipe line runs directly from the canal a distance of about four thousand feet to the power house, and the head of water obtained will not be less than 1,410 feet. The pressure at the bottom will be six hundred lbs. to the square inch. The lower end of the pipe line is of welded steel pipe, three-quarters of an inch in thickness, having special steel flanges and special packing at the joints. The lowest amount of water power available is at least 7,000 H. P. at the head above mentioned. All possible accidents are provided against. Should a break occur near the lower end of the pipe the rush of water would form a vacuum near the upper portion of the pipe and it might collapse under atmospheric pressure. An air valve will be placed near the top to provide against this contingency. The pipes will be made in sections of twenty feet each. At the upper end the metal will be ¾ inch thick and the pipe 24 inches in diameter. It will be fastened to the solid granite mountain sides by steel cables.

The power station will be located at the bottom of the mountain, and will contain three Pelton water wheels 58″ in diameter, driven by a single nozzle. The generating plant will consist of three 340 K. W. General Electric Company's three phase generators. The three phase system has been selected in this case as the system which will give the highest efficiency of transmission with the lowest cost of copper.

From the point in the North Fork of the San Joaquin river, where the water is taken to the power house at the foot of the mountain, is a distance of about seven miles. From the power house to Fresno, where the electricity will be utilized is about 31½ miles in a direct line, or 35 miles over the electric wires. The line will consist of two circuits of bare copper wire, consisting of six wires strung on poles forty feet high. The current will be delivered to the lines at a voltage of 11,000 volts. From the power house the line will rise to the level of the San Joaquin, cross it and pass through a portion of the Auberry Valley, then rising over the Red Mountain, passing about a mile west of Clovis will continue direct on to Fresno. The first five miles will be over moderately level country, the other thirty through an open and practically level country under ideal conditions for transmission. It is estimated that the power which will be delivered in Fresno at present from the three phase generators will not be less than 900 H. P.

At the Fresno end the line will be brought into a sub-station and then the current will be transformed down. From the sub-station power will be delivered to all the mills in town, the water works, machine shops, planing mills, laundries, printing presses, elevators, packing houses, etc. It will also be used to drive the street railway system of the city which will require about 300 H. P. In the sub-station, two arc dynamos, each of 60 lamps capacity will be driven by an induction motor, the motor being mounted on the same bed plate as, and being direct connected to, the dynamo. Current will be supplied for 4400 incandescent lamps.

Gas and fuel in the San Joaquin Valley have always brought an extremely high price and this may be considered as the most potent reason for the present installation. It is believed that power can be supplied when the plant is started, at about half its present cost; and to the towns around Fresno the privileges of electricity will probably be extended as soon as possible. This plant may easily be considered as taking the lead in the use of a high head of water and the distance over which the power is transmitted.

MISCELLANEOUS.

TELEGRAPHIC CIPHER CODES.

The International Telegraph Bureau is a telegraphic clearing house and intelligence office located at Berne, Switzerland, of which all the Governments of Europe, and all the important nations of the rest of the civilized world, with the sole exception of the United States, are members. "Berne," as the bureau is generally referred to, is the central information bureau of the telegraph service of the whole world. Any interruption to a cable or land line, the opening of a new line, or rearrangement and shortening of an old one; all delays to telegraphic communication, anywhere and from any cause, such as storms or earthquakes, or censorship on telegrams because of war or civil disturbance in Cuba or Armenia, or anywhere else; anything and everything that improves or disturbs the telegraph service in any part of the world, is at once reported from the affected locality direct to Berne, and the information is promptly sent out from there to the head quarters of every Government and telegraph company, and so on to every telegraph office of importance in the world. While the United States is not represented at Berne, or in the international conventions, this country shares in the information, and is to a great extent under the domination of Berne. With a few exceptions all the cable lines in this hemisphere are owned by British companies, and in telegraphing to Cuba or South America even, Berne's territory is entered.

Berne is really the center of everything telegraphic, and "CQ," in the nomenclature of telegraphy, is the circumference of everything. Every city in the world has its code, recognized by Berne and known everywhere. Thus "LN" means London, "NY" New York, "BM," Bombay, "SZ" Suez, "CT" Calcutta, "MV" Monte Video, and so on. A message from Berne simply addressed "IQ" would quickly find its way to Iquique, away over in Chili. "CQ" means "all stations," and a telegram sent from Berne telling, perhaps, of an interruption of communication with Australia by reason of an earthquake in Java, addressed simply "C Q," would be passed from one government and telegraph company to another, and from centre to centre, until inside of twenty-four hours it would reach every office of importance in the world.

There has always been a difficulty between the telegraph service and its customers over the use of cipher words. Of course, where the cost of telegraphing runs to several dollars a word, every effort is made to be brief. Most elaborate and really wonderful codes have been constructed, some at a cost of thousands of dollars, by the aid of which one word is made to express a whole sentence, or paragraph, of commercial information. To such a science has this matter of codes been reduced that the bulk of telegrams passing between this country or England and distant places like China and Australia rarely consists of more than two or three words. Many hundreds contain only one word, besides the name and address. And one word often sums up a whole day's business. To insure accuracy and speed the convention decided many years ago that only legitimate words, belonging to one of eight languages, should be allowed in codes, and no word should contain more than ten letters. Arbitrary combinations of letters, such as xup, or wzy, are only accepted on a basis of three letters to a word. While cable operators are not expected to know eight languages, yet there is something about a legitimate word from a modern language that makes it easily recognizable. It sounds all right on the Morse instrument and looks all right on the cable slip. A mutilated word is as readily distinguished, and stopped. The sender of a foreign telegram of eight words may use a word each from English, German, French, Italian, Spanish, Portugese, Dutch and Latin, but they must be good words, and not over ten letters long. The receiving clerk in a cable office will almost infallibly spot an illegitimate word, and, as he is held responsible, at the rate of several dollars a word for any wrong word he may pass, he lets very few indeed get by him.

But so elaborate have codes become that pretty nearly all the good, available, and safe words, not too much alike to cause confusion or liability to error, have been used up, and for many reasons the legitimacy of words is often called in question. Perhaps the sender of the telegram wants to use a word like immediately, in its normal sense. But that word contains eleven letters, and maybe from ignorance of the rule, or, perhaps, because of the money involved, the sender drops out an "m," and attempts to get "imediately" over the wires. But it is not likely to go far, for cable operators are about the most careful and expert craftsmen in the world. One interesting incident of this sort came up in an English office some years ago in relation to the word "pando" which appeared in a telegram offered for transmission to Bombay. Pando is a legitimate Latin word, but the telegram was otherwise in English, and the text showed beyond any doubt that "pando" stood for "P. & O." meaning the Peninsular and Oriental line of steamships running to Bombay. The cable company claimed that it was an evasion, and the sender finding out later that the word happened to be good Latin, insisted on the right to use it and have it counted a single word. But Berne upheld the company.

Such difficulties are continually arising. Others come from the similarity of many code words, where the difference of a letter, or a telegraphic dot, might mean a difference of thousands of dollars in a quotation. To avoid all such difficulties in the future, the last convention held at Paris in 1890 instructed the bureau at Berne to prepare a vocabulary which should, after a specified date, constitute the sole authority as to the legitimacy of code words. A corps of experts was set to work on this vocabulary, and after five years of really great labor the vocabulary has been completed. It contains 250,000 words of not more than ten letters each. Every word has been tested and compared, by chirographic and telegraphic standards, and it is believed that under ordinary circumstances, no two words will become mixed or confused in any way. The amount of labor involved in this compilation will easily be appreciated when it is considered how much alike hundreds of words are. It is said that every word in the vocabulary differs in at least two letters from every other word in the 250,000.

The Berne vocabulary will not go into force until January 1,1898, in order to give opportunity to users of codes to make their ciphers conform to it. But after that date any word not contained in the Berne book will not be accepted for transmission in Europe.—*N. Y. Sun.*

THE DISTRIBUTION OF ANIMALS.

The apparent anomalies in the distribution of animals on the surface of the earth have for a long time attracted the attention of the zoologist. How came the lemurs, those frail inhabitants of the tropical forests, to live along the southern parts of Asia, separated from their kin in Africa and Madagascar by the wide ocean? Why should ostrichlike birds live in in Africa and Australia, and again at the southern part of South America? Not long ago, zoologists, relying upon the current opinion of geology, played the Titan with land and water, inventing great continents and planting them in the oceans. Thus, at their command, "Lemuria" arose from out the sea to make a land passage from Madagascar to India; even at the present moment many assert that a huge continent, now sunk in the waste of waters round the southern hemisphere, stretched from the cape to Australia, and from Australia to Patagonia.

But geology, as it has abandoned the theory of catastrophes for the theory of slow transformation, is also giving up belief in such gigantic alterations of land and sea. The great oceans, the great land masses, it tells us, date as far back as geological evidence goes. Oceans and continents may have altered their outlines; Malaysia, now an archipelago, was once a continent. Africa, now a continuous land mass, may have been broken up into islands by the intruding sea. In great land areas, continuous slow rising and falling has occurred, each area passing recurrently through successive phases; archipelagoes have risen to be indented continents, indented continents to be a continuous mass, and the whole has then slowly fallen back again to its original condition. But the sea and the land in their broad masses remain as when first divided.

What, then is the form of this sempiternal configuration? In the minds of most of us it is a vague image remembered from a distorted "Mercator's Projection," or from the Eastern and Western hemispheres flattened on the pages of an atlas. These images are dimmed toward the poles, and so fail to give the most striking aspect of sea and land. But, taking a globe, turn either pole alternately toward you. In the south a clump of icebound land, well within the Atlantic circle, surrounds the pole. All else is the wide domain of ocean, broken only by tapering and isolated tongues of land, South America, the Cape, Australia, leaning down from the north. On the other hand, all the great continents expand in the northern hemisphere and shoulder each other around the pole. America is separated from Asia only by the shallowest and narrowest of straits; an elevation of a few fathoms would unite Greenland with Europe. The great land area of the globe is as a cap thrown over the northern hemisphere, with only tattered fringes hanging across the equator to the south.

And where did terrestial animals come into being? Tradition places their home eastward in Eden. Science points certainly to some part of the great northern land area as the centre of life for the larger terrestial forms. We know that these arose successively, primitive birds like the ostriches coming before higher forms, like the pheasants and singing birds, the pouched marsupials preceding the antelopes and the lion, the lemurs coming before manlike apes. Each wave of life, spread over the whole continuous area, producing after its kind; then, pressing around the northern hemisphere it met a thousand different conditions of environments, different foods, enemies and climates, and broke up into different genera and species. But there was never a wave of life that had not another following it. In the struggle for existence between the older and newer type, generally the newer prevailed and drove the older southward toward the diverging fringes of the land masses. The vanquished left behind them on the field of battle only their bones to become fossils. Sometimes succeeding waves swept along to the extreme limits of the land, and many early types were utterly destroyed. But others found sanctuary in the ends of the south, and were preserved in islands broken off before the newer types had reached them, or saved their lives by becoming creatures of the night, dwelling in the fastnesses of tropical forests.

Fossil bones of ostrich-like birds occur in Europe and in Asia and in North America; their living representatives are the cassowaries of New Guinea, the emus of Australia, the ostriches of Africa, and the rheas of South America. The oldest mammals now alive, the duck-billed platypus and the spiny echidna, layers of eggs, kinsmen of the reptiles, have allies among American and European fossils; in life they are found only in Australia and New Guinea. The pouched marsupials once ranged all over the earth, covering it with a strange mimicry of existing mammals. Now they have been beaten out of Europe and Asia, even out of Africa, and almost entirely out of North America; but they have found refuge in South America, and, secluded in Australia, they form nearly the whole of primitive fauna. So also with the lemurs; their fossil remains bestrew the whole earth. A few surviving forms remain in the forests of Africa and southern Asia; still more of them, shut off in Madagascar, have defied the advent of newer arrivals.—*From the London Saturday Review.*

ONE RIVER'S THREE NAMES.

"Some queer kinks in nomenclature are discoverable in this country of ours," said Col. William Stapleton of Trinidad, Col. "Running right through the town of Trinidad, in which I live, is a little river, which familiarly and indiscriminately does its muddy, flowing business under three names. It is called variously the Las Animas, the Purgutorio, and the Picket Wire. The names came about in this way:

"Santa Fe, N. M., claims to be and is about the same age as St. Augustine, Fla. Both towns are considerably over 200 years old, although I forget the exact date of their settlement.

"Back in the middle of the sixteenth century the Spaniards at Santa Fe made up a military detachment to go overland to St. Augustine. The old Dons didn't know anything of the country which lay between. All they were posted on was the distance and the general direction, as they knew the latitude and longitude of both places. Rather late in the fall some 700 of them, steel-clad soldiers, camp followers, baggage train, and women pushed in through the Raton Pass over the trail now followed by the Santa Fe Railroad, and at the beginning of winter made a camp at what is now the site of Trinidad, which sits fairly in the mouth of the Raton Canon, looking out on the plains.

"There they were on the very threshold of the Rockies. To the east of them, over which their course must trend, lay an utter waste of plains, apparently without limit. All that winter the Spaniards camped in the mouth of Raton Canon. With wine, woman, and song they put in a hilarious time, and probably had as much fun as they ever had before or since. Winters are not rigorous and spring comes early in the vicinity of Trinidad.

"With the first coming of the early grass the adventurers burnished their armor, fitted up their horses, and got ready to move. The camp followers, the women, and the extra baggage they sent back to Santa Fe. When last seen the party bound for St. Augustine, numbering several hundred, were marching down they valley of the little river by which they had camped.

"That was the last ever heard of them. Not a feather ever floated back to tell the story of their fate. With the last flap of the banner, and the last sun-glint on the rearmost steel cap, they disappeared from the earth. To this day no one is able to make a suggestion even as to what became of them, except that it is supposed they were butchered by the Indians.

"Fifty years ago there was an old Comanche chief named Iron Shirt, because of a rusty old shirt of chain mail which he wore, but neither he nor any of the other Comanches knew anything of the origin of the garment nor where it came from. It had been in the tribe further back than the short Comanche memory could reach. Many have supposed that it was a relic of this Spanish expedition of three centuries ago, which had apparently marched off the earth that far-away spring day in the mouth of the Raton Canon.

"But now for the kink in the nomenclature I was thinking of. The disappearance of these Spanish soldiers seemed so eerie and witchlike that it made a profound impression on the superstitious people they had left behind. They named the little river Rio de Las Animas, meaning the River of the Lost Souls, and it is supposed to hold the story of the expedition's dark fate and repeat it to itself in the river language, which the Mexicans do not pretend to understand.

"When the French fur traders under Sublette and Saint Vrain came trapping in those waters from St. Louis, in a French effort at translation they made out that the 'River of the Lost Souls' must mean the Purgatory river, and so gave the river the translated name of Purgatorio.

"Later, when the American bullwhacker marched through on his way to Santa Fe, he accepted French name, but called it Picket Wire. To this day the river wears all three titles, as the reader would soon learn by turning to the Trinidad newspapers, where he would find cattle brands advertised as having their ranges variously on the Las Animas, the Purgatorio, and the Picket Wire.

"Every man picks out his name for himself, but they all mean the same river. It isn't much of a river, either, only about twenty feet wide at Trinidad. The Mexicans, however loyally stick to the name 'Rio de Las Animas,' and Mexican mothers tell their children of the soldiers who hundreds of years ago marched from there and were never heard of again."—*From the Washington Evening Star.*

KEEPING FRUIT FRESH.

A vast deal of fruit is wasted throughout this country because, as a rule, people are ignorant of the best ways of caring for or preserving it.

For example, no fruits should ever be put into ice closets or refrigerators. "What nonsense!" some will say, "why everybody does it." True, yet it is nevertheless a pernicious and wasteful custom.

Our grandmothers, splendid, economical housekeepers as they were, kept fruit fresher and longer than we do, with our ice chests and coolers. In cool, well-aired pantries or closets, or well-stoned dry cellars, luscious peaches, plums, pears, apples were kept for months undecayed and wholesome.

Some of the best housekeepers I know, after storing ripe or cooked fruits in ice closets year after year and finding them mildewed and spoiled, have changed the errors of their ways and returned to grandma's excellent, thrifty habit of keeping fruits in cool closets, or the store room in the cellar.

Why does fruit keep fresher and sounder in well-cared pantries than in ice chests? Because that is nature's way of of preserving it. Every ripe fruit that falls to the ground in nature's domain, drops to cool dews, is hidden in the tall, shielding grass or covered by fallen leaves. Try a ripe pear, that has lain on the ground all night, at half-past 6 in the morning. No ice-kept fruit begins to compare with its rich, juicy freshness. Then, too, when fruit kept for home in the moist, icy temperature of refrigerators is taken out chilled or half frozen, and suddenly exposed to the heat of kitchens or dining rooms in hot weather, decay sets in with terrible force and rapidity.

No doubt much of the poor digestion prevalent in summer is directly due to our national habit of eating fruit no longer fresh or wholesome, which has been kept all day or night in refrigerators.

How appetizing these remnants of yesterday's fruit look! withered, decaying, mildewing; served up by anxious, penny-saving housekeepers. You would save more fruit, besides the family health, by keeping such materials in pantries or closets. Or better still, stew strawberries, raspberries, currants, blackberries, left over after they have once been offered fresh to the family or guests. If nobody cares for them stewed, with sugar, of course, why just strain them and put the juice into clear jars or bottles.

My word for it, the family will clamor for more of the delicious, healthful, cooling drinks these fruits make added to water, and spend less for harmful compounds at soda water fountains.

Fruits are often served in poor condition, either too green or decaying.

Bananas, when green or unripe, should be kept a day or two in a warm, dark place. Then take them out and the mellow, rich flavor will repay the trouble.

They are very nourishing. Try salt with them if they seem indigestible; the salt brings out the flavor and assists digestion.

Dry your lemon and orange peels under the stove in tin pans or platters, and they will then kindle fires splendidly; there is so much oil in the rind.

Pineapples are more often eaten half-ripe than any other fruit, because so few have ever eaten them where they grow, and know not how delicious they are when fully ripe. To test them, try to pull out the stiff, green leaflets at the top of the fruit. If they come out easily the pine-apple is ripe; if not, keep it in a cool, dark place until it mellows. People in the tropics are extremely careful to remove every speck of the eyes on the rind, and never eat the round, hard core in the middle of the pine-apple. A delicious preserve can be made of pineapple stewed with sugar.—*M. E. Carrel in the Philadelphia Inquirer.*

IS MARS INHABITED?

There is one discovery that was made during the last year which seems opposed to the otherwise strongly supported hypothesis of a close resemblance between Mars and the earth. It relates to Mars's atmosphere. The great English spectroscopist Huggins, the famous Italian astronomer Secchi, and more recently the indefatigable German observer Vogel, have all put on record their belief, based upon studies of the spectrum of Mars, that that planet possesses an atmosphere resembling the earth's and containing the important element aqueous vapor. Vogel, indeed, went so far as to say, about ten years ago, that "it is definitely settled that Mars has an atmosphere whose composition does not differ appreciably from ours, and especially the Martian atmosphere must be rich in aqueous vapor."

More recent observation have appeared to confirm those of Vogel. But now comes Professor Campbell, of the Lick Observatory, employing some of the most powerful and perfect spectroscopic apparatus in existence, and shows that, so far as the spectroscope is able to inform us, there is no evidence whatever of the existence of a Martian atmosphere containing watery vapor, or even that Mars has any atmosphere at all! His observations, made in June, July, and August of 1894, show that the sunlight reflected to us from the surface of Mars undergoes no perceptible absorption such as would arise from the existence of an atmosphere surrounding the planet, and that the lines in Mars's spectrum which other observers had ascribed to the absorptive effects of its atmosphere are really due to absorption by the atmosphere of the earth.

Professor Campbell's observations do not entirely dispose of the supposed atmosphere of Mars. They simply indicate, as he has himself pointed out, a superior limit to the extent of such an atmosphere. He thinks that if Mars had an atmosphere one-fourth as extensive as the earth's, he would have detected its existence. Against the conclusion that Mars has no atmosphere and no aqueous vapor stands the unquestioned existence of the white polar caps of the planet, waxing and waning with the seasons. As to this, Professor Campbell says, "While I believe that the polar caps on Mars are conclusive evidence of an atmosphere and aqueous vapor, I do not consider that they exist in sufficient quantity to be detected by the spectroscope."

In other words, Mars does not possess an extensive atmosphere, but it may have one about one-quarter as extensive as ours. Does such a fact preclude the supposition that Mars is a habitable world? Hardly; for although we should die like fish thrown out of water if three-fourths of the atmosphere were suddenly withdrawn from the earth, yet it is plain that beings resembling ourselves and our contemporaries in the animal kingdom would require comparatively slight adaptations of structure to enable them to live in an atmosphere no more extensive than that which the spectroscope yet allows to the planet Mars.—*From Harper's Weekly.*

ALASKAN SNOW HOUSES.

Many adventurous prospectors have been making their way in the last year toward the Yukon River valley, in Alaska, and they have had to live very much after the fashion of the natives. Caribou and moose abound, though it is not much sport hunting them when the thermometer registers 50° below zero.

The natives construct snow huts in about the time that would be required to pitch a wall tent. They select a place where the snow is about four feet deep. A space 6 by 9 feet is marked out. Blocks two feet square are cut from the surface snow and set on edge around the excavation for side walls. At one end three feet of the space is dug down to the ground; in the balance about two feet of snow is left for a couch. The sides and ends are built up tight and the whole is roofed with broad slabs of crusted snow cut in proper dimensions to form a flat gable roof, and loose snow is thrown over all to chink in. At the end, which is dug down to the ground, a hole is cut just large enough to admit a man crawling in on his hands and knees. The hut is now finished and the sleeping bags and provisions are packed inside. The arms and ammunition are generally left outside. After the outside work is finished everybody crawls into the hut and the opening is stopped up from the inside with a plug of snow that has been fitted carefully, and no one is expected to go out until it is time to break camp. The combined heat from the bodies of the inmates, together with the lamp they use, soon raises the temperature, and a degree of comfort is obtained, no matter how cold it may be on the outside. The Alaska *Mining Record* says that a similar degree of warmth is obtained by no other manner of camping in that region. Snow tents that are occupied for a month or more are more elaborate, and are usually built when the snow is six or eight feet deep, as the roof can then be made higher and the hut entered by a covered way and through an ante room in which the dogs sleep and the sleds and other articles are stowed.

When fuel is obtainable a kichen is added to the structure with a fireplace cut out of the solid walls of snow. Fire in such a fireplace has been used for an hour a day for a month. The first heat softens the exposed snow, but the snow afterward changes into solid ice and remains unchanged so long as the temperature in the open air remains below zero. About the middle of April such snow houses are no longer available as they become too damp for comfort, and the usual practice is to dig a hole down into the ground and roof the abode with skins. In such houses some of the prospectors and travellers lived in comfort last winter.—*N. Y. Sun.*

RIGHT ON TIME.

The science of navigation has been reduced to such accuracy that the modern passenger steamer may be expected almost upon the hour. Take, for example, the "*Campania*." In 1893 she made eight trips, and her average voyage was 5 days, 20 hours and 18 minutes. In 1894 she made ten trips, and her average was 5 days, 20 hours and 17 minutes; only one minute less in 1894 than in 1893, in a voyage of 2,770 miles in all sorts of wind and weather. Nor is this exceptional. The "*Teutonic*" made twelve trips in 1893, on an average time of 6 days, 4 hours and 8 minutes. In 1894 she made eleven trips, and her average was just a trifle slower—6 days, 4 hours and 17 minutes. The "*Etruria*" is a little more irregular. Her average in 1893 was 6 days, 6 hours and 47 minutes. In 1894 it was 6 days, 7 hours and 28 minutes. The "*Havel*" made ten trips in 1893, with an average of 7 days, 7 hours and 38 minutes for a distance of 3,080 miles, from the Needles to Fire Island. In 1894 she made nine trips, with an average of 7 days, 7 hours and 21 minutes. The "*Furst Bismarck*" made nine trips in 1893. Her average for the year for a voyage of 3,080 miles was 7 days and 15 minutes. In 1894 she made six trips, and her average was 7 days and 54 minutes. The "*Columbia*" made nine trips in 1893, with an average time of 6 days, 22 hours and 12 minutes. In 1894 she made six trips, with an average of 6 days, 22 hours and 8 minutes. The "*New York*," though not the fastest, has the best record for regularity of any of the Atlantic fleet. Her average time has not varied for years, and she can be expected almost on the minute every voyage. She has crossed the Atlantic more times, and has carried more passengers than any other steamer of her age, and has been more regular about it. The "*New York*" made fourteen trips west bound, in 1893, with an average time of 6 days, 21 hours and 31 minutes. In 1894 she made fifteen trips, west bound, with an average of 6 days 21 hours and 45 minutes. Her sailing distance was 2,770 miles. In 1893 she made thirteen trips, east bound, with an average of 6 days, 20 hours and 39 minutes, which was just one minute faster than her west bound time that year. In 1894 she made fifteen trips, with an average time of 6 days, 20 hours and 24 minutes. Therefore, in crossing the ocean fifty-seven times in both directions, at all seasons of the year, her widest variation for two years was only 1 hour and 21 minutes. The old "*City of Chester*," also of the American line, is another steady boat, her average being 9 days, 15 hours and 11 minutes in 1893 and 9 days, 15 hours and 28 minutes in 1894.—*Scientific American.*

WHY WE COOK FOOD.

It would be absurd, in the face of the tempting viands daily placed before us, to say that food would be just as well uncooked. Yet to render food more palatable is the least of the reasons for cooking it. Man is endowed with teeth which are suitable for the mastication of both flesh and a vegetable diet; and it would need but a comparatively short time to accustom him to raw food of either description.

Unfortunately, or fortunately, as the case may be, all food has to undergo certain changes before it can be taken into the system as nourishment. Part of these changes take place in the mouth when the food is subdivided by the process of chewing or mastication, and part are made by the action of the juices of the stomach upon the mass.

Nourishment depends upon the completeness with which food is changed by the processes of mastication and digestion. In this modern era, when everything is done with a rush, there is great danger of throwing upon the stomach more work than it can do, by the hasty and inefficient manner in which we chew our food.

Here we perceive the great province of cooking—that of an intermediary agent between an insufficient mastication and an overtaxed stomach. In other words, cooking may be made to serve, to some degree, the purpose of mastication. Potatoes cooked till they are "mealy" need much less time and chewing than those which are boiled hard and "soggy."

On the same principle, the pride of the housewife is in her "light and spongy" bread. It is better than the hard cakes of milled corn and water that were relished in primeval days, because the minute bubbles of air which are incorporated into the bread facilitate its digestion, without the labor of long chewing which the cakes demanded.

Meats and vegetables, upon being properly cooked, lose the covering inside of which the fibres and grains of nutriment are hid, a result which, it is true, may be similarly obtained by mastication. We must not suppose, however, that it is easy to obtain proper results in cooking, or to recognize them when they have been obtained. Because an article of food is palatable and slips into the stomach without effort may be the last of reasons why it should be nutritious and easily taken care of by the stomach.

Indeed, so great are the difficulties in mastering the proper methods of cooking, and so important are such methods to the human economy, that the subject deserves to be treated rather as a science than as an art.—*Youth's Companion.*

AN EARTHQUAKE DETECTOR.

It has become possible to discover an earthquake and to mark its force at a distance of over 7000 miles. This seems to smack of magic, but it is, nevertheless, a scientific fact. Some time ago it was stated as simple truth that the earthquake in Algeria was made known to the scientists in Paris itself while it was actually taking place, by the undulations of certain delicate instruments over a strip of paper. That the movements of the earth could thus transmit themselves almost instantaneously, registering, as it were, across the Mediterranean and nearly the whole of France more quickly than a telegraph message could have been sent, was thought hardly plausible. But it can well be believed now, in view of a recent more marvelous demonstration of the self-registering of an earthquake much further away.

Within an hour from the time it commenced the late earthquake in Japan had revealed itself to the instruments of the Roman College. The oscillations of the earth outlined themselves on a single sheet of paper clearly and distinctly, showing plainly that there were five separate "disturbances" of varying force. Recent scientific reports that have just come from the Japanese Empire confirm the accuracy of the instruments of the Roman College in a most remarkable manner. The practical part of the discovery is that the approach of an earthquake may be told with little chance of error, though it must be confessed that the instruments give no hint of direction, nor do they indicate the starting point.

Instruments of this character were at Nicolaieff and Charkow, cities in the central part of Russia, and here the Japanese earthquake mentioned was registered even more plainly, the distance in this case from its seat being fully 4500 miles. The instruments in these towns were carefully watched at this time and they were seen to oscillate and mark the tremblings of the earth for over an hour.

One of the most remarkable of modern inventions, indeed, is this seismograph, which was invented by Bertelli, the "Father of Earthquakes." The most valuable evidence of its practical benefit to mankind was in 1883, when the sensitive machine gave warning of an eruption of Mount Etna. Up to this time, however, it has only been valuable for foretelling shocks comparatively near at hand. The long-distance instances recorded above are the first in the history of the seismograph.—*New York World.*

"BUILDING" A BOOK.

"ALTHOUGH we are apt to speak of the 'writing' or the 'making' of a book, rather than of its 'building,' each of these is a distinct operation; and when a book, first written, then made, is finally ready it has been built as truly as a house or a ship is built. It has demanded an equal amount of careful planning, skilled labor, and close attention to the thousand details that go to the making of a completed whole." With these words Kirk Munroe begins an exceedingly interesting and valuable article on "The Building of a Book" in *Harper's Round Table* for August 6th. Himself a successful author of tales of adventure, Mr. Munroe is enabled by his own experience to speak with confidence upon such topics as authorship, the training that fits one for the profession of letters, the selection of a subject for a projected work, the preparation of the manuscript, and so on to the moment when "the precious manuscript is put into a box and sent off to a publisher." At that point in the narration the fund of Mr. Munroe's varied experience is still farther drawn upon, and we find him examining the newly arrived manuscript from the publisher's point of view. For the purposes of this article of course the book is accepted, the questions of royalty and copyright and such matters are adjusted, and we are led onward through composing-room, press-room, and bindery, with entertaining descriptions of the mechanical processes that precede publication.

Naturally, the most quotable portions of the article are those relating to the creative period—as where Mr. Munroe says: "So every one, except those who know, imagines book-writing to be so easy that most of those who desire to earn a livelihood without very hard work try their hands at it. The girl of brains and education, thrown upon her own resources, decides to become an author; and, after a desperate struggle, fails because she has no real experiences to draw from. The sea-captain who is too old to follow his chosen profession, but must still make a living, and is brimful of experience and adventures, decides to become an author. When he, too, meets with failure, he blames everybody and everything except himself, and rarely discovers that the reason he cannot become a successful author at his time of life is because he has not been trained to the business, and does not know how to write."

THE TEMPERATURE UNDER US.

Beneath the peninsula of Lower Michigan there are brines and sheets of mineral water lying in basin form, and very rich in salts, bromides, etc., and of great medical and commercial value. They have been reached by numerous wells, which run down to about 3000 feet near the centre of the basin, as at Alma and Bay City. The water comes up from the bottom of these wells hot (over 90 degrees), showing a decidedly more rapid increase in temperature than in the copper mines. But the famous Comstock lode, where fabulous wealth lured the miners on, showed perhaps the most rapid increase in temperature that man has ever dared to face. It was, however, doubtless due to the action of hot water rising from still greater depths—probably the same waters that deposited the silver ores—still at work.

In the mines of this region the miners, naked as savages, reeking with perspiration, drinking pailful after pailful of ice water, (twenty tons of ice, or, in another case, ninety-five pounds per man, were used each day), could labor but ten minutes at the drift (in imminent danger of being scalded by striking a stream of hot water) before being overcome by the heat and reeling to a cooler place. Fainting, delirium, even death, have been the effect of the reaction on coming to the surface. Verily, the Cuban proverb that a Yankee would be found to go after a sack of coffee though it were at the gates of hell, was not far from the literal truth. However, the rate of increase of temperature may vary, all indications thus agree that less than ten miles below us a red heat is attained, and within twenty a white heat. Think of it! Ten miles below us it is red hot. Ten miles above us we have the pitiless cold, far below zero, of interplanetary space. To what a narrow zone of delicately balanced temperature is life confined!—*The Popular Science Monthly.*

SILK UNDERWEAR.

Some years ago, a child, feeble from its birth and the object of the tenderest solicitude on the part of its friends, was, on the advice of a specialist, put into all-wool garments. From underwear to cloak, everything was of pure wool. The plan had worked well for some children, but in this case the little one rapidly declined in health and spirits until its friends were alarmed. Finally an elderly visitor suggested clothing the child in silk. She said that after years of invalidism she had found pure silk garments a most agreeable and healthful change. She made this discovery by accident. Being taken with a heavy chill, there was nothing in the way of wraps available but an enormous old-fashioned shawl of white crepe and a silk patchwork quilt. Being wrapped in these, the sensation of warmth and electric glow came to her almost immediately. As she was subject to these attacks, it occurred to her that the silk might have something to do with the almost instant relief. Time after time she tried the experiment on herself and members of her family, with the most surprising results.

On her advice the little one was provided with silk garments. Her knitted underwear was changed only every other day, being worn constantly day and night. Petticoats, waists and dresses of soft silk were worn, and within ten days the improvement in the little one's condition was remarked by every one.

Several sick persons have been similarly treated with the happiest results. Of course, this may not answer for every one, but when there is a long continued stage of feebleness, when ordinary remedies seem ineffective, it is well worth while to resort to out-of-the-way means to bring about the desired change. There are persons whose temperaments seem to indicate a demand for unusual healing methods. And for these the rule of average is not only absolutely without sense, but sometimes injurious in the extreme.—*New York Ledger.*

HINTS ON FOOD.

It has been demonstrated over and over again that man cannot live on a diet composed of any one of the alimentary principles. Whenever the attempt has been made to support life on any one of them, such as albumen alone, or sugar or starch alone, or simple gelatine, the result has been a practical starvation. An experimenter managed to support life for ten days on a diet composed entirely of albumen, derived from bullock's blood and water. Symptoms of an alarming nature soon showed themselves, and at the end of ten days he was obliged to desist. Attempts of a less rigid kind also terminated in a similar way; and in those cases where life had been supported entirely upon lean meat or upon cheese the health has quickly deteriorated. In some conditions of the constitution, such as diabetes, it becomes necessary to deprive the patient of carbohydrates, because of his inability to assimilate them; and only those who have themselves suffered or have closely watched the sufferings of others can be aware of the misery which a restricted diet of this kind entails on the sufferer, and the terrible longing for the forbidden food. In the early days of his existence man is dependent entirely on one article of diet, viz., milk, and it is a remarkable and most instructive fact that milk contains an admixture of all the alimentary principles we have enumerated—the albuminates, carbohydrates, fat, water and salts. Milk may, therefore, be regarded as a typical food. If milk is allowed to stand, the cream rises to the top, and may be skimmed off. This is the fatty constituent of milk. If to the skimmed milk some rennet be added, the casein will coagulate and can be separated as curd. This is the albuminate or nitrogenous constituent of milk. The fluid left after the coagulation of the casein, which is known as whey, contains the sugar of milk, or lactin, which is the carbohydrate constituent, as well as the salts and most of the water. Roughly speaking, therefore, butter, is almost pure fat, cheese is almost purely albuminous, and whey is the vehicle of the sugar and salts.—*Cassell's Family Physician.*

THE END OF ALL THINGS.

"TAIL-PIECE" This title Hogarth, the celebrated English painter, gave to his last work. Grouped in an ingenious manner, he painted the following list to represent the end of all things; a broken bottle; the butt end of an old musket; an old broom worn to the stump; a bow unstrung; a crown tumbled to pieces; towers in ruins; a cracked bell; the sign-post of an inn, called the "World's End," falling down; the moon in her wane; a gibbet falling, the body gone, and the chains which held it dropping down; the map of the globe burning; Phœbus and his horses lying dead in the clouds; a vessel wrecked; Time with his hour glass and scythe broken; a tobacco-pipe with the last whiff of smoke going out; a play-book opened, with the *exeunt omnes* stamped in the corner; a statute of bankruptcy taken out against nature; and an empty purse.

Hogarth reviewed this work with a sad troubled countenance. Alas something lacks. Nothing is wanted but this, and taking up his palette, he broke it and the brushes, and then with his pencil sketched the remains. "Finis, 'tis done!" he cried. It is said that he never took up the palette again, and a month later died.—*Harper's Round Table.*

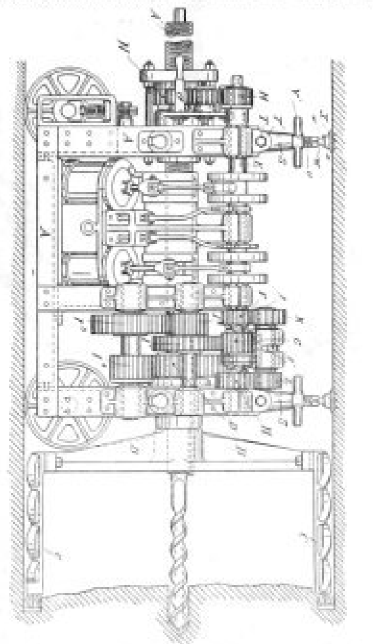
WHERE THE PRESIDENTS ARE BURIED.

George Washington is buried at Mount Vernon, Virginia; John Adams at Quincy, Massachusetts; Thomas Jefferson at Monticello, Virginia; James Madison at Montpelier, Virginia, James Monroe at Richmond, Virginia; John Quincy Adams at Quincy, Massachusetts; Andrew Jackson at Nashville, Tennessee; Martin Van Buren at Kinderhook, New York; William Henry Harrison at North Bend, Ohio; John Tyler at Richmond, Virginia; James K. Polk at Nashville, Tennessee; Zachary Taylor at Louisville, Kentucky; Millard Fillmore at Buffalo, New York; Franklin Pierce at Concord, New Hampshire; James Buchanan near Lancaster, Pennsylvania; Abraham Lincoln at Springfield, Illinois; Andrew Johnson at Greenville, Tennessee; Ulysses S. Grant at Riverside Park, New York; Rutherford B. Hayes at Columbus, Ohio; James A. Garfield at Cleveland, Ohio; Chester A. Arthur at Albany, New York.—August *Ladies' Home Journal*

NEW INVENTIONS

TUNNELING MACHINE.

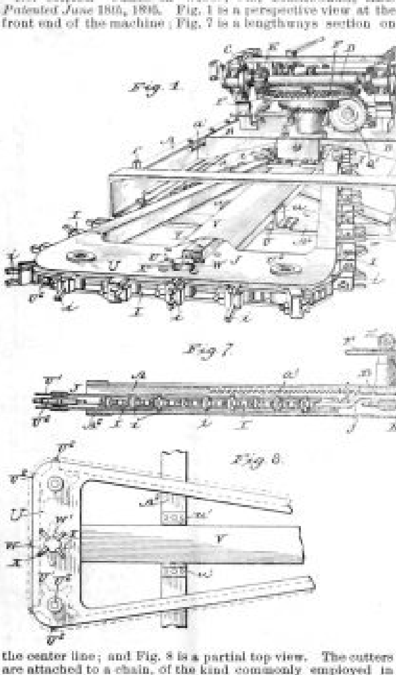
No. 540,396. THOMAS W. FRY, CHICAGO, ILL. *Patented June 4th, 1895.* This invention consists of improvements in the tunneling machine, which is known as the "Stanley Header," and which is described in THE COLLIERY ENGINEER for Dec. 1893. These improvements consist in the addition of gearing, whereby the speed of the revolving cutter head *B*, may be changed to suit the requirements of rock having hard streaks in it, etc. The engine pinion *F*, drives a train of reducing gears *K*, *L* and *H*. The pinion *G*, may be clutched to either *F* for high speed, or to *H* for slow speed.



The wheel *D*, drives the main spindle by means of a feather. The spindle is fed foward by means of a nut wheel *N*. This wheel is connected by a train of three spur gears to the engine pinion *M*, in such a manner that the motion may be reversed at any time, by the handle *O'*. Thus the driving wheel *G* may be thrown out of gear if desired, and the feed nut be turned, either way, at any speed. The jacks *S* are hinged as shown, so that they resist the twisting tendency of the machine, yet may be readily turned down, to facilitate moving forward or back.

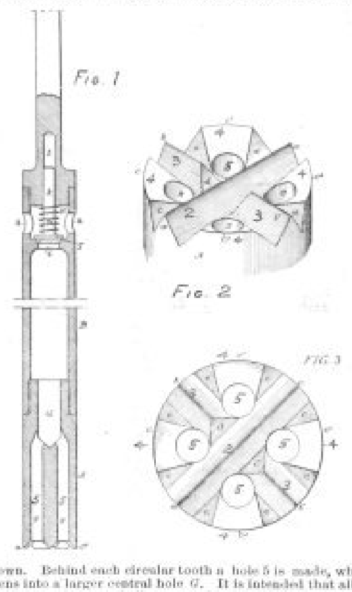
MINING MACHINE.

No. 541,184. JAMES A. WIGGS, JR., BIRMINGHAM, ALA. *Patented June 18th, 1895.* Fig. 1 is a perspective view at the front end of the machine; Fig. 7 is a lengthways section on the center line; and Fig. 8 is a partial top view. The cutters are attached to a chain, of the kind commonly employed in machines of this class, which runs around suitable sprocket wheels at the front corners of the cutting head *U*, and is driven by a sprocket *H* at the rear end of the frame. This sprocket is rotated by means of the gears *F* and *E*, and the engines *C*. The cutting frame is fed forward by means of pinions which engage the racks *a'*, which are secured to the stationary main frame *A*. The feed pinions are driven by means of a train of fast and loose gears which operate in either direction, according to the position given to the clutch lever 3. The cutting frame is guided by means of a central bar *V*, which moves between the clips *u*, on the front cross girt *A²*. It is also guided in the coal by means of a block *Y*, which enters into a narrow groove above the main kerf, which is cut by means of the small cutter head *X*. This head is rotated by means of a sprocket wheel between the upper and lower plates, which engages the main cutter chain.



ROCK DRILL.

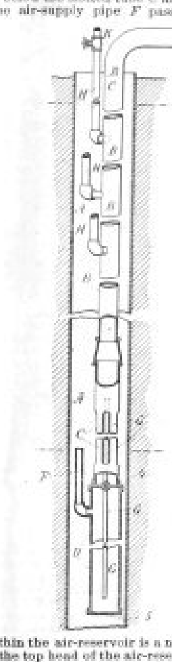
No. 542,542. THOMAS SYMONDS, LEOMINSTER, MASS. *Patented July 9th, 1892.* Fig. 1 is a lengthways section of the drill; Fig. 2 is a perspective view, on a larger scale; and Fig. 3 is an end view showing the plan of the cutting edges. The edge 2 extends across the face of the bit, and the edges 3 extend at right angles with 2, but do not intersect with it. The circular edges 4 are sloped backward and downward as shown. Behind each circular tooth a hole 5 is made, which opens into a larger central hole *G*. It is intended that all of the chips and water shall pass up through these holes while drilling. At the upper end of the drill tube *E*, is a valve *I*, which opens during the down stroke, and closes during the upstroke of the drill. Thus the drill acts like a pump to suck up the borings and water, and to drive them up through the bit and drill tube.



PNEUMATIC PUMP.

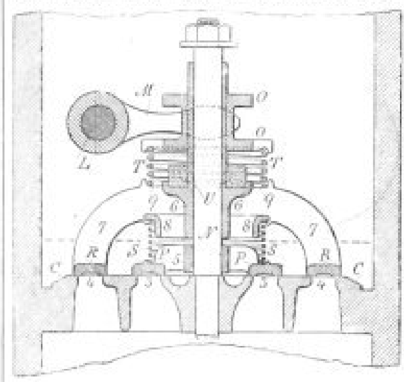
No 542, 622. JAMES E. BACON, RICHMOND, VA. *Patented July 16th 1895.* The well A may be of any desired character. The same is usually bored and provided with a lining-tube extending down to the rock, and the uptake or discharge pipe B is of a size adapted to the volume of liquid to be discharged, and the lower end of this uptake-pipe is slotted, as represented, and below the slotted tube *C* an air-reservoir *D* is provided. The air-supply pipe *F* passes down to the reservoir *D*. Within the air-reservoir is a nozzle or tube *G*, passing through the top head of the air-reservoir and rising above the inlet-openings in the pipe *C*. The pressure of the air in starting the well must be sufficient to drive the water out of the reservoir *D*, and then the air will discharge the water rapidly from the nozzle *G* and start the well suddenly by the upward movement given to the column of water in the uptake-pipe, and in so doing any sediment or foreign materials in the well will be rapidly carried out; and the pressure afterward necessary to continue the flow of water in the uptake-pipe will be but little in excess of the weight of the column in the well above the upper end of the nozzle *G*.

In some instances it is advantageous to supply air to the uptake-pipe at one or more places above the air-reservoir *D*, and with this object in view pipes *H* are provided with elbows screwed into the uptake-pipe *B* at several places, and these separate tubes extend to the top of the well and are provided with valves *K* to regulate the admission of air under pressure, so that its discharge into the uptake-pipe may aerate the water to the extent necessary to raise is to the required place of delivery.



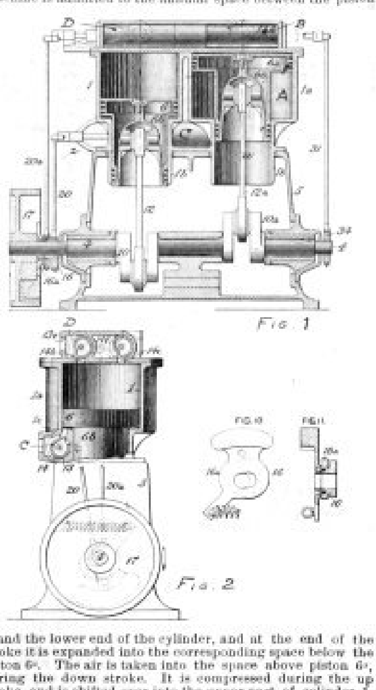
PUMP VALVE.

No. 542,083. GEORGE DE LAVAL, WARREN, MASS. *Patented July 2nd, 1895.* This improved valve is made in two parts *R* and *P*, which are really independent valves. Both are annular in form, and both slide up and down upon the stem *N*. The opening of the inner valve *P*, is resisted by the spring *S*, which bears against the ring 8 on the arms of the outer valve *R*. This spring is made light, so that *P* can open very easily. The outer valve is held down by a spring *T*, which bears against a moveable collar *O*. This collar is moved vertically by an arm *M*, which is connected to the piston rod or plunger, so that it moves in unison therewith. As the plunger begins its stroke, the arm *M* rises and takes the pressure nearly off the valves. The resistance of the valves to the passage of water is thus reduced. As the plunger nears the end of its stroke, the arm *M* descends and compresses the spring *T*, thus urging the large valve to its seat. The smaller valve *P* remains open until the stroke is finished, but being quite small, it takes its seat without perceptible shock or jar. Thus the advantages of a positively moving valve are attained, without positively arresting the current of water, allowing the momentum to be spent in useful work instead of useless shocks.



AIR COMPRESSOR.

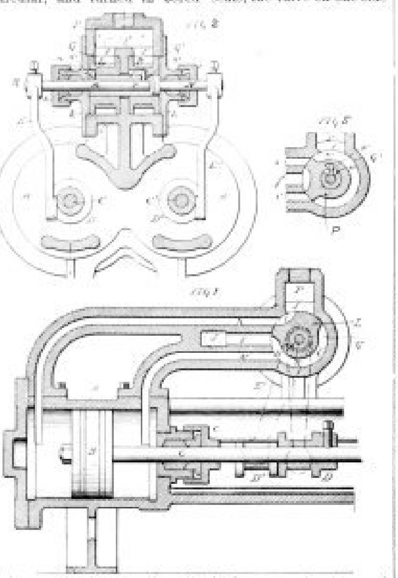
No. 542,426. FRANCIS M. RITES, PITTSBURGH, PENNA. *Patented July 9th, 1895.* Fig. 1 is a vertical section of a double compressor; Fig. 2 is a vertical cross-section; Figs. 10 and 11 show the construction of the governor eccentric. The cylinders are different in size, 1 being the high pressure, and *A* the low pressure cylinder. The steam to drive the machine is admitted to the annular space between the piston 6, and the lower end of the cylinder, and at the end of the stroke it is expanded into the corresponding space below the piston 6ᵃ. The air is taken into the space above piston 6ᵃ, during the down stroke. It is compressed during the up stroke, and is shifted over into the upper part of cylinder 1, where the compression is completed. Thus, the steam is used expansively, and the air is compressed in two opera-



tions. The inlet air valve *B* is moved positively by the eccentric 34 and rod 31. The air discharge valve *D* is moved by the eccentric 16², and rod 20², and the steam valve *C*, which controls both cylinders, is moved by the eccentric 16 and rod 20. As shown in Fig. 10, both eccentrics are made in one piece, but are on opposite sides of the shaft, so that when they are shifted by the governor 17, the throw of one will decrease exactly as that of the other increases, and vice versa. Thus, when the governor alters the point of cut-off of the steam, it simultaneously opens the discharge valve earlier, and so adjusts the work done in the compressor cylinder to the power exerted in the steam cylinder. Both compressor pistons are coupled by rods 12 and 12² to double cranks, which are exactly opposite to each other. By the construction shown, a very compact machine is secured, which is capable of operating at high speed.

DUPLEX PUMP.

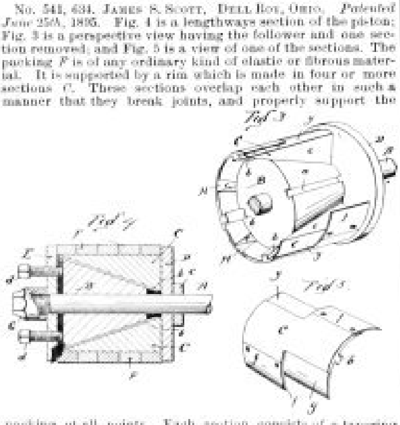
No. 540,898. John W. Booth, Philadelphia, Pa. *Patented June 11th, 1895.* Fig. 1 is a vertical section through one of the cylinders and its corresponding valve chest; Fig. 2 is a cross section through the valve chest; and Fig. 5 is a cross section of the valve on the opposite side of the pump. Both steam cylinders have ports which extend to the steam chest *F*, as shown. This steam chest would, of course, be located closer to the cylinders, in actual practice. Both valves are circular, and turned in bored seats, the valve on one side



being moved by a lever *E* or *E'* which engages the piston rod on the other side of the pump. The shaft *E* extends into the hollow body of the shaft *N*, and operates the valve *P*, by means of a pin *p*, which projects through a slot in the shaft *N*. The valve *L* is moved by the shaft *N* and lever *E'*. The steam valves *L* and *P* are so constructed, that they must move in opposite directions to admit steam to the corresponding ends of the cylinders, because the pistons are moving in opposite directions, at the moment that either valve is reversed. The valves are easily accessible, and the working parts are very few in number.

PUMP PISTON.

No. 541, 634. James S. Scott, Dell Roy, Ohio. *Patented June 25th, 1895.* Fig. 4 is a lengthways section of the piston; Fig. 3 is a perspective view having the follower and one section removed; and Fig. 5 is a view of one of the sections. The packing *F* is of any ordinary kind of elastic or fibrous material. It is supported by a rim which is made in four or more sections *C*. These sections overlap each other in such a manner that they break joints, and properly support the



packing at all points. Each section consists of a tapering block which fits upon the surface of the cone *B*, and has a tongue or rib which slides in a dovetailed groove *a* in the cone. The ends of the sections are gripped between the follower *E* and the head *D*, by means of the nut *G*. When it is desired to expand the packing, the nut is eased off a little, then the cone *B* is forced forward by the set screws *d*, and *G* is again tightened, thus securing all parts firmly in place.

METHOD OF SINKING SHAFTS.

No 542, 765. Friedrich Honigmann, Aix La Chapelle, Germany. *Patented July 16, 1895.* This method of sinking bore-holes and shafts in water-logged ground or quicksand differs mainly from the methods heretofore employed, in that the lining of the bore-holes with tubes, or of shafts with masonry, is not done during the boring, but only after the bore-holes and shafts have been carried down to the firm ground which it is desired to reach. To enable this to be done, a resistance is offered by artificial means to the inrush of the fluid soil, to prevent the caving in of the sides of the hole during the progress of the boring. For the purpose of this resistance the hole is filled with liquid having a head considerably exceeding the natural pressure of the water in the water-logged ground through which the hole passes, and the liquid is composed of a mixture of clay and water or similiar materials, which brings the specific gravity of the liquid up to 1.2. The object of using such a semi-liquid is to increase the pressure of the internal column of liquid against the sides of the bore-hole or shaft, and more especially to render the sides of the boring water-tight down to a certain depth by the penetration of the clayey materials, and thus to prevent the escape of water to waste, from the interior of the boring into the surrounding soil. *A*, Figs. 1 and 2, designates a guiding-tube or filling-tube; *B*, the filled-in water. *C*, Figs. 1, 2, and 3, designates the clay infiltered into the wall of the hole by the water. *D*, Fig. 2, designates the bottom piece below

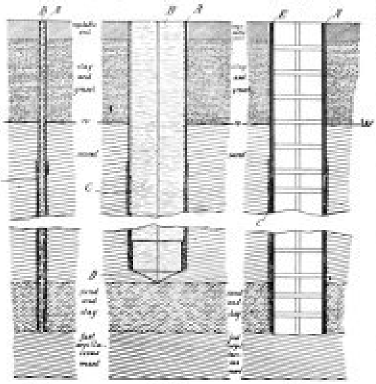


Fig. 1. Fig. 2. Fig. 3.

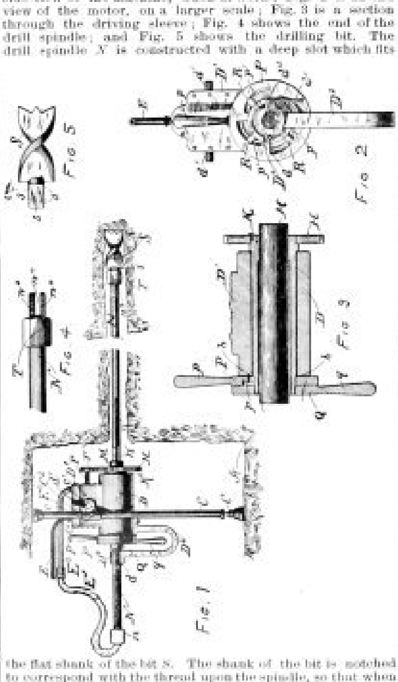
the tube *A*. *E*, Fig. 3, designates the complete lining. *w w* indicate the water-level. The operation is as follows: In the case of bore-holes of small size, such as are shown in Fig. 1, and in Fig. 2, the tube *A*, which may be called a "filling tube," is first sunk according to the method heretofore in use for a depth of from ten to twenty yards below the water-level for the purpose of keeping out the upper strata of loose ground and gravel, and of thus obtaining a firm guidance for the boring tools, &c., during the subsequent boring operation. When this work is completed, then the means above described are resorted to. For this purpose the tubing *A* of the hole, or the lining *A* of the shaft, is carried up as high as possible above the natural water-level *w w* and is filled with water. The specific gravity of the liquid is brought up to about 1.2 by mixing with clay or similiar material. While continually attending to these precautions, the sinking of the bore-hole or shaft is proceeded with by means of the usual boring apparatus, until the firm ground is reached, where the hole or shaft is to end. Then, but only after the boring has been completed, the lining-tubes or the shaft-lining *E* is inserted and carried down to the bottom of the hole, and thus the external soil is kept out.

COAL DRILL.

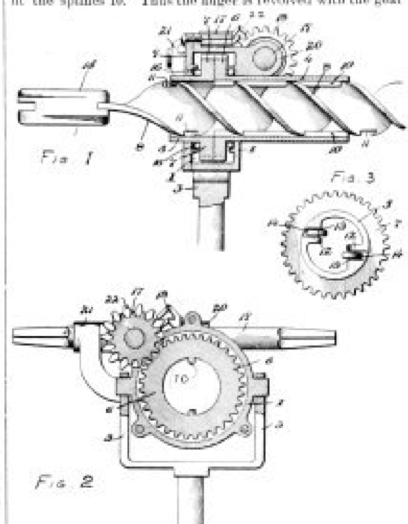
No. 542, 153. Robert H. Elliott and John B. Carrington, Birmingham, Ala. *Patented July 2, 1895.* Fig. 1 is a side view of the machine, when at work; Fig. 2 is an end view of the motor, on a larger scale; Fig. 3 is a section through the driving sleeve; Fig. 4 shows the end of the drill spindle; and Fig. 5 shows the drilling bit. The drill spindle *N* is constructed with a deep slot which fits



the flat shank of the bit *S*. The shank of the bit is notched to correspond with the thread upon the spindle, so that when the nut *T*, is screwed forward it secures the bit firmly in place. The spindle is tubular, and the exhaust air from the motor *D'*, is conducted by the hose *E'* to the rear end of it. The air passes through the spindle and escapes from holes near the bit, and serves to blow the chips and dirt out of the hole. The spindle is fed forward by means of the hinged half nut *D²*, which can be opened and released when desired. It is turned by the motor *D'*, gears *F'*, *H*, and the sleeve *M*. The spindle is turned by means of a feather in the sleeve *M* which engages the keyway shown. The connection between the sleeves *M* and *K* is frictional, and can be adjusted so as to slip, at any certain degree of resistance. The rear end of *K* carries several blocks *R*, see Fig. 2, which can be driven inward against the sleeve *M*, by means of the cam plate *P*. By turning *P* to the right, the blocks may be made to sieze *M* with sufficient force to drive the drill. If the bit encounters anything too hard to cut, *M* will slip and stand still, while the motor continues to turn. The cam plate is clamped in any position by means of the large circular nut *Q*.

COAL DRILL.

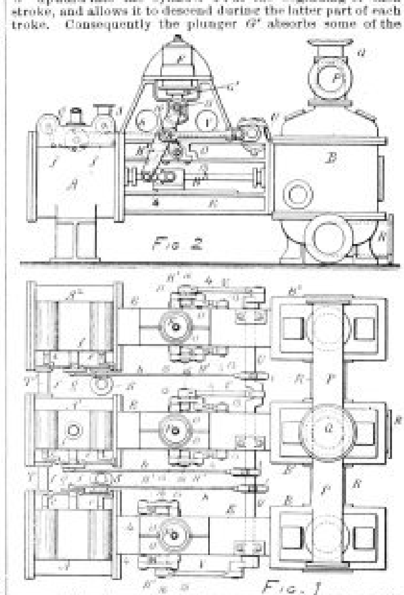
No. 539,491. John T. Snyder, Luzerne, Pa. *Patented May 21st, 1895.* Fig. 1 is a section along the axis of the machine; Fig. 2 is a cross section through the wheel 6; and Fig. 3 is a front end view of the wheel 7. In this machine the usual feed screw is discarded, and the spiral blade of the auger is used to secure a proper feed motion. The main driving gear 6 is constructed with a long tubular hub 4, having two splines 10, cast or otherwise secured to the inside of the bore. Each spiral of the auger is notched, as at 11, to fit the splines 10. Thus the auger is revolved with the gear



6, the central part of the bore remaining open. The feed motion is produced by the revolution of the gear 7, at a little slower speed than that of the wheel 6. This is accomplished by making the number of teeth in 7, one or two more than in 6. Both wheels are driven by the same pinion 17, and the bevel gears 22 and 18. The crank shaft 19 is fitted for a crank at each end. The feed wheel 7 is fitted with rollers 14 which engage the auger blades, and feed it forward with little friction. Both wheels run on ball bearings 16, so that the machine operates very easily. The working parts are mounted on trunnions, in a yoke 3, in the ordinary manner.

PUMPING ENGINE.

No. 542,084. George DeLaval, Warren, Mass. *Patented July 2nd, 1895.* Fig. 1 is a top plan of a triple pump; and Fig. 2 is a side view of the same. The piston rod of each pump is connected by a link 4, to a lever *H'*, which is attached at 15 to a plunger *G'*. The lever *H'* is suspended on a pin 16, upon a crank *O*. The crank together with the upper half of the lever, forms a toggle, which forces the plunger *G'* upward into the cylinder *F*, at the beginning of each stroke, and allows it to descend during the latter part of each troke. Consequently the plunger *G'* absorbs some of the



power of the steam, which is in excess at the beginning of the stroke, and gives it out again during the latter part, thus equalizing the driving force. The cylinder *F* may by supplied with pressure, or it may contain only a charge of air, which is alternately compressed and expanded. The form of connection shown ensures that the pump will always make full strokes. The steam valves are moved by eccentrics *i*, upon the shaft *U*, which is revolved by means of rods *V* connecting the levers *H'* to the cranks shown. No fly wheel is necessary.

The Colliery Engineer

AND

METAL MINER.

VOL. XVI.—NO. 3. SCRANTON, PA., OCTOBER, 1895. WITH WHICH IS COMBINED THE MINING HERALD.

Written for THE COLLIERY ENGINEER AND METAL MINER.

PROSPECTING FOR PLACER GOLD.

A NOVEL AND GIGANTIC SCHEME IN CLEAR CREEK CANYON, COLORADO.

Showing how Gold is Obtained on a Large Scale from Gold Bearing Gravels under Favorable Conditions.

(By Prof. Arthur Lakes, Golden, Colo.)

Having given an account in the September issue of THE COLLIERY ENGINEER AND METAL MINER of the general plan of the Roscoe placer scheme, describing the locality, the character of the undertaking and its aim, we will proceed to give a detailed account of the construction and of the progress of the work from its inception to the present. Two things had to be done at the outset; one was to build a big ditch or flume to carry off the water of the river and leave the river bed dry for a space of about half a mile or more; the other to get a sufficient head of water to work the nozzles and sand pumps at the places chosen for excavation.

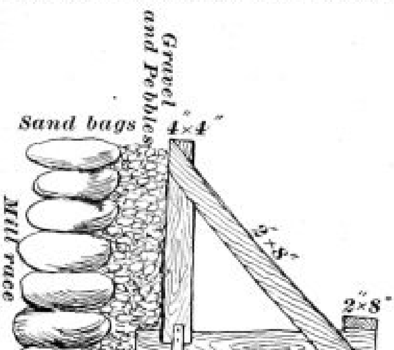


FIG. 1.—STRUCTURE OF EMBANKMENT.

Both works were begun simultaneously and whilst one party was making the flume to carry off the water another was laying pipes to bring on the water.

Beginning then with the great flume. By a natural widening of the bank on one side of the river the water was thrown to the other side and compressed into a comparatively narrow channel, thus affording a sort of natural flume to start with to aid in diverting the water from the coveted area of half a mile of river bottom. Starting with this natural advantage an artificial flume had to be built by sacks filled with sand placed along the natural flume so as temporarily to keep back the water till a more substantial triangular dam of timber partitions filled with stones could be built. Thus a "ground flume" was constructed as shown in figures 1 and 2. First a pile of bags filled with sand next the mill race, then a frame work of timber with triangular partitions set against it, and the intervals between the partitions filled with stones and pebbles faced or riprapped on the outer side with heavier stones, until the nature of the ground required and admitted of a flume of wholly sawn timber being constructed.

DESCRIPTION OF FLUME.

This flume that carries the river is 10 feet wide by 6½ feet high and 2,600 feet long. It averages about 22 000 gallons per second. The "bents" are made 4"x8" and are 16 feet long, with brace on outer side at an angle of 11½ degrees; the braces are made 2"x8" and are 5 feet long bolted to the 4" x 8" sill and upright post. Flooring 4" thick, boards 12" wide, length 16 feet. As the flume is not straight but curves, the curving on the floor is done by elevating the outside of the flume to the degree of curve like on a railway curve, which makes the water run level, the grade is 1½ inches in 16 feet. This grade is required by curving a flume and when the flume is straight the grade is ½ inch to 16 feet. The angle at which floor is cut for joining is not over 30 degrees, sides are made of boards 2" by 12" wide.

Next to get sufficient head and water power for the nozzles. To do this they had to go two miles up the river to a point where the descent of the stream was somewhat steep and rapid. There they built an intake flume of wood 6 feet wide and 4 feet deep and 800 feet long to a penstock or sand-box which is connected with an Allen wooden stave pipe 48 inches diameter. Before entering the penstock the water passes through a screen or iron grating or sand-box which catches the coarse rubbish floating in the water, and the overflow passes through gates on the south side. The main current passes into the penstock which is 8 x 8 ft. wide and 16 feet high. At the bottom is a well which collects any debris so the water passes clean and clear through the penstock into the 48 inch Allen pipe.

FIG. 2.—MAKING EMBANKMENT OF FLUME.

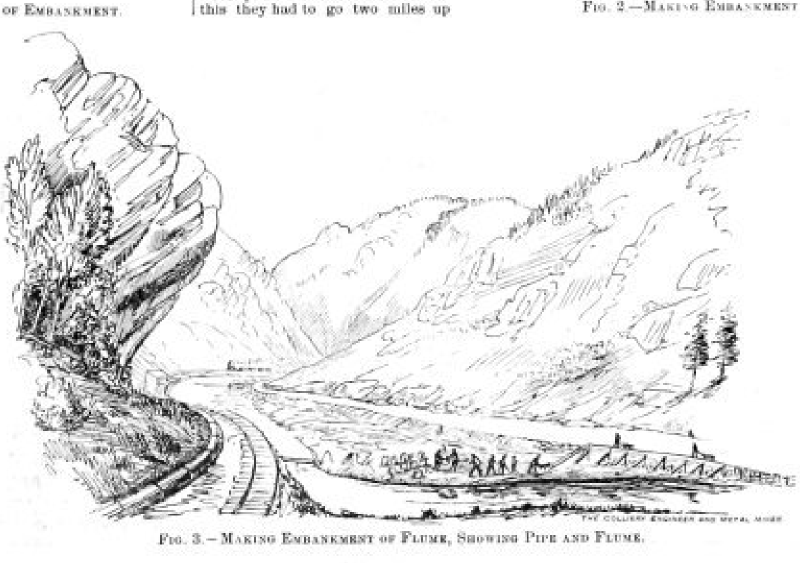

FIG. 3.—MAKING EMBANKMENT OF FLUME, SHOWING PIPE AND FLUME.

DESCRIPTION OF THE ALLEN STAVE PIPE.

This pipe is a modern invention by Mr. C. P. Allen, Chief Engineer of the Citizens Water Company in Denver. It originated in the problem of having to bring water in large volume a distance of many miles to Denver, in pipes which demanded unusually large diameter, and which if constructed of the ordinary metal, or earthenware material would have entailed very great expense. Mr. Allen, therefore, had recourse to the cheapest material on hand, viz: wood, and the now celebrated Allen stave pipe was evolved, which has stood both the effects of time and pressure. The pipe is made of staves of pine, banded with steel hoops. The staves may be from 2 to 8 inches wide and of any length, from 12 to 24 feet, the thickness from 1 to 2½ inches according to diameter and pressure. The flat sides are dressed to true circular lines and the edges are made radial to those circles, a certain number forming a circular ring composing the shell of the pipe. The staves are cut off squarely at the ends and have a saw-kerf cut across the face of each end, ¾" inch deep, for inserting a metallic tongue 1½ inches wide 2½ inches longer than the width of the stave.

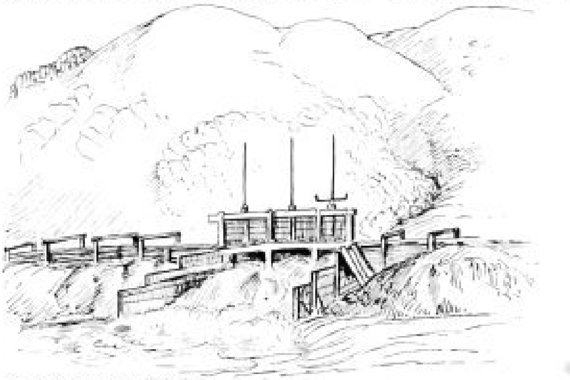

Fig. 4.—Floodgate Sluice on the Flume.

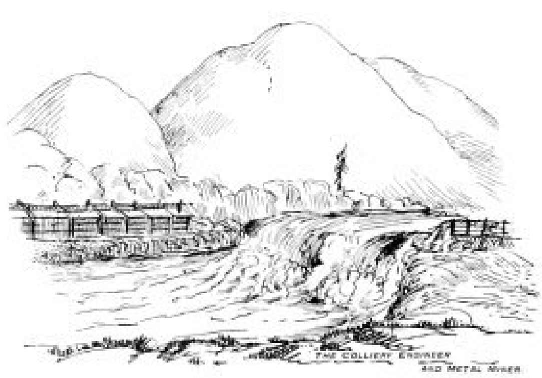

Fig. 5.—A Bad Break in Flume After a Freshet.

This slot is so made that the tongue will fit into it closely by tapping with a hammer. In construction all staves must break joints and although all the joints of one section are brought within a space of 2½ to 3 feet (over which 2 to 4 extra bands are distributed) no two adjoining joints are placed nearer each other than 6 inches. This insures great strength of joint and the overlapping of the metallic tongue into the staves on each side make a perfect butt joint.

The bands are of round steel with a head at one end and a thread 3 to 5 inches long at the other, the two coming together in a malleable iron shoe of peculiar make, fitted to the form of the pipe, and so arranged as to enable the staves to be drawn tightly together. When these bands are spaced for high pressure, the power of th numerous nuts turned up at moderate tension is sufficient to crush the wood and collapse it if carelessly exerted. The effect of this construction when the bands are at proper tension is to produce a stiff, hollow beam of wood of enormous strength.

The pipe is constructed in the trench where it is to lie which is made wide enough at the bottom to give standing room for the pipe layers on either side.

Two U shaped outside forms are first placed in the bottom of the trench 10 to 12 feet apart, and the bottom staves with the tongues placed in the ends, are placed loosely in position to form the bottom half of the pipe, inside which is then placed a ring of proper size.

The remaining staves are added, the bands are put in position, plac d the proper distance apart, and the nuts are tightened up part way. The staves are then coopered out to complete the true circle. When the pipe is round and true, and all the staves drawn up tight, earth is tamped all around the pipe and it is covered over and the trench refilled. Where the pressure is heavy the bands are but two to three inches apart. Gangs of men on a long pipe are placed every 1,500 feet, and

Fig. 7.—Connecting Wood and Iron Pipe.

when working in opposite directions and the gangs meet, coupling of the ends is effected by cutting the staves about ¼ inch longer than the space they are to occupy, and springing them into position, the bands closing all tightly together make the butt joints at the coupling very tight. Soon after the pipe is laid, water is slowly admitted, and the pipe allowed to soak, before the full pressure is applied which stops all minor leaks. The bands are made of mild steel bearing a strain of 70,000 lbs. per square inch. At one end they have a square head of special form, at the other a thread is cut 5 inches long for which distance the rod is upset. These bands are shipped in bundles as straight rods and bent on the ground around wooden tables. They are painted with asphaltum or red oxide.

The shoes are made of malleable iron. The tongues which are used in the butt joints are of strap-iron.

The Allen stave pipe is in use now all over the West for long water work systems, for irrigation and for mining purposes, with much success.

Figs. 7 and 8 show the method of connecting the wood and metal pipe as at Roscoe.

At Roscoe after leaving the penstock, (See Fig. 9) the pipe is buried for a distance of about 100 yards under a stone embankment and passes by a stone arch under the railroad.

Fig. 6.—Penstock and Intake Ditch on Flume.

It emerges from the ground on the other side of the railroad track, and follows the grade of the road the rest of the way close to the track, to its junction with the metal pipe. As this pipe has to withstand great pressure, it is somewhat closely banded, the bands being not more than 1 foot apart, and at places where a joining of the staves took place, extra bands are placed, and still closer togther. Still farther along the pipe with diminishing diameter, the pressure being increased, more bands are placed, and still closer together, sometimes not over 4 inches apart. The pipe is made to grow smaller and smaller in diameter, and is diminished and united on the principle of a telescope, and by this compression greater force and pressure is obtained. The pipe begins at the penstock with a diameter of 48 inches for a distance of 300 feet, then 42" for 400, 38" for 600, 30" for 800, 32" for 600, down by gradation to 22 inches diameter when it connects with the steel pipe, which also in course of its length tapers down to 16 inches. This steel pipe is ½ of a mile long. Another pipe after a certain distance connects with this, forming a double pipe for ½ of a mile, each pipe 12 inches diameter. One of these is for hydraulic giant nozzle purposes for blowing the gravel out of the banks and river bottom, the other to supply the sand pump for forcing or elevating the gravel some 45 feet or more from the bottom of the excavation up into the gravel and goldsluices.

Laying down the Allen pipe took 4 weeks and employed 34 men and cost at the rate of $1 50 per foot. The capacity or pressure of these pipes given at the giant nozzle is 87 lbs. per square inch and will throw a column of water 165 feet high from nozzle 4 inches diameter. With a closed pipe it would give a pressure of 189 lbs.

(TO BE CONTINUED.)

ACETYLENE GAS.

Its Properties and Its Commercial Value.

An exhibition and test of acetylene gas was given in the Board of Trade room in Scranton, Pa., on the evening of September 5th, by the following gentlemen, who represent the "Acetylene Light, Heat and Power Company" of Philadelphia, Pa.: Joseph A. Vincent, Edward C. Naphey, C. C. Adams, F. N. Lewis and Samuel L. Kent.

Through the kindness of the Board of Trade, the exhibition rooms were thrown open to those of the public who are interested in the new artificial light.

After the gentlemen from Philadelphia were introduced to the audience by Mr. D. M. Atherton, the Secretary of the Board of Trade, Mr. Vincent proceeded to explain the properties of acetylene gas, and calcium carbide from which it is obtained, substantially as follows:

"It is a well-known fact that carbon will combine directly with various metals under the influence of heat, and the resulting compounds are called carbides. The carbides of the alkali and alkaline earths, such as potassium, sodium, barium, strontium, and calcium whose oxide is known as lime, have the property of decomposing water upon being brought in contact with it, and thereby forming hydrate oxides of the metal and acetylene gas. Of all these carbides, carbide of calcium is the most interesting because of the low cost of the raw material (lime and coal) and of the commercial value of the residuum or by product (hydrate of lime) which is formed by the subsequent decomposition of the carbide of calcium upon contact with water. The chemical formula for acetylene gas is C_2H_2, which indicates that it is a satura ed hydro-carbon, containing in 100 parts, 92 3 parts of carbon to 7.7 of hydrogen. That such a gas as acetylene existed has long been well-known to the scientific world, but it remained for accidental discovery to learn that its preparation for commercial uses was a possibility. In 1888 Mr. T. L.

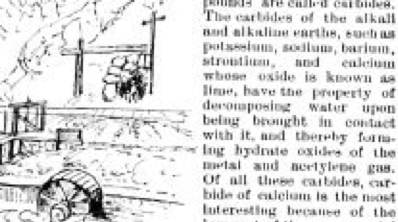

Fig. 8.—Showing Connection With Cast-Iron 24 to 20-Inch Reducer.

Wilson began a series of experiments relating to the reduction of the refactory metallic oxides by carbon under the intense heat of an electrical furnace, and found that lime, baryta, etc, when subjected to this heat were liquefied and formed molten masses which could be brought to ebullition.

An addition of carbon caused decomposition of the oxides, carbon monoxide being formed and driven off while the fused metal instantly with the excess of carbon formed a carbide. Further experiments showed that when a mixture of powdered lime and coke dust was introduced to the furnace, a syrupy mass of pure carbide of calcium was formed, also that this carbide became upon cooling, a dense, crystalline dark brown substance with a metallic fracture of blue or brown, and having a specific gravity of 2.62, and chemical composition represented by the formula $Ca\ C_2$ viz., 62.5 calcium, 37.5 carbon, which evolves a peculiar garlicy odor when exposed to a damp atmosphere, but is odorless in dry. When lumps of it were long exposed to the air the surface absorbed sufficient moisture to become changed to hydrate of lime, a thin layer of which protected the interior from subsequent decomposition.

"Carbide of calcium is now being manufactured at Spray, N. C., at a cost of about $30.00 per ton. Experiments have demonstrated that 87½ lbs. of lime and 56¼ lbs. of carbon will produce 100 lbs. of carbide of calcium, and 43¾ lbs. of carbon monoxide; and 100 lbs. of carbide of calcium with 56¼ lbs of water will produce 115.62 lbs. of slacked lime, and 40.62 lbs. of acetylene. The carbon monoxide is equal to 18¾ lbs. of carbon and 25 lbs. of oxygen. The above formulae will give some understanding as to the chemical reaction.

"Carbide of calcium is not inflammable, and can be exposed to a temperature of a blast furnace without melting, but when placed in water or its vapors, each pound of it will generate over 5½ cubic feet, (5.892) of acetylene gas, having a temperature of 64° F. It may also be decomposed by exposure to snow at a temperature of —24° F. The gas is colorless but makes its presence known by a strong garlicy odor. It is soluble in water equal to the volume of the latter, and can readily be condensed to a liquid form at much less pressure than is required for carbonic acid gas ($C\ O_2$).

"Acetylene gas at 67.27° F. requires a pressure of 39.76 atmospheres to solidify it. Carbonic acid gas, requires a pressure of of 58.84 atmospheres to solidify it, and as this represents the difference between 600 lbs. and 900 lbs. to the square inch, it may readily be seen that it has an important bearing upon the question of safety in handling and use. The carbonic acid gas tubes require a sustaining pressure 50% greater than is necessary for acetylene.

and 1,000 cu. ft. 4.000 candle power; as $1.00 produces in acetylene gas, 25,000 candle power, it would be necessary to sell city gas at 16c. per 1,000 cu. ft. in order to compete with acetylene gas on this basis.

"As there is less gas used, the oxygen of the air is not required to so large an extent in its combustion, and it is demonstrated that the air of a room lighted by this gas is vitiated at the rate of only ⅓ that of ordinary gas. The brilliancy of the acetylene flame would suggest the highest incandescence, but from actual test, it is much cooler than that of an ordinary gas flame. The temperature of an ordinary gas flame is about 1,400° C, but no part of an acetylene flame is higher than 900° C. In fact there is very little difference between the heat of an incandescent electric light and acetylene based upon the same illuminating power. It is apparent from this that in rooms where acetylene gas is used, there will be less danger of over-heating, and the products of combustion will not be so noxious as in rooms lighted with city gas. Another very important point in acetylene, as compared with the ordinary illuminating gas is, that the amount of carbon dioxide and water vapor produced is very small. A 5 foot burner of ordinary gas produces an amount of carbon dioxide that would equal the exhalations of about 18 adults, while the acetylene would equal the exhalations of about 3 adults.

"To sum up, acetylene gas is easily detected by its odor. It gives more light, throws out less heat, consumes less oxygen and can be produced at much less cost. It is capable of being stored as a solid, in the shape of carbide, as a liquid or as a gas. It may be shipped long distances as carbide or as gas manufactured from it, and as a liquid may be applied to all purposes of isolated lighting, especially as in railroads, street-cars, carriages, bicycles, steam-ships or sailing-vessels, street lighting and individual houses, or it may be used to enrich the gas in the city houses, stores or manufactories, its application for the latter purpose permitting the manufacture of a gas sufficiently low priced to be used for heating or fuel purposes.

"With all these facts in view it requires no gift of prophecy to foretell the early substitution of acetylene or all other forms of illuminating gas as well as electric lighting, and while it will work a revolution in the methods of lighting, it is bound from its very simplicity, safety, effectiveness and low cost, to work as well, a great revolution in all manufacturing processes. The city or town which can supply its street lamp from the tank concealed in its post, will not be slow in doing away with costly mains and connections. The small manufacturer will soon learn the utility of cleaner and cheaper gas fuel. The suburban resident may discard his dangerous oil or gasoline apparatus, and the city householder may laugh at gas corporations' exactions when he divorces his house from the meter and stores his six months' gas supply in his cellar closet."

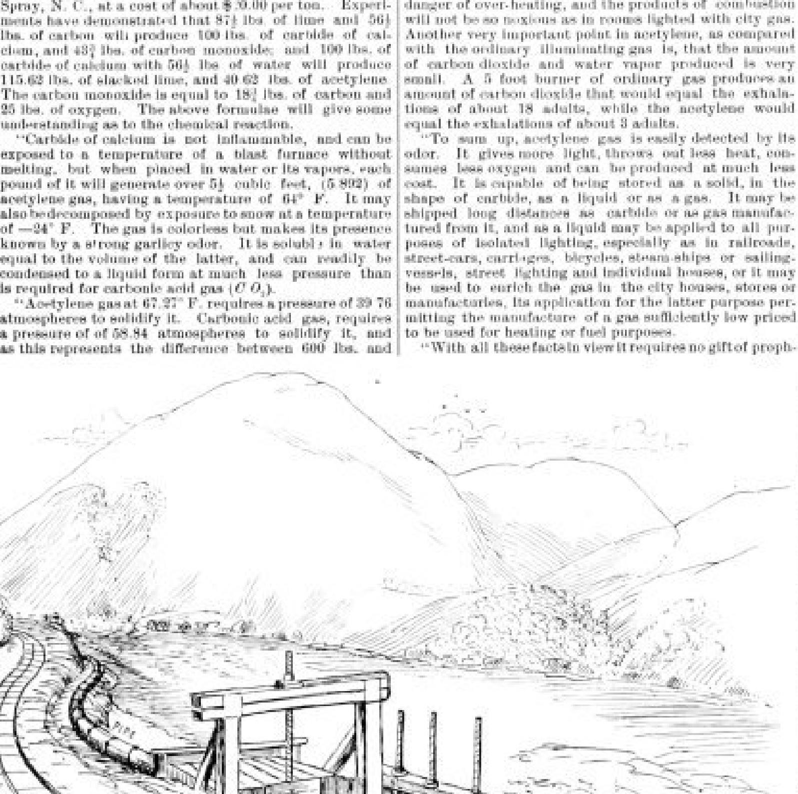

FIG. 9.—PENSTOCK WITH ALLEN'S STAVE PIPE ATTACHED, AT ROSCOE PLACER.

"Acetylene gas when subjected to sufficient pressure becomes a colorless mobile liquid and as the pressure is slightly relieved it commences to boil and evolve a gas, which upon ignition, burns with an intensely white flame, but if suddenly liberated would instantly solidify and form into a snow having a temperature of —118° F. and at this low temperature it possesses the same illuminating power as at the higher temperatures. The liquid gas is manufactured commercially by decomposing the carbide with water in a closed vessel, conducting the gas under pressure to a condenser, where it is liquefied and then drawn into tanks for distribution.

"One pound of the liquid when evaporated at 64° F. will produce 14½ cu. ft. of gas at atmospheric pressure, or a volume 400 times larger than that of the liquid. In ordinary service conditions the gas is not affected by the temperature, as it can be cooled to 100° F. below zero, or heated to 600° F. above, without impairing its illuminating power.

As an illuminant acetylene possesses lighting power and economy superior to any other illuminant known. When burned at the rate of but 5 cu. ft. per hour, its light is equivalent to 250 candles, and as good common gas is rated at about 20 candle power, it will produce 12½ times more light for the same quantity of gas. It has therefore 12½ times the value of illuminating gas.

"Assuming $20.00 as a cost to manufacture one ton of carbide of calcium which will produce 10,000 cu. ft. of acetylene gas, with a candle power of 50 candles per cubic foot, this would place the cost of the gas at $2.00 per 1,000 cu. ft. of 50,000 candles; $1.00 would therefore produce 25,000 candles. With good coal gas at $1.00 per 1,000 cu. ft., we get about 20 candles for each 5 cu. ft. burned, therefore, 1 cu. ft. produces 4 candle power,

A Successful Boiler.

H. E. Collins & Co., Bank of Commerce Building, Pittsburg, Pa., Sole Sales Agents for the Cahall Vertical Water Tube Boiler, manufactured by the Aultman & Taylor Machinery Co., of Mansfield, Ohio, report the following recent sales of Cahall boilers for the use of blast furnace gas: Illinois Steel Co., Joliet, Ill., 500 h. p.; Douglas Furnace Co., Sharpsville, Pa., 250 h. p.; Shoenberger Steel Co., Pittsburg, Pa., fifth order, 500 h. p.; Salem Iron Co., Leetonia, Ohio, third order, 500 h. p.; Sharon Iron Co., Sharon, O., second order, 500 h. p. Those for the utilization of waste heat from heating furnaces, are: St. Louis Stamping Co., Granite City, Ill.; second order, 150 h. p.; National Tube Works Co., McKeesport, Pa., 200 h. p.; Mahoning Valley Iron Co., Youngstown, O., second order 600 h. p. In addition they have secured the following recent orders for the direct fire type of Cahall Boiler: Wm. Tod & Co., Youngstown, O., 250 h. p.; Armstrong Cork Co., Pittsburg, 250 h. p. Messrs Collins & Co., have just issued a card containing a list of repeated orders received for Cahall boilers, the length of which shows the great favor with which these boiler are received.

MINING IN BRITISH COLUMBIA.

The Mineral Wealth of the Province and Its Rapid Development.

In a letter to the London *Times* of Aug. 23, Mr. Clive Phillips-Wooley calls attention to the great mineral wealth of British Columbia, and to the fact that Yankee enterprise is fast making that province "American in men, manners, money and sentiment." Mr. Phillips-Wooley as a loyal Englishman, deplores this, but he forgets that Yankee enterprise and bustle will do more for British Columbia in ten years than British conservatism will do in twenty, and, therefore, American influences in the province are the best.

While the silver deposits of British Columbia have proved themselves rich enough to pay "with silver even lower than at present," silver is not the only precious metal found. During the past year a gold-bearing belt of ore has been discovered and opened up, which added to the gold-bearing gravels of the province, seems likely to give British Columbia a prominent place among the gold producing areas of the world.

The completion of the Canadian Pacific Railway to Vancouver in 1886, made the province accesible to the world, but it is by no means sufficiently opened up by railroads, roads and trails to-day. Up till 1890 everyone in the province was too busy with town lot speculation to do anything towards developing the country. Since 1890 American capital and energy have proven the intrinsic value of the mines.

In speaking of the progress of development since 1890, Mr. Phillips-Wooley says:

"In 1890 there were no railways into West Kootenay. To-day there are three competing for her ores. In 1893 there were no shipping mines in the country. During the past 12 months, in spite of the silver panic and such difficulties of transportation as still exist, our silver-lead mines alone have shipped 26,500 tons of ore. An idea of the value of this ore may be obtained from considering a return now lying before me. A shipment of 2 114 tons sent from seven different mines to the Omaha and Grant Smelter, netted to the owners $107 per ton. This shipment is not selected for its exceptional value, but at hazard, as the first absolutely reliable statement of fact which comes to my hand.

"Last year a smelter, representing an investment of $750,000, was opened at Pilot Bay (close to Nelson), and not only is this to be enlarged, but within the last fortnight representatives of four of the greatest American smelting companies have been hovering about the district, their apparent aim being to make arrangements for the establishment of a great custom smelter at or near Nelson.

"What has been written so far concerns our West Kootenay galena fields and the one great bornite deposit at Nelson only, but since the autumn of 1894 another belt of mineral of an entirely different character to the mineral of Slocan has been opened up.

"We know that from the Kettle river to the Salmon river (a tributary of the Pend d'Oreille), at least, there is a belt of pyrrhotite, with some chalcopyrite, carrying gold in very considerable quantities, some silver, and a percentage of copper. In September, 1894, there were only four houses at Rossland, the principal camp, so far, on this belt. To-day, Rossland is a town of from 1,400 to 2,000 people, growing with truly American rapidity, from which last month four of her young mines shipped to Helena and Tacoma 2,330 ¾ tons, of the value of $115,386. New machinery is on its way into Rossland, and this monthly output will shortly be doubled. One mine alone is under contract to the Montana Ore Purchasing Company to supply 75,000 tons during the next four years, and another the War Eagle, has since its purchase in December last paid dividends amounting to between $84,000 and $90,000, thereby covering its original cost and all subsequent expenses. For this mine I am credibly informed that $940,000 is now offered and half a million for an adjoining property. Unless readers bear in mind the time in which these things have been done, the limited population we have to draw upon, and the abnormal scarcity of cash in this country, these developments may not seem great, and yet there must be some great intrinsic value in our mineral belts. If it were not so, our mountains would not be alive with prospectors from the Coeur d'Alene, our camps with middlemen representing the greatest American mining capitalists and ore-handlers, neither should we have in such a young country so many shipping mines. In the new belt we have already the War Eagle, Le Roi, Josie, Nickel Plate, Cliff, and Northern Star, whilst scores of prospects are being rapidly developed.

"In the silver-lead district the mines which have shipped are too numerous to mention, but the chief are the Slocan Star, Noble Five, Idaho, Dardanelles, Reco, Ruth, Blue Bell, and Alpha. Of these the Slocan Star bids fair, in the opinion of the most trustworthy authority whose opinion I have heard, to rival the famous Broken Hill Mine.

"Near Nelson there is one great bornite mine which should have long ere this made our country known on the London Stock Exchange. At last it seems as if it was to be worked in something like earnest. An aerial tramway is being put in to deliver 100 tons per diem, and within the next 12 months London ought to know as much of the Silver King as Nelson knows.

"Scattered throughout the country are free milling properties, one at McKinney, on which they have sunk 150 ft., another (the Poorman) near Nelson, which has paid for itself over and over again, and others at Fairview and elsewhere. Throughout the country companies like the Parrot Mining and Smelting Company, of Butte, Montana, and mining men like A. W. M'Cune, of Salt Lake City, Utah, are buying greedily, but every day fresh strikes are being made, prospects can be bought or bonded for a mere song, and camps like Boundary Falls, with huge deposits of comparatively low-grade ore, are neglected, because they are still 85 miles from a railway.

"It would be unfair to the province to conclude this letter without some mention of our gold gravels especially as local and eastern Canadian capital is being largely employed in their development. The story of Cariboo's gold returns to the poor men who worked with pan and shovel in the sixties has been told too often to need repetition. Since 1859 British Columbia has contributed $ 0,000,000 to the world's store of gold, of which by far the greater part came from Cariboo. This total does not include gold taken out by Chinamen, of which it seems difficult, if not impossible, to obtain an accurate estimate. To-day machinery can be taken into the gravels of the Fraser, the Semilkameen, and the Tulameen, and over a million dollars has already been expended in hydraulic work on these three rivers, whilst it seems likely that another field will be opened up this winter on China Creek, in Vancouver Island.

"The two great mines so far are the Cariboo and the Horsefly. Of these the Cariboo has just cleaned up $14,000 after a run of 127 hours, and the result of the first clean up of the Horsefly is daily expected, while the Anglo-American on the Semilkameen should be heard from early next month. The clean up of another small property on which $20,000 has been expended has just come to hand. The Nelson Hydraulicing Company has cleaned up between $4,000 and 5,000 in 120 hours' run.

"In considering the results it is only fair to remember that none of the mines are yet in fair working order, or at any rate not in such a state as to make a thoroughly representative showing of what they can do when fully under way. The Cariboo mines I have not personally visited, but upon the Semilkameen the results of panning in all sorts of places, likely and unlikely, from the river-bed to the grass roots, and in shafts 40 ft. deep, was an average of 25c. to the cubic yard. A large amount of platinum is also found in the gravels of the Semilkameen and Tulameen, which has been sold hitherto in the local stores at $4 an ounce."

In conclusion Mr. Phillips-Wooley says:

"It is worth while adding that the mining fields spoken of are so situated as to enjoy the advantages of water communication afforded by the Arrow Lakes, Kootenay river and lake, and the Columbia river, have all the lumber they require, and deposits of coal near the Crow's Nest Pass and elsewhere (near Boundary and in the Semilkameen) which can be tapped by railways at a very small expense."

MINE SURVEYING.*

LATEST AMERICAN IDEAS AND MOST APPROVED PRACTICE.

Rewritten for the use of Mine Officials, Surveyors and Engineers, from Lectures Delivered Before the Students of Columbia School of Mines.

(By Edward B. Durham, E. M.)

CHAPTER VI. (CONCLUDED.)

In the Hoosac Tunnel,† work was begun at both ends and at an intermediate shaft. At the shaft, two instruments were firmly bolted to foundations on each side of the shaft. They had a slit in a movable frame whose position could be determined by a series of observations, noting its position each time by means of an attached vernier scale. The mean of the different positions was taken and the slits were set in this position. Then two fine steel wires were stretched across the shaft between the sides of the slits, and between these were lowered the plumb wires, 25 feet apart. The wires were enclosed in boxes to protect them from falling water and air currents. At the bottom, a platform was built a few feet above the floor on which horizontal scales were placed behind the wires, and by them the centers of the swings were determined, and from these the center line was prolonged in both directions. The shaft was 1028 feet deep and the tunnel excavated for 1563 feet to the east and 2056 feet to the west of the shaft. The tunnel was carried in 11274 feet from the east portal, and 10138 feet from the west before meeting the headings from the shaft. The errors in alignment at meeting were 0.045 foot on the west and only 0.025 foot on the east side of the shaft. The error in grade is given as 1¾ and 1½ inches by someone, and by another writer as nearly 3 inches. Taking either figure for the grade as correct the results show very careful and creditable work on the part of the engineers. The total length of the tunnel was 25,031 feet.

On the Comstock Lode,‡ shafts were satisfactorily plumbed to depths as great as 3,000 feet, by hanging a plumb line in each of two compartments, so as to get them as far apart as possible. This gave a 9 foot base. At the surface a plank 12 x 2 inches was placed across the shaft and the wires let down by the edge of this and twisted around a nail in the floor. At the bottom a platform of two planks was placed across the shaft a little above each tub. One plank of each pair was used as a walk, and the other was placed about an inch from the wire. To this was nailed a small piece of white board so as to be only ¼ inch from the wire. Then a light was placed in line with the two wires, so as to throw the shadow of one of them on the board. As the wire swung to and fro the extreme positions of the shadows on the board, were marked with a pencil. The mean of any pair gave the central position and a number of observations were made to check the work. If in doubt as to whether the wires swung freely, at a given signal, the man at the top moved them an agreed distance, and they noticed whether they moved a like distance at the bottom, which they would only do if they were free.

On the new Crofton Aqueduct§ the shafts were placed with the longer dimensions parallel to the axis of the tunnel, so as to give the engineers as long a base as possible, and to one side of the centre, so as to leave a passage way at the foot of the shaft, through which the construction cars could pass around it. The shafts overlapped the centre line a few inches so the engineers could place their plumbing wires exactly on the centre line, and the two corners on this line were reserved for them. The large shafts were 17½ feet long and the small ones were 11 feet. The shafts were kept plumb in sinking by lines in the four corners, and on reaching the grade of the tunnel, the line was given for 50 to 100 feet on each side of the shaft by stretching a line along the center line as given by two plumb wires down the shaft, and marking it by points in the roof. When work had progressed a little further a more accurate line was given with the transit, set up in line with the wires, and finally when the work had advanced far enough, so that the points would not be disturbed by blasting, the permanent line was carefully determined.

The wires were set, at surface, on the center line by a transit placed 40 to 50 feet from them, and over a monument located on the line of the tunnel. The further wire from the instrument was adjusted first and then the near one. The wire was No. 8 piano wire, annealed, and wound on a six inch reel with a braker fastened to the head frame and from there the wire was led to a clamp with a tangent screw motion from which they hung down the shaft, and by which they were brought into line. The clamps were fastened to posts set in the ground, to prevent vibration from the machinery in hoisting. The wire was lowered by one pound bobs, which were exchanged at the bottom for 25 pound ones. The wires were examined to see that they hung clear, by a man who climbed down the shaft. After adjusting the bobs to clear the floor, they were hung in buckets of linseed oil, which were then covered loosely.

To get a steady sight at the bottom, an illuminated slit, Fig. 17, was devised to replace the wires. It consisted of two vertical strips of brass about 3 inches high, each attached to a horizontal bar moving in guides, and provided with separate tangent screws, so the vertical slit between them could be varied in position and in width. These were secured to a plank bracket close behind each wire, so that the further one appeared above the near one when a light was placed behind each. The slits were adjusted until slightly wider than the wires, and then, when they were exactly behind them the light would appear evenly on each side of the wire. This could be estimated very closely by

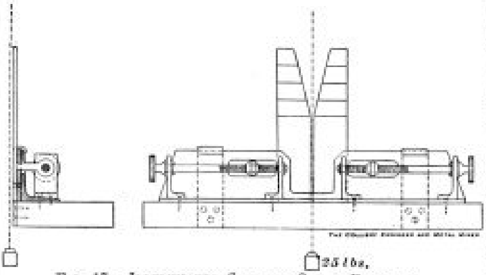

FIG. 17.—ILLUMINATED SLIT FOR SHAFT PLUMBING.

the eye placed in line with the wires. The plummets were then removed and the slits used to sight at. These remained fixed and could be easily bisected, and the center line transferred to the roof and afterwards prolonged to the headings. The first points were placed about 150 feet on each side of the shaft, giving a base 300 feet long. For these first points, holes were drilled in the roof, and plugs inserted, into which iron spikes were driven, Fig. 18. To each spike was bolted a brass plate with the zero mark cut in the lower edge, and below this was a vernier plate to whose zero was attached the plumb bob, and which was made to slide so as to bring the bob into line. The position of the vernier was then noted, and the plumbing repeated until they got three good determinations of the line, that agreed closely. Then the sliding verniers were set on the mean of the observations, and the line prolonged to the headings, putting in permanent marks in the roof at intervals.

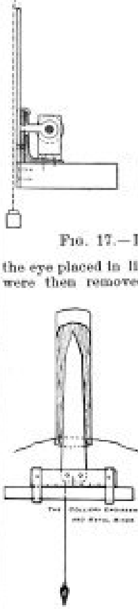

FIG. 18. TEST SPIKE AND VERNIER SCALE.

As the roof was over 15 feet high, the engineers used a tripod ladder Fig. 19, to reach their points. These might be useful for mine work. The cross-sections were

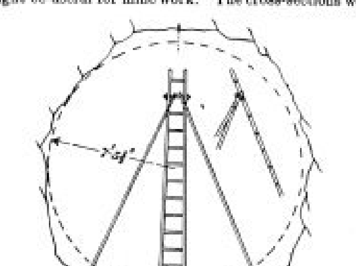

FIG. 19.—TRIPOD LADDER.

taken by a special instrument of their own design, for the description of which the reader is referred to the original articles.

Mr. Brough, in his "Treatise on Mine Surveying," gives the following method of determining the alignment of the underground survey, where it is not convenient or possible to set up the transit in line with the wires, Fig. 20. The two plumb wires A and B, are hung in the shaft as far apart as possible and located in the usual manner on surface. Then the transit is set in the mine at a point C, on one side of the line through the wires, and the distances A-B, A-C and C-B are measured with the greatest care. The three sides of the triangle are thus known, and the angles can be calculated by the formula,

$$\text{Sin.}\ \tfrac{1}{2}\ A = \sqrt{\frac{(\frac{1}{2}\,s-m)\times(\frac{1}{2}\,s-n)}{m\times n}},$$

in which A is any angle of the triangle, m and n are the sides adjacent to that angle, and s is the sum of the three sides.

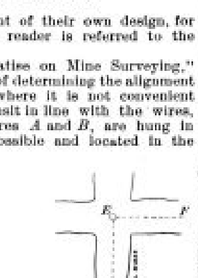

FIG. 20.—METHOD OF SHAFT PLUMBING SUGGESTED BY MR. BROUGH.

The angle at C can be measured with the transit, as a check on the calculations, and the angle between A C and the next course C E of the mine survey should also be measured. From the data thus collected we know the direction of A-B and the location of A as determined on surface, the angles $B\ A\ C$ by calculation, the angle $A\ C\ E$ by measurement and the distance A-C, hence the direction of the line C-E, and the location of C is known, and from these the relation of the whole mine survey to the surface can be determined. The position of C, with regard to the base A-B, makes a good deal of difference in the error in the angle at A due to small errors in the measurements of the sides. The worst cases are where the angle at A is large, as in the case of isosceles triangles with the base on A-B, and where the angle at A is very small, and A-C is the base of an isosceles triangle. The best case is where the point C is on a perpendicular to A-B from B and quite close to it.

Even under the best conditions a slight error in measurement would cause too large a one in the results to depend on the method for accurate work.

The "COLLIERY ENGINEER" strongly recommends a similar method to above, but more accurate, as superior to setting the transit in line with the wires. Four wires, x x x x, are hung in the corners of the shaft, Fig. 21-A, and are located on surface by radiating sights from four stations, which are arranged, one on each side of the shaft, so that the lines, joining opposite stations, run north and south, and, east and west, respectively. These lines serve as base lines from which the angle can be read by repetition from each of the stations to each of the wires. The distances from each station to each of the wires, and the six distances between wires are also measured. Then from the angles and distances, the co-ordinates of each of the wires can be calculated

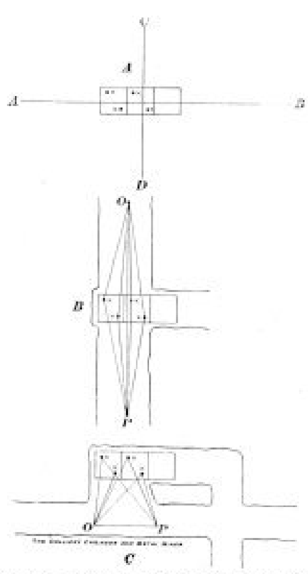

FIG. 21.—SHAFT PLUMBING WITH FOUR WIRES.

for the position determined from each station, and the results tabulated. Any observation which causes much variation in the position of a wire can be thus detected and repeated. The mean of the four locations is taken as the final position of each wire. The bearings of the lines joining each wire to each of the others are then computed.

There may be two positions of the shaft with respect to the gangway, Fig 20-B and C,—either the shaft is in it or to one side, both cases are lettered alike, so description will apply to either. Stations, O and P, are chosen as far apart as possible, so as to give the longest available base line. From both stations, radiating sights are taken to all four of the wires, reading the angles by repetition from the line O-P as a base, and measuring the distances as carefully as possible. The distances between each of the wires should have been previously measured, to see that they agreed with the surface measurements. Each station will then be at the apex of six triangles, each having the line between two wires for its base. Then the angle between the sides of these triangles, and their base can be calculated, and, knowing the direction of the base joining the wires from the surface survey, the direction of each of the sides can be determined. From these and the distances, there will be twelve locations of each of the stations, if all the sides of the triangles are used, since the co-ordinates of each wire are known. These locations can be tabulated, examined, and the means taken as the positions of the two stations. The direction of the line joining the stations can be calculated from the co-ordinates, and will thus form the base for the underground work. The distance down the shaft will give the elevations.

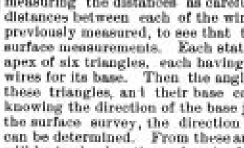

FIG. 22. PLUMBING BY TWO SHAFTS.

Speed and accuracy are claimed for this method, and the base can be determined, without regard to the position of the shaft with relation to the gangway.

Two Shafts.—Where there are two shafts entering a mine, a plumb-bob can be hung in each, and the alignment of the underground survey can be obtained much

* Begun in March, 1895.

§ "Tunnel Surveying on Division 6 of New Croton Aqueduct," F. W. Watkins, Trans Am. Soc. of Civil Eng. Vol. XXIII, 1890, p. 17-28 ill. Also "Sanitary Eng." Vol. XVI, p. 39, June 11, 1887.

more easily than with only one shaft and at the same time, more accurately. In Fig 22, *A* and *B* are wires hanging down their respective shafts.

The location of the two wires must be determined on surface by a traverse, and the direction of the line connecting the wires must be calculated.

Proceeding underground the two wires, *A* and *B*, are connected by a traverse, *A* — 1......9 — *B*. Then in the office, the underground survey is calculated, and the latitude and departure of *B* is found, with relation to *A*, using the course A — 1 as the assumed meridian with an azimuth of zero.

Course	Angle	Assumed		Hor. Dist.	Latitude		Departure	
		Azimuth	Bearing		N	S	E	W
A-1	0°00'	0°00'	North	17.6	17.6	......	0	0
1-2	177°33'	357°33'	N 2°27' W	42.4	42.3	......	......	1.8
2-3	284°07'	102°31'	S 77°31' E	131.0	......	28.1	128.9	......
3-4	177°56'	100°26'	S 79°34' E	167.5	......	30.3	164.7	......
4-5	181°54'	101°18'	S 78°42' E	93.0	......	18.2	91.1	......
5-6	158°33'	79°51'	N 79°51' E	82.8	14.5	......	81.5	......
6-7	184°53'	84°44'	N 84°44' E	37.4	3.4	......	37.2	......
7-8	184°26'	89°10'	N 89°10' E	61.2	0.9	......	61.1	......
8-9	94°53'	3°03'	N 3°03' E	61.2	61.1	......	3.2	......
9-*B*	135°11'	318°14'	N 41°46' W	11.8	8.8	......	......	7.8
					148.6	76.6	567.7	9.6
					76.6		9.6	
					72.0		558.1	

In this case the wire *B*, is 72.0 feet "north," and 558.1 feet "east" of *A*. The bearing of *A* — *B* will, therefore, be in the northeast quadrant and equal to the angle *CAB*, but $Tan.\ CAB = \frac{558.1}{72}$, hence CAB = 82°—38'. The azimuth of a line in the northeast quadrant will be the same as the bearing, hence the azimuth of *A* — *B* = 82° 38', on the assumption that the azimuth of *A* — 1 = zero. From the surface survey, the true azimuth of *A* — *B* was found to be 118° 36', hence the assumed azimuth is 35° 58' too small. The true azimuth of courses of the underground survey, can be found by adding 35° 58' to their azimuths, based on the assumed meridian *A* — 1. The true locations of *A* and *B* are known, and so the underground survey is fully connected with the surface.

The surveys connecting *A* and *B*, both on surface and in the mine, must be carefully checked, and the same precautions taken with the plumbing as with one shaft. If there are more than two shafts, the meridian can be determined by two and checked by the others.

At Przibram* in Bohemia, it became necessary to deepen the Franz Josef shaft, then down 1,380 feet, to the depth of the Adalbert and Maria shafts, which were 3,280 feet deep in order to facilitate the extraction of the mineral. In order to hasten the operation, it was decided to work from five different levels, by rising and sinking. To determine the position of the new portion of the shaft at each of these levels, they first placed plumb lines in each of the three shafts, and ran a traverse on the lowest level, which was open to all of them, to determine the triangle formed by them. Then by connecting the plumb wires in the two deep shafts, the surveys on each of the five levels could be oriented, and a cross cut driven to the site of the new shaft, and work begun. The shaft was driven full size, and lined up as it progressed. The holing through was so exact in every case, that no change was needed in the masonary lining. Each time a shaft was broken through from one level to the next, the survey was checked and the corrected triangle formed by the shafts, used for the next determination. The work required 11 miles of traverse with 684 set-ups.

One Shaft and One Slope.—Here the engineer would have a choice of several ways of determining his alignment. A plumb line could be dropped down the shaft, and from there with an assumed meridian the line could be run through the workings and out the slope, connecting it with the surface line, and then calculating the alignment backwards. Or, a line could be run in through the slope, measuring the horizontal angles only, to the foot of the shaft, then from there commence the surveys. The location of the plumb line in the shaft would be known from surface, and the line through the slope will give the alignment. Where the slope is flat so that an eccentric telescope will not be needed, a regular traverse can be run in through the slope, most easily, and then checked on the plumb-line in the shaft.

MEASURING THE DEPTH OF SHAFTS.

The methods, already described, of connecting the mine and surface surveys through shafts, give only the horizontal position of the underground survey referred to the origin, it is therefore necessary to determine the elevations of the workings, by measuring the depth of the shaft.

If the depth is measured directly with a tape, its weight and the pull upon it will tend to stretch it. In shallow shafts this can be made to equal its normal tension, but in deep shafts the weight of the tape, and the necessary pull to keep it taut, may exceed the normal. In such cases the upper end of the tape may be passed over a roller at the top of the shaft, and carried horizontally before winding on the reel. In this horizontal stretch, may be placed two points at an exact distance apart, then with the tape under tension as it is being used to measure the depth of the shaft, the distance between the fixed points is measured, this will then give the ratio of the measured to the true distance. Or the same ratio may be obtained by measuring with a tape at its normal tension, the distance between two graduations on the tape under the excessive strain. The horizontal piece of the tape thus compared with the standard, should be at least 100 feet long, so as not to multiply errors of observation to too great an extent.

Another method of determining the depth of a shaft is by using a steel wire (piano wire) with a weight attached to it, and measuring the wire as it is let down the shaft, and again as it is drawn up. This can be done by running the wire from the reel horizontally across a gauge, 50 or 100 feet long, then over a pulley and down the shaft. When the bottom of the weight is just even with the top of the shaft, a pencil mark or clip, is put on the wire opposite the end of the gauge nearest the reel, and then the weight is lowered until the mark is opposite the other end, thus one gauge-length of wire has been lowered, and another mark can be placed at the first end and another length lowered. This can be continued until the weight reaches the bottom, when the number of lengths let out multiplied by the length of the gauge, will be the depth of the shaft. If there is a fraction of a length lowered at the end, its length can be measured at the surface, as it will be the distance between the mark and the first end of the gauge.

Instead of a wire, the hoisting rope may be used in the same way.

The depth may also be measured directly by applying rods, chains or tapes to the guides, provided they are straight. For this purpose a seat is fastened to the hoisting rope, at the proper distance above the cage, on this an assistant sits, and holds one end of the tape, while the engineer rides on the roof of the cage, and holds the lower end. They can then apply the tape directly to the guides. A third man on the cage gives the signals for raising or lowering. A shaft 1095 feet deep was measured in this way three times in six hours, locating eight levels entering the shaft, and the distances agreed within $\frac{1}{10}$ inch. Another shaft 1,152 feet deep was measured four times and the greatest difference in any two distances was a little less than $\frac{3}{4}$ inch.

[THE END.]

Written for THE COLLIERY ENGINEER AND METAL MINER.

THE ORE DEPOSITS OF CRIPPLE CREEK.

The Geology, Character, and Extent of This Famous Colorado Mining Region.

By Francis T. Freeland, B. S., C. S. S., A. I. M. E., A. S. M. E., General Manager Isabella C. M. Co., Cripple Creek; Durant Mg. Co., Aspen; Aspen Contact M. Co., Leadville, Colo., etc.

The northern part of the Cripple Creek district,—Tenderfoot, Gold, Globe, Iron Clad and Bull hills consist of andesite and andesitic breccia, bounded on the east, north and west by granite and gneiss. A tongue of granite runs into this region from the northeast just west of Bull hill and covers part of the headwaters of Squaw gulch. Mineral hill and Rhyolite mountain are masses of andesite surrounded by granite. Many of the hills are capped by phonolite flows. Dykes of phonolite are common and infrequent exhibitions of other eruptives may be noticed among which, basalt and diorite have been provisionally determined.

The ore occurs in fissure veins, as impregnated dykes, as an alteration of the edge of dykes, as chimneys at the intersection of a fissure vein and a dyke, and in the joints and cleavages of the country rock near the main fissure.

The valuable metals contained in the ores are gold and silver. Probably about $\frac{1}{4}$ of an ounce of silver is mined for each ounce of gold. Some of the gold is free, but with moderate depths the tellurides appear. The country rock shows some pyrite but the veins contain little and that low grade.

While some of the ore gives surprisingly rich returns, the product of the camp will probably average 3 ounces. This is to be considered a very high average grade for a gold camp giving this tonnage.

The principal associated mineral is quartz, both crystallized and massive. Some of the dull brown quartz is very rich. The opaque white and blue black quartz is poor. In the deeper workings a grey blue quartz will often show sylvanite on examination. Fluorite is also associated with the ores, and when dark purple or transparent it is considered a sign of value. The gouge in the fissure veins is usually a brown clay but sometimes white and rarely black. The gold in the clay and decomposed ores is fairly free. The quartz may be "frozen" to both walls, but in other parts the vein will have a "casing" of decomposing country rock, carrying small values.

The impregnated dykes are usually softer than the country rock, and the boundaries of the pay ore often indefinite. The ore occurring as a selvage to a dyke in andesite is generally an altered part of the dyke and shows a quite uniform greyish yellow color and contains more silica than the country rock. This selvage is locally called "jasper," as in the Moose mine. Such segregations and impregnations are apparently in chimneys associated with a crossing fissure vein. Yet often the fissure and the dyke too will be barren at some distance from the intersection. The Anna Lee shaft is on such a chimney. It is 760 feet deep and the deepest shaft in the camp at present. The Specimen and Bogart may also be put in this class. The dykes may be traced for considerable distances and shows much irregularity in thickness.

The principal fissure veins in many cases cut through the dykes and are but little affected by them. One vein has been seen to fault another, in the Zenobia. Most of the fissures run northwest or roughly parallel to the front range and main drainage system. While the veins maintain a general direction they vary greatly in strike and dip in their different portions. In some mines a particular course will correspond to a particular dip and bear some relation to the size and value of the ore bodies. See L. Moissenet. Observations on the Rich Parts of the Lodes of Cornwall. Trans. by J. H. Collins, London, 1877. The Isabella-Victor vein has been opened up for a length of a mile almost continuously and to a depth of five levels at the main shafts, and plainly shows this peculiarity. The Zenobia and Pharmacist veins have also been traced to some distance the latter to a depth of 520 feet. In Cripple Creek the veins seem in some instances to be in groups forming a plexus of veins with a large body of ore at their intersection. The Summit and Deerhorn mines are of the class. The Portland in the southern district is also a remarkable example. Other peculiarities of fissure veins such as splits, feeders, robbers, splices, horses and throws may be noticed.

The dykes and fissure veins also occur in the granite. In this case the ore is usually an impregnation of the granite for some feet from the fissure, the mica being replaced by the tellurides and the wall not well defined.

It was thought in the early days of the camp that the dykes and veins in the granite were barren. Recently a pay vein in the granite not associated with a dyke has been found in the Home Run claim near Victor; and several veins have been found in the granite on the north slope of Tenderfoot hill which give promise of turning out well.

The normal contact of the andesite with the underlying granite has not been systematically prospected as yet, but should be tried even if at first sight the chances seem to be against finding pay ore. Such a contact if made by a faulting fissure has a high prospective value. The large and valuable ore body in the Independence in the southern district seems to fill these conditions.

Among the deeper mines are the Isabella, Victor, Anaconda, Moose, Elkton, Anna Lee, Independence and Portland. While I will not assert that the veins increase in size and value in depth, yet I can say that the deeper workings of the mines mentioned certainly show that the average vein is as profitable below as nearer the surface. The change to unoxidized ore in depth in this district is a matter of little note, for but a small part of the product is free milling ore, hence no check in the output is to be expected such as occurred in Leadville and Central City on reaching sulphides.

It is probable that a number of vents, through which the andesite was thrown up and spread out over the granite, exist in the district and they are probably of great extent, so that in many places deep sinking will continue to show andesite. In other parts the granite may be reached. In some of the deeper workings an increase in the included granite may be noticed, indicating an approach to the massive granite. When the vein arrives at the granite, the change of walls may influence the character of the mineralization, but there is no reason to believe that the vein will be cut off by the contact with the granite.

The boundaries of the district are not yet clearly defined and may be susceptible of considerable extension. Several outlying bodies of andesite are known, the Home Run mentioned above is a pay fissure entirely in the granite, and the new discoveries on the north slope of Mineral hill on phonolite dykes in the granite add largely to the possibilities in every direction. The territory now being actively worked is about six miles square.

For a time the wonderful discoveries in the southern portion of the district somewhat overshadowed the northern region, but during the current year a great increase in activity here has been noticed. The older mines such as the Isabella, Victor, Gold King, Union and others are sinking additional shafts, putting in heavier machinery, perfecting their surface improvements by extending their ore bins and sorting houses, and pushing extensive development work. Many new and important discoveries have been made, among which are the Brooklyn, Anchors, Midget and Geneva. More than a dozen new steam hoists have been erected on Gold hill since last February. The output both in tonnage and total value is steadily increasing and bids fair to double the product of the state in gold.

The camp is exceptionally well provided with facilities for the transportation and reduction of ore. The higher grade rock is sold to the great lead smelters at Denver and Pueblo. The medium grade product is sold to the two chlorination works at Gillette and Lawrence, and the two cyanide plants at Florence and Lawrence. The low grade surface ores are worked up in the local custom stamp mills by amalgamation and concentration with a fair degree of success. Transportation is provided by two railroads and good wagon roads in every direction.

To one looking back but a few years, the change from a peaceful cattle range to a group of a dozen cities and villages with a population of 12,000, the surrounding hills dotted with puffing hoists and substantial buildings, the air rent by the sharp blasts of giant powder and the roads blocked with endless processions of four-horse quartz teams, is marvellous, and a monument to western, and principally local, mining energy. The camp attracted but little attention in its beginning, partly on account of the fruitless stampede to Mount Pisgah some ten miles west in 1885. But an output of over $300,000 00 from one mine in one month and over $8,000,000 00 in gold in a year from the district, indicates the cause of this wonderful transformation.

Cableways for Open-Work Mining.

An interesting fact to contractors is revealed by the use of the various systems of handling rock on the Chicago Main Drainage Canal. A day's work for a man in filling lime stone into shallow skips, as used on the Lidgerwood cableway, averages between 16 and 17 cubic yards of rock in place for each ten hours' work, while the work of filling the cars, which are about 3' high, averages only about 9 cubic yards per man. This is a remarkable saving and alone would justify the use of the cableway in hundreds of localities. It may be mentioned in this connection that there are now twenty Lidgerwood cableways, which, by the way, are manufactured solely by the Lidgerwood Manufacturing Company, New York, in use in the construction of the Chicago Main Drainage Canal.

CABLEWAYS AT COAL STRIPPINGS.

The Suspended Cableway in Use for "Stripping" the Coal Seam at the Coleraine Colliery, Beaver Meadow, Pa.

The suspended cable system of hoisting and conveying has been in use for many years in slate and stone quarries, open work iron mines, excavating &c. For these purposes it has attained great popularity, and it is considered almost impossible to do without it. However, for "stripping," (removing ground and rock from the coal strata) it is but recently that its utility and and efficiency have been tested.

Messrs. Crawford & Dugan and Dick & Muntz, contractors at the Lehigh & Wilkes-Barre Coal Co.'s mines, were the first to introduce the system in the anthracite coal district. These operations were closely observed by all interested parties desirous of getting the best method by which the work could be accomplished. Although these plants were not erected to operate on a large scale, they demonstrated that the system met a long felt want, and because of its adaptability had come to stay, and to a certain extent take the place of the steam shovel.

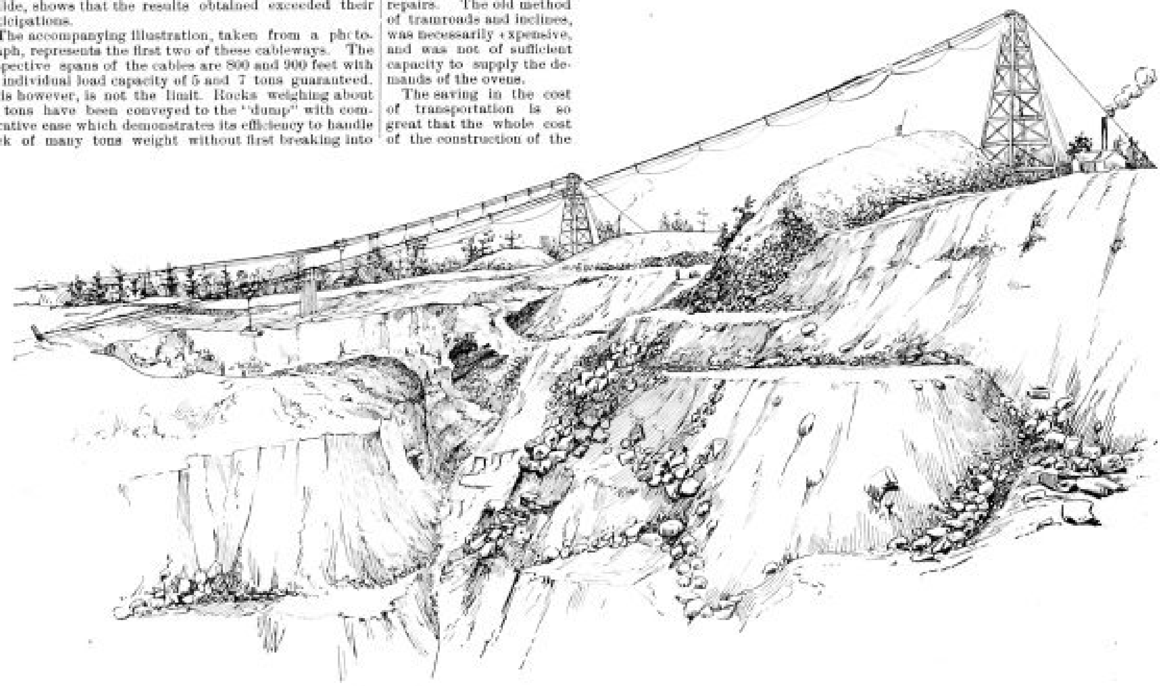
Mr. A. S. VanWickle adopted the cable system at his Coleraine Colliery, Beaver Meadow, Pa. and erected the first plant in the early part of last spring. The stripping at this place is quite extensive, and in order to remove the top as quickly as possible several more cables were erected during the summer. In starting a new place there are certain disadvantages, and while the conditions were unfavorable to work to the full capacity at the beginning, the expression of satisfaction by Mr. D. Levan Supt., and Purchasing Agent W. B. Wilde, shows that the results obtained exceeded their anticipations.

The accompanying illustration, taken from a photograph, represents the first two of these cableways. The respective spans of the cables are 800 and 900 feet with an individual load capacity of 5 and 7 tons guaranteed. This however, is not the limit. Rocks weighing about 10 tons have been conveyed to the "dump" with comparative ease which demonstrates its efficiency to handle rock of many tons weight without first breaking into smaller pieces as has been the practice for the steam shovel.

To handle smaller stones and ground, skips, or boxes are provided of suitable size.

The third plant at Coleraine is of the horizontal type. A 2¼ inch diameter steel cable having a clear span of 1000 feet is suspended from two towers one of which is 120 feet high. The amount of material handled with one of these plants depends on the conditions surrounding it. A fair average, however is from 300 to 500 cubic yards per day. Any doubt, or objection which may have existed as to their practicability has been dispelled, and other operators are adopting the system at their "strippings." Mr. E. L. Bullock, Supt. of the Dodson Coal Co.'s mines, Morea, Pa., is erecting a plant of the same capacity as those refered to above. For open pit mining, after the top has been removed, the system will no doubt greatly facilitate the work of taking out the coal.

The machinery, hoisting engines &c., for the plants refered to was furnished, and erected by S. Flory & Co., manufacturers, Bangor, Penna. who are prepared to furnish estimates for complete plants. Those contemplating the use of plants of this kind will find it to their interest to communicate with them.



CABLEWAYS AT COLERAINE COLLIERY STRIPPINGS.

About Pumps.

A rise in prices is indicative of two important facts: First that there is a strong demand for the article, and second that the quality of the article is of so high a grade that the producers do not fear the competition of of cheaper and inferior articles. The fact that The Laidlaw-Dunn-Gordon Co. has sent out notices to all its branch houses and agents throughout the country advancing prices fifteen per cent. is indicative of a heavy demand for Laidlaw-Dunn-Gordon pumps, and is also strong evidence of their superior qualities.

Written for THE COLLIERY ENGINEER AND METAL MINER.

A FLUME CONVEYOR.

COAL FOR COKE OVENS CONVEYED 8,400 FEET BY WATER.

Description of the Montana Coal and Coke Company's Method of Reducing the Cost of Handling Coal.

(By B. L. Lloyd, C. E.)

The Montana Coal and Coke Co., operating mines and a coking plant at Horr, Montana, completed in April last a flume for conveying the washed coal from the washer to the drying bins near the coke ovens. The flume is working very successfully to the first bins, which are 8,400 ft. distant from and 1,000 ft. lower altitude than the washer. New bins 1,200 ft. nearer the ovens have been constructed, and the flume has been extended to them. The flume is constructed over such rough ground, and has such a variety of grades and curves, that a description of it from its inception will no doubt prove interesting.

While the writer does not in any sense lay claim to the invention or conception of a flume for the purpose of carrying crushed or washed coal short distances on good grades, he does claim that the transportation of the output of a mine, except the lump coal, over a long distance and rough country to the coke ovens is a novelty. It is true, it is simply an application and extension of an old idea, but it is of such magnitude that it is worthy of notice. It is now transporting all the coal required for the coke ovens at a cost of simply the interest on the investment and very slight repairs. The old method of tramroads and inclines, was necessarily expensive, and was not of sufficient capacity to supply the demands of the ovens.

The saving in the cost of transportation is so great that the whole cost of the construction of the flume will be saved in a few months. It was the necessity for a greater supply of coal that led to the construction of the flume.

The location of the mines is at the southern terminus of the branch line of the Northern Pacific Railway, which leads from Livingston, Montana, to Cinnabar, the entrance to the Yellowstone National Park. We are about 5 miles from the line of the park, and are, therefore, in the Rocky Mountains. Our railroad station is on the banks of the "Upper Yellowstone," in the famous Yellowstone Canon. Only a few miles away is the Electric Peak, 12,000 feet high, while between the mining camp and the station is the "Devil's Slide." This is the out croppings of a perpendicular vein of the red ore of cinnabar, which is about 15 ft. thick, and which is flanked on either side by perpendicular walls of rock ranging from 75 to 150 feet high, and which extend from the top of Cinnabar Mountain to the foot, and form a sight well worth travelling a long distance to see. When the trains come by bringing tourists to the Yellowstone Park, they stop just before they reach our station, in order that the tourists may get a view of this beautiful sight. Our station is 5,200 feet above the level of the sea, while the mine workings are 1,100 feet higher. The works are situated relatively as follows: The washer is situated about 80 feet below the mouth of the mines and is the point of discharge into the flume. The loading track, under the former drying bins, is 95 feet lower. By the old method, in use when the writer came here, the coal was hauled by mules over a tramroad 4,500 feet long; thence, down an incline 1,300 feet long, which is at an angle of 22°; thence, over another tramroad 2,500 feet long; thence, down another incline 900 feet long, with an angle of 26°, to a bin; thence, it was hauled in a "larry" by a "dummy" engine (such as is used on street railways) down another tramroad with 3, 4 and 5% grades to the coke ovens.

When it was represented to Mr. John H. Conrad, the owner and manager of the mines, that, having the water at hand, a greater and adequate supply of coal for the ovens could be transported without cost by means of a flume, he, with the sagacity and promptness which characterizes him as well as the western mine manager generally, saw a good thing in it and ordered it put in at once.

When the writer ran the levels he found that there was 128 feet fall from the washer to the track at the first "divide", which is at the end of the first tramroad and the head of the first encline. This gave him a minimum gradient of 2.8% or 0.7 feet per station of 25 feet. This gradient he kept in mind during the balance of the survey. He made a reconnoisance of the ground, finding it rough on every route. One route which had been suggested to the Manager, and which followed in part an old pipe line and led finally down the last incline (which has an angle of 26°), was considered objectionable at first, from the fact that the flume was to be made of plank 2 inches thick, and of course jointed, and the incline being two-thirds trestle, the continued vibration would keep open the joints, which otherwise would fill up with fine coal, and because the coal and water coming down the angle of 26° into the settling tanks on top of the drying bins would necessarily keep the contents in a turmoil with little chance to settle. Therefore, a route going straight down the mountain following the side of the first long incline, (average pitch of 22°) and from the foot of this down a very steep ridge, and over a bluff, to the bottom was adopted. About 200 feet of this was on 45° grade or more. On reaching the bottom of the mountain, the grade was rounded out with a vertical curve by means of a trestle until the grade of the small branch which comes down near by was secured. This branch was then followed and good alignment and good grades, starting with 15% and gradually lessening until it got to about 6% were secured. The writer then went to the new drying bins and located the line back, using the same minimum grade as on top *viz.*; 2.8% and followed this until it crossed the line coming down the branch. Then the 6% grade was rounded into the 2.8%. Of course when following the minimum grade we took the best alignment we could get without to much grade work. It was side hill work. We only excavated on an average enough room for the boxes to rest on solid ground, making about half a dozen thorough cuts, and putting in about a dozen small trestles. Some of the curves were pretty sharp, but we figured that when we made a thorough cut or trestle, that the shortening of the distance would about even it up, and give enough compensation for the curves; the compensation required in this case being to increase instead of lighten the gradient.

Some of the "wiseacres" of course criticised the flume and were ready to say, "I told you so." They claimed that with such a diversity of grades it would never work; that the coal and water would travel faster on the very steep parts than on the minimum grade. This we did not dispute, but we held that while the speed was greater, the volume must be the same; that it could not go down the hill any faster than it got there over the long stretch of 4300 feet of minimum grade from the washer to the divide; and that after it got down the hill, it would travel as fast over the minimum grade of 1000 feet at the lower end as it did at the top. The successful behavior of the flume has proven that it will work beautifully on even as light a grade as 2.8% and that with an established minimum, care being taken not to get flatter than the minimum and to compensate even very lightly for curvature, it will work very nicely, no matter how steep some parts of it may be, and at almost any curvature.

As was mentioned above nearly all the grading that was done was on the side hills where we established the minimum grade. Pegs were set to grade at intervals of 25 feet, or on the "grade contour." As we commenced the work on the 4th day of March, the surveying was done before, and at a time when the ground was covered with snow and was frozen. It was found necessary to take a short drill along to make holes down into the frozen ground, using pegs a little larger than the drill, which went in tight and were set to grade.

The side hills were graded with the objects, first, of getting as much as possible solid ground bearing for the boxes; second, of covering up before cold weather to keep from freezing, the intention being to make embankments at the side and barely cover the top, it having been observed that the short flume from the washer to the former drying bins, which was covered the same way, did not freeze all last winter, and we had some pretty cold weather here.

Where we went straight down the mountain, the flume was built almost regardless of grades or curves. It was simply put in the quickest and most convenient place, some care being taken to get through the snow, and well into the ground with blocks at each joint. The intention being to put an embankment of earth at each side, and cover it with boards and some earth before cold weather comes.

The boxes were made of undressed 2 inch fir plank, having 8 inch bottoms and 10 inch sides thus giving an 8x8 opening. The sides were spiked to the bottom with 30-penny wire nails which were put at intervals of about 6 inches; and collars of 2″x6″ plank were fitted with some care at each joint and were put around the boxes at the center to keep them from warping or twisting. They were in lengths of 12, 14 and 16 feet, mostly 14 feet, and were generally cut in two, making short lengths to go around the curves. They were set at slight angles with each other to make the curves, or as the carpenters would say with a "bevel cut," which was as much in some cases as 4 inches in 24, or that much deflection from the line of the last box. To make the joints close, the boxes were set in position as they were intended to lay, in which position the "bevel cut" was measured and made; then being set end to end and leveled up to the required grade, a saw which had the teeth set wide was run down through the joints, cutting out where the boxes did touch the width of the saw set. If this did not make the joint tight it was repeated, often three or four times, until it was tight. Then the bottom piece of the collar being already on the front end of the last box and, the back end of the next box being fitted was spiked down to the collar piece. This held it in position for the man coming behind who put on pieces of 2″x6″ on either side after taking a chisel and making the sides of the joint smooth so that the peices would cover the joint and have a bearing on both boxes, then another piece of 2″x6″ was nailed across the top thus completing the collar. The joints could not be better. It was calculated that while at first a very little water might leak at the joints, they would soon fill up with fine coal, which was found to be the case, the flume not leaking at all now.

The trestles, not being in any places very high, were built of 4″ x 4″ stuff, with simply a cap piece 4 ft. long and two batter posts which were clapped into and "toe-nailed" to the cap piece. Where trestles occur it is intended to box in the flume with boards and fill in with saw dust.

The flume has almost exceeded our expectations. It is working beautifully. It carries over all the coal that is put into it without cost except interest on its construction.

In a few places where the "frost" was not all out of the ground, the flume settled some below the grade line, and would block up to a certain extent and overflow. But since we went over it and put it true to grade it has given us no trouble at all. This is like regulating the little details of machinery or any other mechanical contrivance, but we find that like some of them it is an important detail, and the grade must be set with great accuracy, and nowhere at less than the minimum. And where there is a long stretch of minimum grade we find that, as anticipated, a steeper grade for a short distance with the minimum on either side of it is nearly as bad as one too flat, by tending to cause pulsations in the flow at the bottom of this steep part. This is absent where the grade is uniform, or only compensated very lightly for curvature.

We also find the coarser part of the washed coal, or pieces as large as the end of the finger down to "buckwheat" size, travels the best, seeming to roll over the other and finer part. The most of our coal being fine it is harder to carry than if it were pea coal or buckwheat size. From 40 to 50 per cent. as it comes from the mines (miners are paid R. of M.) would be called "slack" coal in Eastern bituminous markets, and when put through the rolls at the washer, crushes to very fine coal. In fact one can take in his fingers the percentage mentioned above and wash it until it becomes almost as fine as meal. But it is the best coking coal in the State of Montana, and as we believe west of the Allegheny Mountains. It is used almost exclusively by the smelters in Butte City and Helena, and in Idaho. The management is contemplating building 100 more ovens in the very near future, and also to put in a large flume to carry over the lump coal as soon as the lumber can be gotten out.

Of course there must be settling tanks on top of the drying bins. Those in use here are built in pairs, over the bins, 6 ft. wide 6 ft. deep and the length of the bins with an overflow from first to second and from second to discharge spout. They are *not* built *level*, the end at which is the overflow being built 3 or 4 inches lower than the other end, and the second tank lower than the first of each pair. The coal comes from the flume and pours into the first tank. When this tank fills and the water first overflows, it is perhaps ½ full of coal, and the water overflowing from the first to the second, carries with it, in suspension, very fine particles of coal, almost as fine as flour. This will be carried over from the first on account of the turmoil, but will settle in the second, very little if any going out of the second tank. This is nearly as fine as flour, but will make as good coke as any; in fact it is claimed by the yard boss, that the finest specimen of coke coming off the yard was made from some of this very fine coal, put into a can and set in one of the ovens to burn.

The power used in our washer is a Pelton water wheel, the 18 inches No. 3 motor, having a head of 300 feet. This not only runs the machinery of the washer, the crushing, the elevating and the jigs, but supplies almost enough water to carry over the coal in the flume, and to carry off the rock discharge or waste.

The flume on all except the minimum grade was lined with sheet iron to prevent wear. It seems to be something like the "Kodak." You put in the coal and water and the flume "does the rest."

A NEW ELECTRIC COAL DRILL.

A Convenient and Efficient Portable Machine.

The application of electric machinery to mining is becoming more general every day. This is particularly the case in coal mining. Naturally in coal mining the most laborious operation in the getting of the coal is the drilling of the holes for blasting out the coal.

During the past year The Jeffrey Manufacturing Co., of Columbus, Ohio, has made some radical improvements in machinery designed to accomplish this laborious work. An electric power portable drill that is compact, strong and at the same time light enough to enable one man to handle it with ease has long been desired. The drill which we illustrate herewith combines all the best points

Jeffrey Improved Electric Coal Drill.

of the successful electric drills, formerly furnished by The Jeffrey Manufacturing Co., together with a number of new improvements. The motor running the drill is practically the same as on the other style of drill manufactured by The Jeffrey Company. The iron-clad armature, commutator, brush holder and in fact all the electrical parts are encased in a steel box-like casting which protects them thoroughly from mechanical injury and keeps them perfectly clean and dry.

The drill is universally mounted on a single post standard and can be easily turned to point in any direction by the loosening of a single nut. Holes can be drilled at any angle from vertical to horizontal. One of the great advantages of this single post is the increased range of adjustment; for instance, the drill illustrated can be worked in either, a vein 8′ 6″ thick or one 6′ thick, the extension screw covering the difference in height. Another advantage of the single post arrangement is that the drill can be placed much closer to the rib than is possible with any other type of frame. A very important improvement that has been made on this machine is the application of the friction screw feed by means of which the operator is given full control of the speed with which the drill is fed into the coal or material to be drilled. The drill can be fed at any speed from nothing to 9 feet per minute. Another advantage of this form of feed is that it thoroughly protects the drill, both mechanically and electrically, from injury as the feed is controlled entirely by the flexible friction band. The shock to the auger point in striking rock or iron pyrites (sulphur balls) is relieved by the yielding of the friction band allowing the nut to slip slowly, but at the same time continuing work; in other words, the rate of feed is decreased in a perfectly automatic and reliable manner the moment the bit strikes an extraordinarily hard material.

With these drills, as now arranged, there is a small reel carrying 300′ of concentric, rubber insulated, triple braided cable, connected at one end permanently to the reel; the other end having on it clamp hooks for attaching to the main electric conductors in the mine. A light truck having a false bottom in which to carry the extra augers, feed bars and tools is furnished to provide transportation from one part of the mine to another. When the driller finishes work in one room or chamber he places the drill on the truck, on which is also mounted the reel and cable, and pushes it into the next room which is to be drilled. When he gets to the room neck he takes the spring clamps on the end of the cable and hooks them on the main line, the cable on the reel unwinding as he goes along. After setting the drill at the face of the coal in its proper position he takes a short piece of cable, having insulated plugs on each end of it, and places the plugs one in each end of the reel and makes connections for drilling with the end of the cable to the motor. No rheostat or intervening starting apparatus is used. In this manner the operator is practically placed in an automatic position where everything is made for him and he has only to place certain things in certain positions and the machinery does the rest. It is very evident from a close examination of the drill illustrated and this description, that the Jeffrey Manufacturing Co. has devoted a great deal of time, expense and attention to the details of this machine and it is undoubtedly a successful and practical contrivance.

Pointers for Mine Managers.

With this number of The Colliery Engineer and Metal Miner, Messrs. Roberts, Throp & Co., of Three Rivers, Mich., begin an advertisement of a steel mining car wheel made by them. This wheel, which is very light compared with cast iron wheels of equal size, the manufacturers' claim is equal in every way to the severe demands of mining service. This firm also builds light cars of every description, and will gladly furnish full information as to their specialties on application. They have recently been distributing to their trade a very neat and convenient pocket-memorandum book and card case, which they will be pleased to send to mine superintendents and engineers on application, so long as their supply lasts.

The American Injector Co., of Detroit, Mich., begin with this number an advertisement of the U. S. injectors and brass goods made by them. This firm will be pleased to quote prices and give full information to all users of their class of goods in the mining trade, and we bespeak for them a share of the patronage and good-will of the mining fraternity.

The Chicago Fire Proof Covering Co., of 48 Franklin St., Chicago, announce in this issue that they make a special steam pipe covering for mine use, that has met with great favor and which is guaranteed. Well covered steam pipes at mines are not only desirable because they furnish dry steam and higher pressure to the engines, but when the pipes run underground they prevent the heat radiating from the pipe drying out the timber and disintegrating the roof. In fact good mine management demands the use of a good pipe covering both on account of economy and increased safety.

Water Tanks for mine supply are a prime requisite at every well managed mine. Where to get a good cedar tank is often a question that mine managers find hard to answer. The Williams M'f'g. Co., of Kalamazoo, Mich., make a specialty of tanks, and therefore make them cheaper and better than their competitors.

A good chain pulley block is one of the most convenient as well as the most necessary appliances around a well-equipped mine. There are many different varieties, but that style made by the Moore M'f'g. and Foundry Co., of Milwaukee, Wis., is notable for its strength, convenience and ease of operation.

Special Electrical Appliances for Mines.

Although The Ohio Brass Company has but recently made any special efforts to introduce its line of construction material, among mining companies, who are using electricity for traction purposes, yet the results which have so far been obtained are of the most pleasing character.

Among the largest installations recently made on which its material has been used may be mentioned the following: Blossburg Coal Company, Arnot, Pa.; Crozer Coal & Coke Company, Elkhorn, W. Va.; Great Kanawha Colliery Company, Mt. Carbon, W. Va.; St. Clair Company, Eagle, W. Va.; M. I. Davis Company, Eureka, W. Va.; Corona Coal & Coke Company, Corona, Ala.; Card Upson Coal Company, Shawnee, Ohio; Vinton Colliery Company, Vintondale, Pa.; Pulaski Iron Company, Eckman, W. Va.; Monongah Coal & Coke Company, Monongah, W. Va.

Engineering Views.

Engineering Views is the title of an exceedingly handsome album of half-tone view of bridges, blast furnaces, steel works, water works, mine tipples, coke plants, etc., designed by Messrs. Wilkins & Davison, engineers, Westinghouse, B'l'd'g, Pittsburgh, Pa. Though both young men, Messrs. Wilkins and Davison show in this album a scope of work, such as few of the older members of the profession can show. In point of magnitude, the album shows that the firm enjoys the confidence of the leading investors in industrial establishments in western Pennsylvania and Ohio.

Industrial Railways.

The Ansonia Brass & Copper Company, Ansonia, Conn., use industrial railways of 21½ inches gauge, designed by the C. W. Hunt Company, New York. The Thorndike Company, Thorndike, Mass., have also installed the Hunt system of narrow gauge railways for handling materials in their works.

Written for THE COLLIERY ENGINEER AND METAL MINER.

THE DRAINAGE OF FLOODED MINES.

The Self-dumping Water Tanks Used at Luke Fidler Colliery in Removing a Large Body of Water.

(By Baird Halberstadt, E. M.)

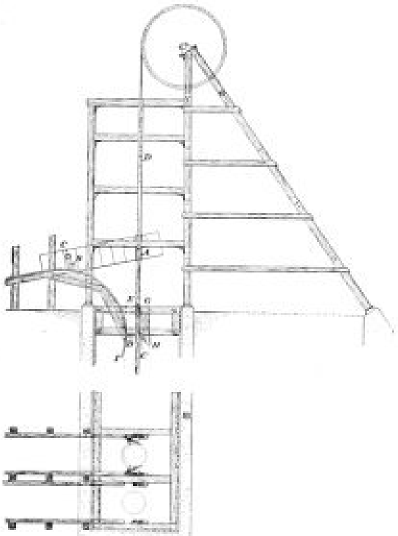
In an article on the fire at the Luke Fidler Colliery, Shamokin, Pa., in the August number of the COLLIERY ENGINEER AND METAL MINER, reference was made to the self-dumping water tanks used to assist in removing the water from the mine after the fire had been extinguished; and a description of them was promised in a later number.

The removal of water from mines by means of specially constructed tanks, as well as by utilizing old boilers or sections thereof, mounted on trucks for use in slopes, is by no means of recent origin. In most of these appliances however, the removal of the contents required from a comparative standpoint, too much time, whether the discharge was through valves either at the bottom or side near the bottom. The time lost, though seemingly short, amounted in twenty-four hours to considerable, and to obviate this a more rapid method of discharge was desired. At the Luke Fidler Colliery this was doubly necessary, since an immense body of water was to be removed, and to put the mine in working order as quickly as possible was of great importance. The conditions here were entirely favorable. The shaft was securely and finely timbered and the new shaft engines were of great power, developing a high rate of speed, yet through modern devices, such as steam brake and reversing appliances, under perfect control.

In the illustration we show the elevation and end view of the tanks now in use at this colliery. They are constructed of iron boiler plates ½″ in thickness. They are twenty feet long and four feet in diameter, with a capacity of 15,500 lbs. or over 1700 gallons each. When lowered to the water, a valve in the bottom of each tank is opened by the weight of the tank striking the water. When the tank it completely submerged, it is full of water, and the weight of this water closes the valve as soon as the hoisting begins.

Instead of discharging from valves either at the side or bottom, these tanks discharge from the top, the whole tipping over as shown and discharging the contents in a few seconds. The tanks are suspended in iron frames fastened at *A*, this frame passes along the guides and serves to keep the lower end of the tank along the guides, the upper part being held by guide wheels *B* and *C*.

The frame extends several feet above the top of the tank. At point *D* a strong bar of iron serves to keep these side bars apart; at the same point the spreader chains from the wire rope are connected. For a short distance below point *E* the guides are cut away. It will



DRAINAGE OF FLOODED MINES.

be noticed that a space is left between point *G* and the guide to permit the passage of the frame, but not sufficient for the guide wheel *C*, which passes through the guide, cut away below *G*. Guide wheel *B* then meets and runs along the T rail *I*, supporting the weight of the tank.

Under ordinary circumstances, the rapid and repeated discharge of so large a body of water would cause, in a short time, a serious washout. To prevent this the tanks discharge their loads into a wooden tank of sufficient size, from which the water is removed through an aperture in the side at the bottom.

From this tank to the creek below, wooden troughs are laid, the fall of the ground being too rapid to permit the water to run over the surface of the ground without serious washouts.

Dependent upon the height of the water in the shaft, these tanks discharged their loads at rates varying from 125 to 75 per hour.

A rate of 100 tanks per hour for thirteen consecutive hours was maintained and in that time 10,075 tons of water were removed.

The plan of hoisting water in tanks is in use at a number of the deep shafts in the region and it is claimed to give better results than could be obtained by pumping. In the matter of cost the advantage is said to be in favor of the tank system.

I wish to acknowledge the courtesy of Mr. Morris Williams, Supt. M. R. R. & M. Co., who planned these tanks, for kindly placing at my disposal the drawings from which the cuts have been made.

WILLIAM D. DODDS.

Almost a week after the terrible hotel disaster in Denver, Colo. in August, the writer was startled and grieved to read in his morning paper that "the body of William D. Dodds, of Albany, N. Y. was taken from the ruins of the Gumry Hotel yesterday. It was identified by a letter found in his pocket from his little daughter in Albany, across which he had endorsed 'Baby's first letter to Papa.' "

Affecting as this was to ordinary readers, it was doubly so to the writer, who was not only personally acquainted with Mr. Dodds, but who was also connected with him in a business way, as he was commissioned to represent THE COLLIERY ENGINEER AND METAL MINER in Colorado. At the time of his death Mr. Dodds had only been in Denver a few days, and had not commenced work.

He was born in Fayetteville, Ind. on January 12, 1854. His early life was spent in Indiana, Pennsylvania and Kansas. He was educated in the public schools, and later was under the private tutorage of his father, who was a Presbyterian clergymen in Topeka, Kansas. Early in life he was dependent on his own exertions, and it may be truly said, he was a self-made man. His first business experience was gained in clerical work. About fourteen years of his life was spent in Colorado and Montana, where he was connected in different capacities

WILLIAM D. DODDS.

with the mining industry. In 1890 he went to Granite, Montana, as assistant superintendent of the famous Granite Mt. Co., and later he became manager of the Elizabeth mine at Granite.

On August 31st, 1891 he married Miss Effie Russell Buck, of Albany, N. Y. who with one daughter, the "baby" whose little letter identified her father's body, survives him.

During the business depression in 1893, when silver mining came to a standstill, he with his family came east to Albany. In October of that year he accepted the position of superintendent of the Santa Lucia Mining and Milling Co's. mines in Honduras, Central America, where he remained one year. Upon his return to the United States he was employed by The Colliery Engineer Co. to assist in preparing Instruction Papers on gold and silver mining for The Correspondence School of Mines. This work was completed a short time before his death. After the completion of this work, he decided to go to Colorado and visit the principal mining camps with a view to seeking a location. While travelling through the State, he expected to act as a special agent for this journal. He was a man of very industrious habits, and in connection with his active work, was a deep student. Inside of two years he almost finished the Full Mining Course in The Correspondence School of Mines, and acquired a practical knowledge of the German and Spanish languages.

His moral character was above reproach. A consistent member of the First Presbyterian church of Albany, he rigidly adhered to the high moral standard expected of members of that denomination.

Written for THE COLLIERY ENGINEER AND METAL MINER

Ventilating Fans.

(By F. W. Sperr, Michigan Mining School.)

In Vol. XX. Transactions of the American Institute of Mining Engineers, pp. 642-3, Mr. R. Van A. Norris has published a table, giving the volumes of air delivered by a large number of different fans at various velocities. The results serve the interesting purpose of helping to ascertain the law of variation between the radial velocity of the air and the number of revolutions of the fan. If we let n represent the number of revolutions of the fan per unit of time and V the volume of air delivered, V will vary as some power of n, the general equation being $n_1^x : n_2^x :: V_1 : V_2$.

The radial velocity of the air varies as the volume. Then, for No. 1 fan, A and B, $84^x : 100^x :: 236.684 : 336,862$; and therefore, $X \log. 84 + \log. 336862 = X \log. 100 + \log. 236.684$.

$$\therefore X = \frac{\log. 336,862 - \log. 236,684}{\log. 100 - \log. 84} = 2.02$$

$$B \text{ and } D,\ X = \frac{\log. 347,396 - \log. 336,862}{\log. 111 - \log. 100} = .29.$$

$$D \text{ and } E,\ X = \frac{\log. 394,100 - \log. 347,396}{\log. 123 - \log. 111} = 1.23.$$

Average value of X for the double fans = 1.18.

For F and G, the single fan

$$X = \frac{\log. 247,876 - \log. 188,888}{\log. 130 - \log. 100} = 1.48.$$

$$\text{No. 2, } A \text{ and } B,\ X = \frac{\log. 82,969 - \log. 59,587}{\log. 83 - \log. 59} = .97.$$

$$\text{No. 3, } A \text{ and } B,\ X = \frac{\log. 137,760 - \log. 49,611}{\log. 70 - \log. 40} = 1.82.$$

For No. 4 fan we have only one observation published, and no comparison can be made.

$$\text{No. 5, } A \text{ and } B,\ X = \frac{\log. 147,232 - \log. 68,337}{\log. 50 - \log. 28} = 1.32.$$

$$B \text{ and } C,\ X = \frac{\log. 205,761 - \log. 147,232}{\log. 69 - \log. 50} = 1.04.$$

$$C \text{ and } D,\ X = \frac{\log. 299,600 - \log. 205,761}{\log. 96 - \log. 69} = 1.14.$$

Average value of X = 1.17.

$$\text{No. 6, } A \text{ and } B,\ X = \frac{\log. 92,160 - \log. 66,560}{\log. 100 - \log. 80} = 1.46.$$

$$B \text{ and } C,\ X = \frac{\log. 109,440 - \log. 92,160}{\log. 120 - \log. 100} = 1.19.$$

Average value of X = 1.32.

There is but one observation published for No. 7 fan, and one for No. 8.

$$\text{No. 9, } A \text{ and } B,\ X = \frac{\log. 277,380 - \log. 234,830}{\log. 55 - \log. 46} = 0.93.$$

$$\text{No. 10, } A \text{ and } B,\ X = \frac{\log. 194,200 - \log. 134,602}{\log. 73 - \log. 66} = 3.63.$$

$$\text{No. 11, } A \text{ and } B,\ X = \frac{\log. 215,200 - \log. 177,280}{\log. 180 - \log. 150} = 1.06.$$

$$\text{No. 11½, } A \text{ and } B,\ X = \frac{\log. 257,520 - \log. 217,338}{\log. 50 - \log. 45} = 1.61.$$

$$\text{No. 13, } A \text{ and } B,\ X = \frac{\log. 57,120 - \log. 28,896}{.301030} = .98.$$

$$B \text{ and } C,\ X = \frac{\log. 66,640 - \log. 57,120}{.096910} = .87.$$

$$C \text{ and } D,\ X = \frac{\log. 73,080 - \log. 66,640}{\log. 30 - \log. 25} = .50.$$

$$D \text{ and } E,\ X = \frac{\log. 94,080 - \log. 73,080}{\log. 35 - \log. 30} = 1.26.$$

$$E \text{ and } F,\ X = \frac{\log. 112,000 - \log. 94,080}{\log. 40 - \log. 35} = 1.30$$

$$F \text{ and } G,\ X = \frac{\log. 132,700 - \log. 112,000}{\log. 50 - \log. 40} = .76.$$

$$G \text{ and } H,\ X = \frac{\log. 173,600 - \log. 132,700}{\log. 60 - \log. 50} = 1.47.$$

$$H \text{ and } I,\ X = \frac{\log. 203,280 - \log. 173,600}{\log. 70 - \log. 60} = 1.02.$$

$$I \text{ and } J,\ X = \frac{\log. 222,320 - \log. 203,280}{\log. 80 - \log. 70} = .67.$$

Average value of X = .87.

No. 14 and 15 have but one observation published for each.

$$\text{No. 16, } A \text{ and } B,\ X = \frac{\log. 117,573 - \log. 84.149}{\log. 80 - \log. 58} = .32.$$

$$\text{No. 17, } A \text{ and } B,\ X = \frac{\log. 98,512 - \log. 85,285}{\log. 80 - \log. 70} = 1.08.$$

$$B \text{ and } C,\ X = \frac{\log. 107,300 - \log. 98,512}{\log. 90 - \log. 80} = .73.$$

Average value of X for No. 17 fan = .90.

$$\text{No. 18, } A \text{ and } B,\ X = \frac{\log. 29,498 - \log. 17,640}{\log. 52 - \log. 26} = .74.$$

$$B \text{ and } C,\ X = \frac{\log. 51,842 - \log. 29,498}{\log. 104 - \log. 52} = .81.$$

Average value of X for No. 18 fan = .78.

The observations on No. 19 fan were not fairly made, as explained in the note, and we shall not consider them here.

The observations on No. 20 fan were made on different mine orifices, and, therefore, do not answer the purpose in hand.

$$\text{No. 21, } A \text{ and } B,\ X = \frac{\log. 201,135 - \log. 177,855}{\log. 110.8 - \log. 88.6} = .55.$$

The average value of X for all these observations is 1.14, and it will probably be found to be unity by more extended and careful determinations; or, in other words, the radial velocity of the air varies as n.

EXAMINATION QUESTIONS ANSWERED.

THE EXAMINATION OF CANDIDATES FOR CERTIFICATES AS MINE FOREMEN,

Held in the Office of the State Mine Inspector at Birmingham, Alabama on October 26th and 27th, 1894.

(Continued from July, 1895.)

QUES. 22. What is the safe working load of a steel rope $1\frac{1}{8}$ inches in diameter?

ANS. Multiply the square of the diameter of the rope in inches by 9.4, and the result will be the safe working load in tons, as $\frac{9}{8} \times \frac{9}{8} \times 9.4 = 12$ tons nearly.

QUES. 23. What is the pressure per square foot at the foot of a stand pipe filled with water to a height of 105 feet?

ANS. As a cubic foot of water weighs 62.5 pounds, the pressure must be, $62.5 \times 105 = 6562.5$ pounds per square foot.

QUES. 24. If a water-gauge of 2 inches passes 15,000 cubic feet of air per minute, what water-gauge will pass 30,000 cubic feet per minute in the same air-way?

ANS. As the air-way is the same, a double quantity will be the result of doubling the velocity, and as the pressures vary as the squares of the velocities, the water-gauge will be $\frac{30,000^2}{15,000^2} \times 2 = \frac{30^2}{15^2} \times 2 = \frac{6^2}{3^2} \times 2 = \frac{2^2}{1^2} \times 2 = 8$ inches of water-gauge for the increased quantity.

QUES. 25. If two horse-power passes 14,000 cubic feet of air per minute, how much must the power be increased to double the quantity?

ANS. In the same air-way, the powers vary as the cubes of the quantities; and as the quantity has to be doubled the power in the second case must be as the cube of 2 multiplied by 2 the power for 14,000 as $2^3 \times 2 = 8 \times 2 = 16$ horse-power to circulate $14,000 \times 2 = 28,000$ cubic feet of air in the second case given.

QUES. 26. If you have two air-ways under the same pressure, one $6' \times 6' \times 5,000'$, the other $8' \times 4\frac{1}{2}' \times 5,000'$, which will pass the greater quantity and why?

ANS. Call the air-way $6' \times 6'$ A, and the other $8' \times 4\frac{1}{2}'$ B, then as the areas of section are both equal to 36 square feet and the lengths are both 5,000 feet it follows that the airway that encloses one of the equal areas with the largest perimeter, will offer the greatest resistance; and as the velocities (or quantities in this case) vary as the square roots of the resistances inversely, and as B's perimeter is larger than A's, if A's quantity is 1, that of B must be $\sqrt{\frac{p}{P}} = q$, taking A's perimeter as p and B's perimeter as P and B's quantity as q or, $\sqrt{\frac{(6+6+6+6)}{(8+8+4\frac{1}{2}+4\frac{1}{2})}} = \sqrt{\frac{24}{25}} = .97985.$

QUES. 27. What is the horse-power of an engine, the cylinder being $15''\times20''$ running 175 revolutions per minute, the effective steam pressure being 60 pounds per square inch?

ANS. If the total pressure on the piston in pounds per square inch, be multiplied by the piston speed in feet per minute, the result will be the units of work per minute done by the engine, and if the units of work per minute are divided by the units of work in one horse-power that result will be the answer required, namely, the horse-power of the engine; as

$$\frac{(15 \times 15 \times .7854 \times 60) \times 20 \times 2 \times 175}{33,000 \times 12} = 187.42 \text{ or}$$

187.42 H. P. the answer required.

QUES. 28. Your main-entry from bottom of second shaft runs due north 3,600 feet. A cross-entry is started due east at a distance of 200 feet from the face and driven 2,465 feet. What length of roadway started 250 feet from shaft will be required to connect with the face of the cross-entry?

ANS. The base of the right angle triangle in this case measures 3600 feet, minus the distance from the face plus the distance from the shaft, that is $200 + 250 = 450$, then $3600 - 450 = 3150$. The perpendicular of this triangle is 2465 feet, then

$\sqrt{2465^2 + 3150^2} = 3999$ feet nearly, the length of the roadway required.

QUES. 29. In approaching an abandoned mine filled with water, 400 feet deep, how large a pillar would you leave to be safe, the seam being 7 feet thick?

ANS. In a soft bituminous seam 7 feet thick, and at a depth of 400 feet I would leave a barrier pillar 95 feet, or $31\frac{2}{3}$ yards thick.

In the anthracite region of Pennsylvania, the accepted rule for the thickness of barrier pillars, is: Multiply the thickness of the workings (in feet), by one per cent. of the depth from water level (in feet), and add to this product, 5 times the thickness of the workings (in feet) and the result is the thickness of the barrier pillar in feet. For a soft bituminous coal, $1\frac{1}{2}$ time the thickness provided by the anthracite rule has been taken.

QUES. 30. A shaft employes 800 men, 85 day hands, and 35 mules. How many cubic feet of air per minute would be required according to law?

ANS. The provisions of the State of Alabama Mining Law, Section 24, read as follows: "Be it further enacted; That the owner, agent or operator of every coal mine, whether worked by shaft, slope or drift, shall provide and hereafter maintain for every such mine sufficient ventilation for each and every person employed in such mine, which shall be circulated around the main headings, cross headings and working places to an extent that will dilute, render harmless and carry off noxious and dangerous gases generated therein." Where no gas is generated we would therefore allow as a minimum 100 cubic feet of air per man employed in the mine, and per mule 300 cubic feet, therefore under these conditions the total would be

800 at 100 per man	80,000
85 at 100 per man	8,500
35 mules at 300 per head	10,500
Total	99,000

If the mine generated much gas, I would allow 300 cubic feet of air per minute per man, as

800 at 300 per man	240,000
85 at 300 per man	25,500
35 mules at 900 per head	31,500
Total	297,000

QUES. 31. When rooms are to be driven from the entry at an angle of 45°, what distance must they measure from center to center in the entry, to make the rooms 25 feet in width, and leaving between them pillars 15 feet thick?

ANS. Divide the breadth of the room and pillar by the sine of the angle the room and the pillar makes with the entry, and the result will be the distance between the rooms center and center as $\frac{(25+15)}{\sin 45°} = \frac{40}{.7071} = 56.561$ feet; or the opening of the room by the side of the entry is $\frac{25}{.7071} = 35.348$ feet, or the measure of the pillar along the side of the entry is $\frac{15}{.7071} = 21.213$ feet.

QUES. 32. How many gallons of water will a circular shaft 8 feet in diameter, and 16 feet deep contain, and how long will it take an 8-inch pump having a velocity of 100 feet per minute to empty it?

ANS. The contents of the shaft are

$8 \times 8 \times .7854 \times 16 \times 7.48 = 6015.787$ gallons, and the time occupied by the pump in emptying the shaft will be found as follows: Let 8 inches equal $\frac{2}{3}$ of a foot, then, $\frac{8 \times 8 \times .7854 \times 16}{\frac{2}{3} \times \frac{2}{3} \times .7854 \times 100} = 23.04$ minutes, or the shaft would be emptied in 23.04 minutes.

QUES. 33. How many 2-inches pipes will it take to supply an 8-inch pipe?

ANS. The pipes are supposed to be equal in length, for no lengths are given, and as the velocities vary as the square roots of the resistances inversely, it follows that the velocity through the small pipe will only be equal to

$$\sqrt{\frac{8 \times 3.1416}{8 \times 8 \times .7854} \div \frac{2 \times 3.1416}{2 \times 2 \times .7854}} = \sqrt{\tfrac{1}{2} \div \tfrac{2}{1}} = \tfrac{1}{2}.$$

The velocity then through the 2-inch pipe, will be $\frac{1}{2}$ of that through the 8-inch pipe, and as 16 two-inch pipes have a joint area of 64 circular inches, and one 8-inch pipe has an area of 64 circular inches, it is clear that as the velocity through the 2-inch pipes is only $\frac{1}{2}$ of that through the 8-inch pipe, it will require 32 two-inch pipes to supply an 8-inch pipe.

Mine Foremen's Examination in the Bituminous Fields of Pennsylvania, Jan. 22, 1895.

QUES. 1. Write an essay in detail explaining the use of dynamite in blasting. Is frozen dynamite fit for use? If so, or if not, say how you would treat it?

ANS.—Dynamite is one of the strongest explosives used for blasting in mines, and is a *shattering* compound contrasted with gun-powder, or blasting-powder. The latter is a *rending* explosive preferred for breaking coal. The efficiency of dynamite for breaking stone depends on the correct adjustment of the diameter of the shot hole, the position of the drill hole in reference to joints in the rock, and the best angle that the axis of the hole should make with the plane of the face.

The weights of the cartridges require adjusting to the work to be done, and the blaster should understand that the weights of the charges in ounces should be proportionate in inches to the cubes of the lengths of the lines of the least resistances in the rock to be broken. Detonators should either be of sufficient strength to fire every cartridge used, or detonators should be provided for cartridges of greater and lesser weights or otherwise primer cartridges should be used to fire the large cartridges. Great care must be taken in fixing the detonator within the end of the plug of dynamite or in securing the detonator to the end of the cartridge, so that it may not be dislodged during the progress of stemming; further, if the firing is by electricity, then judicious care must be taken not to use such stemming as consists of angular particles of hard stone with sharp cutting edges, otherwise they cut through the insulation, and either short circuit the current or cause leakages; and in either case the chances of misfires are increased in number.

The stemming should be done with rough round sand, or clay for upward or side holes; water will often be sufficient for downward holes in wet ground.

Detonators are sometimes fired with powder thread fuses, but oftener by electricity. In electric firing, care must be taken to use just such magneto-electric machines, as supply a current of sufficient strength to fire a given number of shots simultaneously in circuit.

Frozen dynamite is dangerous to handle, as the tritrition of its particles is sufficient to explode it; it therefore should be kept warm or at a temperature equal to that of the human body. In the event of its being frozen, it should be warmed by being placed near a hot water pipe or steam pipe, but it should never be heated beside a body whose temperature exceeds 212° F.

QUES. 2. Is machine mining safe when the mines are dry and produce firedamp? Is it safe to use electric motors in machine mining? and do you think machine mining is safe where there is no gas?

ANS. When the mines are dry and produce fire-damp, machine mining is no more unsafe than when mining is done by ordinary methods. Compressed air cannot be a source of danger, nor can electricity, for all sparking can be prevented by using alternating currents, and polyphase motors that are absolutely sparkless, as there are no commutators and it is impossible, from the design of these machines, for them to produce a spark; therefore the three points in the question are answered by saying: No increase of danger can arise in mines that are dry and produce fire-damp, by using machines for mining. It is quite safe to use electric polyphase motors actuated by alternating currents for machine mining.

There is nothing in machine mining that can be a source of danger when the roof and the floor will allow the machine to cut along a timberless face.

QUES. 3. What would you consider a good grade for a haulage road and a water way?

ANS. A fall to the shaft or slope of 1 in 150, would be a good grade for a haulage road or a water way in a bituminous mine.

QUES. 4. A circular sump 20 feet in diameter and 25 feet in depth, is full of water. What is the quantity in gallons and cubic feet? If a double acting steam pump, with a water cylinder 9 inches by 18 inches was set to pump, how many strokes would be necessary to empty the sump?

ANS. The cubic feet of water in the sump are $.7854 \times 20 \times 20 \times 25 = 7854$ cu. ft. The gallons of water in the sump are $7854 \times \frac{1728}{231} = 58,752$ gallons. The theoretical number of cubic inches of water discharged at each single stroke of the pump is $.7854 \times 9 \times 9 \times 18 = 1145.1132$, and allowing 10 per cent. for the slip of the pump, the actual number of cubic inches of water discharged by each stroke is $1145.1132 \times .9 = 1030.60188$, and the number of single strokes of the pump to empty the sump is $\frac{7854 \times 1728}{1030.6} = 13168.84.$

QUES. 5. A bore-hole from the surface is 6 inches in diameter and enters a rib fall in the mine. A mixture of 50 per cent. CH_4 and 50 per cent. of air is passing up the hole with a velocity of 130 feet per minute. What is the volume in cubic feet? and what would be the volume if sufficient air was added to bring the mixture up to the highest explosive point?

ANS. In the first case the volume passing up the bore-hole is equal to $\frac{.7854 \times 6 \times 6 \times 130}{144} = 25.5255$ cubic feet per minute.

In the second case, 9.5 parts of air to one of CH_4 is the maximum explosive mixture, and as the mixture already consists of equal volumes of gas and air; the unit volume of the gas is $\frac{25.5255}{2} = 12.76275$ cubic feet; the volume of air required will be $12.76275 \times 9.5 = 121.246125$, and the volume demanded that contains sufficient air and gas to make the maximum explosive mixture, is equal to $12.76275 \times 10.5 = 134.008875$ cubic feet of a mixture of 9.5 of air to 1 of gas or CH_4.

QUES. 6. If the bore-hole in the above question was allowed to remain closed up for 12 hours what would be the volume of the gas at the end of the time, and what would the volume be if sufficient air was added to make a maximum explosive mixture, and what volume of air should be added to the gas to make it a harmless mixture?

ANS. The volume of fire-damp CH_4, that would accumulate in 12 hours would be equal to, $12.76275 \times 60 \times 12 = 9189.18$ cubic feet. The volume of the maximum explosive mixture of 9.5 of air to one of gas, would be equal to $9189.18 \times 10.5 = 96486.39$ cubic feet.

To make the mixture harmless, I would mix 30 of air with one of gas, and therefore the air required to make 9189.18 cubic feet of CH_4 perfectly safe would be $9189.18 \times 30 = 275675.4$ cubic feet.

QUES. 7. What would be the cost of an overcast containing the following material, and having spent on it for labor the following amounts?

6½ cubic yards of stone at	$1.05	per yard
5,250 bricks at	6.25	per thousand
35 bushels of lime at	.0775	per bushel
70 bushels of sand at	.0625	per bushel
10 days masonry at	2.25	per day
10 days attending masonry at	1.60	per day
37 days taking down slate and delivering material at	1.50	per day

ANS.—

6½ cubic yards of stone at $1.50 per yard	$ 4.9250
5250 Bricks at $6.25 per thousand	32.8125
35 bushels of lime at .0775 per bushel	2.7125
70 bushels of sand at .0625 per bushel	4.3750
10 days masonry at $2.25 per day	22.5000
10 days attending masonry at $1.60 per day	16.0000
37 days taking down slate and delivering material at $1.50 per day	55.5000
The cost of the overcast will be	$138.72½

QUES. 8. What are the indications sometimes met with at the face of working places, which should serve as a warning that you are approaching old workings, and what precautions would you take to provide for security and safety under the circumstances?

ANS.—In approaching old workings containing water and gas at a high pressure, water is seen running out above and beneath, and through the coal. When the old workings do not contain water, the danger arising from gas is considerable, as the danger is on you unexpectedly, and when the old workings contain water not more than roof high, the danger is very great, because the water seldom gives warning.

Whether the old workings give warning by bleeding or not the Act relating to The Bituminous Coal Mines of Pennsylvania, provides by Section 3, Article V.

"In any place that is being driven towards, or in dangerous proximity to an abandoned mine or part of a mine suspected of containing inflammable gases or which may be inundated with water, boreholes shall be kept not less than twelve (12) feet in advance of the face and on the sides of such working places, said side holes to be drilled diagonally not more than eight (8) feet apart; and any place driven to tap water or gas shall not be more than ten (10) feet wide, and no water or gas from an abandoned mine or part of a mine and no borehole from the surface shall be tapped until the employes except those engaged at such work are out of the mine, and such work to be done under the immediate instruction of the mine foreman."

Should the proximity of the old workings be unknown and water is bleeding out of the advancing face, then no further advance should be made without boring according to the provisions of Section 3.

[TO BE CONTINUED.]

This department is intended for the use of those who wish to express their views, or ask, or answer, questions on any subject relating to mining. Correspondents need not hesitate to write for any fancied want of ability. If the ideas are expressed, we will cheerfully make any correction in composition that may be required. Communications should not be too lengthy, and personal reflections should be carefully avoided.

All communications should be accompanied with the proper name and address of the writer—not necessarily for publication, but as a guarantee of good faith.

The Editor is not responsible for views expressed in this Department.

☞ Correspondence should be in as simple language, and as free of technical terms and formulæ as possible, consistent with clear solution.

Questions on subjects not directly connected with mining will not be published.

Correction.

Editor Colliery Engineer and Metal Miner:

SIR:—Answer (2) to questions asked by A. P. Smith, Chico, Mont., published in your July issue should have been supplemented with the following:

This is the theoretical velocity and orifice necessary to discharge the required quantity, but in consequence of the contraction of the stream a short distance from the orifice, the velocity of efflux is slightly reduced from the theoretical value, and the quantity discharged is greatly reduced, friction also reduces the speed. In order to allow for these losses Budge gives the following rule:

$$D = 0.497 \sqrt[5]{\frac{L \times W^2}{H}} = 23.35'' \text{ diam. of pipe} = 20.7''$$

square flume.

D = Diameter of pipe in inches.
H = Head of water in feet.
L = Length of pipe in feet.
W = Cubic feet of water discharged per minute.

Eytelwein's formula gives $D = 0.538 \sqrt[5]{\frac{L \times W^2}{H}} =$ 25.29″ diam. of pipe = 22.5″ square flume.

Hoping that you will make this correction. I am

Yours etc.,
STEPHEN H. NORTHEY.

The 5th Root.

Editor Colliery Engineer and Metal Miner:

SIR:—Please insert the following in your valuable paper in answer to question given by A. McDonald, Port Morien, in your August, 1895 issue.

The following is the formula worked out showing the method employed to extract the 5th root of a number.

Then let $(3)^{\frac{2}{5}} = \sqrt[5]{3^2} = \sqrt[5]{9} = \sqrt[5]{9.0000000000}$ 1.55+

```
                                   1
         5×10⁴ = 50000     800000
     10×10³×5 = 50000
     10×10²×5² = 25000
      5×10×5³ = 6250
           5⁴ =   625      659375
              131875 | 14062500000
  5×150⁴        = 2531250000
  10×150³×5²  =  168750000
  10×150²×5³  =    5625000
   5×150×5³   =      93750
        5⁴   =        625   13528596875
          2705719375 |      533903125
```

In the above the root is only extracted to two decimal places, but by a continuation of the above it can be be extended to the required number.

Yours etc.,
ARCHIE LAFFERTY,
Wampum, Pa.

PRIZE CONTEST.

PRIZES GIVEN FOR THE BEST ANSWERS TO QUESTIONS RELATING TO MINING.

For the best answer to each of the following questions, the value of $1.00 in any of the books in our book catalogue, or six months' subscription to THE COLLIERY ENGINEER AND METAL MINER.

For the second best answer to each question, the value of 50 cents in any of the books in our book catalogue, or three months' subscription to THE COLLIERY ENGINEER AND METAL MINER.

Both prizes for answers to the same question will not be awarded to any one person.

Conditions.

First—Competitors must be subscribers to THE COLLIERY ENGINEER AND METAL MINER.

Second—The name and address in full of the contestant must be signed to each answer, and each answer must be on a separate paper.

Third—Answers must be written in ink on one side of the paper only.

Fourth—"Competition Contest" must be written on the envelope in which the answers are sent to us.

Fifth—One person may compete in all the questions.

Sixth—Our decision as to the merits of the answers shall be final.

Seventh—Answers must be mailed us not later than one month after publication.

Eighth—The publication of the answers and names of persons to whom the prizes are awarded shall be considered sufficient notification. Successful competitors are requested to notify us as soon as possible as to what disposal they wish to make of their prizes.

Competition Questions for October.

QUES. 181. I am about to invent a new miner's safety lamp, and I intend to make the capacity of the tank or oil vessel large enough to supply sufficient vegetable oil for a consumption of 8 cubic inches per day of 10 hours, and as I require your valuable assistance, will you answer me three questions, as follows:?

1. What volume of air will be required to supply the necessary oxygen to burn the oil?

2. If only 20 per cent. of the oxygen of the air entering the lamp is consumed, what volume of air is necessary to feed this flame?

3. If, after allowing for the *vena contracta* and the interference of the wires, the available aperturage is in the ratio of .3, and if the velocity of the air on entering is equal to 3 feet per second, how many square inches of gauze covered entrance must I provide for the admission of air?

QUES. 182. We have found a large fault in one of our coal seams, and the cheeks or sides are 6 inches apart, and the interspace or vein is filled with calcite and galena. Our mine foreman says that galena always contains gold and silver, and his statement has so excited me with surprise that I have been trying to extract the metal by raising the ore to a high heat on an open fire, but it all wasted away in white smoke. I will, therefore, be obliged to you if you will tell me what I must do to obtain about seven pounds of the metal, and while you are busy please say what I must do to separate the silver from the lead.

QUES. 183. We have 1,000 acres of a seam of good and clean coking coal, 2 feet, 10 inches thick, and at an average depth from the surface of 600 feet: the roof consists of 30 inches of bad shaley coal, or bone; the mean inclination or dip of the seam is 4° 15′ to the east. How do you think I should work this seam to obtain all the coal, as I can only sink the shafts on the western side of the estate, the eastern side being all under water?

QUES. 184. I am engaged by a powerful syndicate to be the chief of a large staff of prospectors to search for useful minerals in Asiatic Turkey, and my instructions are to confine the work to be done to the valleys of the great rivers, the Euphrates and the Tigris, and the valleys of their tributaries, the reason for the restriction being, that the country is not opened up with railways, and therefore the water-ways are the only routes open for transport. In the North of Asia Minor where the great rivers take their rise the stratified rocks belong to the Cenozoic period, and nearly all the exposed rocks found in the valley of the Levant belong to the Mesozoic period such as those that are found on the east of the Tigris and the west of the Euphrates, and between the great rivers, as west of the Tigris and east of the Euphrates, the rocks are mostly of the Eozoic age, although rocks of later ages are found in patches. Now the great stone records of Babylon and Nineveh are cut on slabs of gypsum taken from their near hand quarries, and I will be obliged if you will give me such information as I require.

First.—We know that salt, coal, lignite, copper, lead, silver, gold, and iron abound within the rocks of the valley of the Levant, then please tell me where to send my men to search for them.

Second.—Tell me briefly what class of tools I ought to give each set of prospectors to find the particular minerals they will be sent in quest of?

QUES. 185. As I am anxious to obtain a good example of a magnetic survey. Will you give me your notes of one where the figure only has seven sides, also the plot, and the results of the traverse to prove its accuracy?

QUES. 186. We have a pump that forces with two six inch plungers the drainage water of the mine to an elevation of 660 feet. From the commencement this pump had a heavy "knock" and it was found to occur at the moments when the plungers began their advance on the forcing stroke and it seemed to result from the chambers not being filled close with water during the suction or intake stroke, and the consequence was the knock by the plunger advancing on the force, and the heavy strain that destroyed the packing of the glands and ultimately the "skin" of the plungers that became scored and fluted. Some mechanical engineers declared that the cause of the knock was the softness of the iron plungers that became fluted and leaky, and that the only cure would be in getting nickel steel or bronze plungers; our engineer, however, thought differently and said the only cure would be found in soaking the glands and drowning them with water. He then fixed cases over the outsides of the glands and filled them with water when the knock was completely cured. Will you then explain to me the cause of the knock and how or by what means it was cured by drowning the glands?

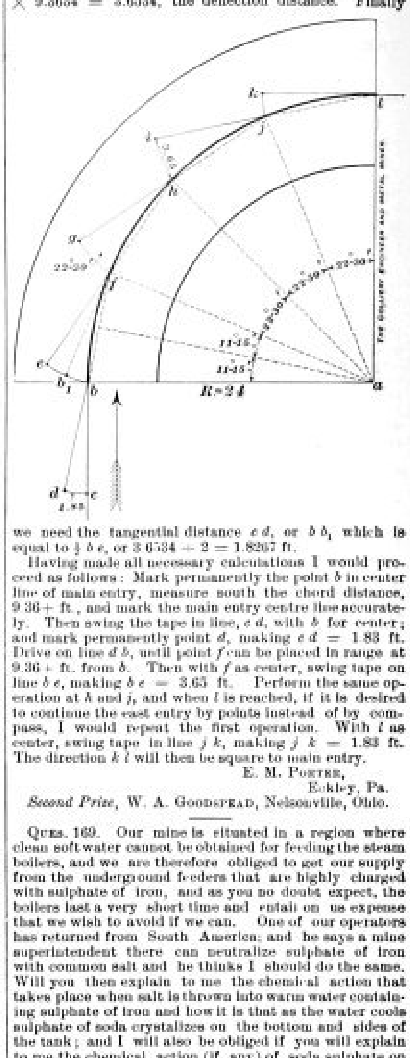
Solutions to Questions which Appeared in the August Number, and for which Prizes Have Been Awarded.

QUES. 166. For an extension of the haulage in a coal seam we are about to make a branch road going due east from the main entry and going due north from the shafts. Now the junction of the branch road with the main road has to be done with a curve of 24 feet radius, and as I would like to show off a bit with this curve, will you give me a plan showing how to set up the center lines with chords, and the fewest angular measurements required for a complete quadrant, the curved road being 12 feet wide?

ANS. To plan the road without the aid of a transit instrument, I would draw it to a large scale, say 1 inch to 10 feet, and divide the quadrant into four equal parts of 22° 30′ each. This is the least number of *equal* parts into which it may be divided for the purpose.

The chord of each arc, as $b\,f$, $f\,h$, etc., will be two times the sine of ½ the angle multiplied by radius, or 9.3634 ft.

The deflection distances, $b\,e$, $f\,g$ and $h\,i$, are equal to two times the sine of ½ the angle $b\,f\,e$ multiplied by $b\,f$. The angle $b\,f\,e$ being equal to the central angle $b\,a\,f$, then we have ½ $b\,f\,e$ = 11° 15′. Twice the sine of 11° 15′ × 9.3634 = 3.6534, the deflection distance. Finally



we need the tangential distance $c\,d$, or $b\,b_1$ which is equal to ½ $b\,e$, or 3.6534 ÷ 2 = 1.8267 ft.

Having made all necessary calculations I would proceed as follows: Mark permanently the point b in center line of main entry, measure south the chord distance, 9.36+ ft., and mark the main entry centre line accurately. Then swing the tape in line, $c\,d$, with b for center; and mark permanently point d, making $c\,d$ = 1.83 ft. Drive on line $d\,b$, until point f can be placed in range at 9.36+ ft. from b. Then with f as center, swing tape on line $b\,e$, making $b\,e$ = 3.65 ft. Perform the same operation at h and j, and when l is reached, if it is desired to continue the east entry by points instead of by compass, I would repeat the first operation. With l as center, swing tape in line $j\,k$, making $j\,k$ = 1.83 ft. The direction $k\,l$ will then be square to main entry.

E. M. PORTER,
Eckley, Pa.

Second Prize, W. A. GOODSPEAD, Nelsonville, Ohio.

QUES. 169. Our mine is situated in a region where clean soft water cannot be obtained for feeding the steam boilers, and we are therefore obliged to get our supply from the underground feeders that are highly charged with sulphate of iron, and as you no doubt expect, the boilers last a very short time and entail on us expense that we wish to avoid if we can. One of our operators has returned from South America; and he says a mine superintendent there can neutralize sulphate of iron with common salt and he thinks I should do the same. Will you then explain to me the chemical action that takes place when salt is thrown into warm water containing sulphate of iron and how it is that as the water cools sulphate of soda crystalizes on the bottom and sides of the tank; and I will also be obliged if you will explain to me the chemical action (if any) of soda sulphate on the shell of the boiler.

ANS. The chemical action to which the question refers proceeds as follows:

$$Fe\,SO_4 + 2\,Na\,Cl = Na\,SO_4 + Fe\,Cl_2.$$

Soda sulphate then remains in solution in the hot water and crystallizes from saturation, as when the water cools. Sulphate of soda produces no injury on the shell of the boiler, but does good in removing lime scale.

J. JENKINS,
Dingess, W. Va.

Second Prize, J. VIRGIN, Holsopple, Pa.

QUES. 170. A wealthy land owner has just granted me a lease to mine a lignite bed 10 feet thick and making an angle 70° with the plane of the horizon. The lease confers on me the right of way and the power to utilize any of the surface or underlying strata. The surface is on a bed of sand 20 feet thick and at first sight that would appear to be an unfavorable condition, but the lignite coal is good, and can secure an open market at a high price; we have however certain difficulties that must be overcome in the mode of working; for example, this coal is exceedingly subject to spontaneous ignition, and any small in the gob, or pillars left in, takes fire as soon as subjected to increased pressure. Therefore we must extract the *whole* of the coal, and I wish you to instruct me how to do it with the use of very little timber, at a small cost per ton, and with safety to the miners. To secure a good plan, think over all the modes of *vein* and *bed* mining in general use.

[None of our friends are even approximately right with this question, and many give evidence in their answers that they have not carefully read the question before answering it, as "any small in the gob or *pillars* left in, takes fire." Had they noticed this, they could not have given us their pillar system. Try! try!! try again. ED.]

QUES. 171. I am the principal director of a mining company, and we have the choice of one of two mine properties, and in either of which, we could work the same valuable seam of bituminous coal at a depth of 900 feet. There are two seams of coal overlying the one we wish to work and we will call the bottom one No. 3, and the one above it is No. 2, and the top one No. 1. All the seams are lying level and their depths are, No. 1, 450 feet; No. 2, 630 feet; and No. 3, 900 feet. Between Nos. 1 and 2, is a bed of coarse sandstone that sheds much water, and in one of the offered properties *A*, the top seam has been all worked out, but in the other property *B*, none of the seams have been worked. I will therefore deem it a great favor if you will say which of the properties *A* or *B* would be the safest investment, and for what reasons?

ANS. The property *A* is of very little commercial value because by working out the top seam first, the cover is broken and the natural arch over the seam 3 is therefore now a doubtful roof. Even, although the No 2 and 3 seams in *A* may be thicker than those of *B*, the latter will be the best investment, because the bottom or No. 3 seam can be worked first with safety, with a cover of 900 feet in thickness. Second, No. 2 and No. 1 can then be worked together, and No. 3 will make an excellent sump or lodgement for the water of the sand feeder.

WM. A. THOMAS,
Nanticoke, Pa.

Second Prize, JOHN FLETCHER, 428 Tonti St., La Salle, Ill.

QUES. 172. In prospecting for coal, rotary tube boring is the best, because the cores furnish fine examples of the fossils peculiar to the strata in question. This being so, will you tell me the names of some of the fossils peculiar to Permian and Silurian rocks; for example, suppose you are boring in a bed of fine shale, and the core when broken shows a featherlike fossil, made up of cells arranged in regular order, after the manner of the structures of the hydrozoa. Which formation would that shale belong to? and what is the general name of that variety of fossils? Again you are boring in a limestone, and the core when broken shows several examples of a starlike netted structure, something like a spider's web, and undoubtedly belonging to the hydrozoa, which formation is this? and what is the name of the fossil in question?

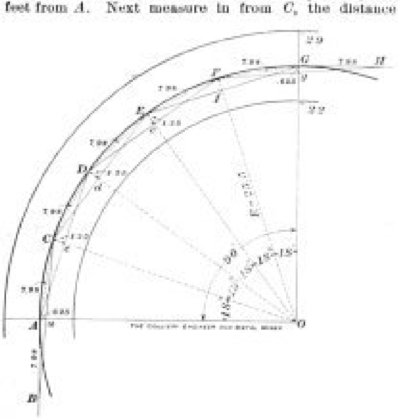
ANS. The fossil the question refers to as common in the Silurian shales, and distinguishing them by their profusion, as they are found in nearly every sample of the shale examined, is *Graptolites*, and the example of the hydrozoa that distinguishes the Permian limestone is the Aster Reticulatus.

JOS. VIRGIN,
Hollsopple, Pa.

QUES. 173. For the purpose of haulage in a level seam, a branching road has to be made, at a right angle with the main entry, and we have to make the connection with a curved entrance, the radii of which are to be 22 feet for the inside, and 29 feet for the outside of the curve. Give a plan with all the necessary explanation of how you would proceed to secure the correct curvature for this junction.

ANS.—The mean radius of the center line is $\frac{(22+29)}{2} =$ 25.5 feet.

By this method the quadrant is divided into five angles as $\frac{90°}{5} = 18°$, and therefore, taking the radius at 25.5, the versed sine is 1.25 feet, and each of the five chords are 7.98 feet. To begin, first measure in, on the radius $\frac{1.25}{2} = .625$ equal to half the versed sine, and locate this point at *a*; next lay off on the tangent from *A*, a distance equal to the chord 7.98, as *AB*. Next stretch a cord to cut *a*, and to locate the point *C*, 7.98 feet from *A*. Next measure in from *C*, the distance



equal to the versed sine = 1.25 feet to *c*, then a straight line from *A* through *c*, will with the intersecting line or chord = 7.98 feet, enable us to to locate *D*, and so on finishing as we began with the half of the versed sine $\frac{1.25}{2} = .625$ as *G g* and on to the tangent at *H*.

WILLIAM WYLIE,
Washington Pa.
Washington, Co.,

Second Prize, JOS. VIRGIN, Holsopple, Pa.

QUES. 174. My Uncle George is a mine superintendent and he asked me to-day if I had given due attention to the study of mine machinery, and steam engines and boilers? and I said oh! yes, I know all about them, and nobody can teach me any more than I know; and he said, "hem," and continued, solve me this question and let me have the answer in a few days.

We have a semi-portable hauling engine in the Burdock mine, and it is rather light for the work, and therefore, always runs with full steam. It is 80 horse power, and the highest pressure of the steam at blow-off is 90 pounds on the square inch.

The train has a speed of 10 miles an hour on the level road when the steam pressure falls to 50 pounds on the square inch, and on coming within 850 yards of the shaft the train of cars has to ascend an incline, when the speed reduces and the pressure of the steam in the boilers rises to 90 pounds on the square inch. Now the boiler fire (before the start) is banked up to keep the horse power of the boiler uniform throughout the journey.

The question makes three demands:

1st. Why does the boiler pressure vary?

2nd. What is the gradient of the incline?

3rd. What is the speed of the train on the incline?

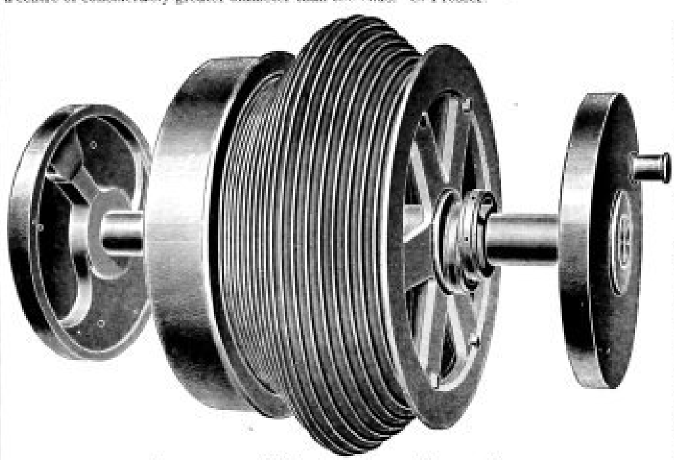
I frankly confess, I have made a mistake in bouncing to my uncle George, and I hope you will help me out of the dilemma by answering the questions for me.

[We are sorry to say this "easy" question has not been answered even approximately, thus showing that imitation is a very poor substitute for understanding. The velocity on the incline can been seen without calculation and the grade of the incline can be found nearly as easy. Our object in framing these questions is to show our friends the importance of having a complete grasp of the mechanical principles involved in the subjects of their study, and we have caught them sleeping. ED.]

The Crawford and McCrimmon Drum.

Messrs. Crawford and McCrimmon, of Brazil, Indiana show in their advertisement, in this issue, a pair of hoisting engines equipped with a double conical drum. To show the construction of this drum we present our readers with a view of it large enough to make clear the features claimed for it.

This drum resembles two similar cones placed base to base, which furnishes two ends of equal diameter and a centre of considerably greater diameter than the ends.



CRAWFORD AND MCCRIMMON DOUBLE CONICAL DRUM.

The drum is grooved from one end to the other, and the rope winds from the small diameter at one end over the large diameter in the middle and thence to the small diameter at the other end.

This plan starts the load easily and slowly and gradually increases the speed to the middle of the hoist and then gradually reduces the speed till the landing is reached.

That is, this would be the case if the engines were run at the same speed continuously. But, as the engines are always started slowly, and the speed gradually brought to a certain maximum point and held there till the load is almost at the landing, when it is gradually slowed down, it is evident that the greatest speed is secured at the proper time and the slower speed is ensured at the start and end. This principle of construction embodies the requirements for an ideal drum. Besides regulating, in a large measure, the speed of hoisting, it also makes possible the successful use of a smaller engine than would be otherwise required.

BOOK REVIEW.

THE MINERAL INDUSTRY, Its Statistics, Technology and Trade in the United States and Other Countries. Vol. III, edited by R. P. Rothwell, C. E., M. E., and published by The Scientific Publishing Co., of New York, is at hand. Price $5.00.

The two former volumes, embracing the statistics to the end of 1892 and 1893 respectively, have been previously noted in our columns. The present volume brings the subject matter down to the end of the year 1894 and is fully up to the standard of the preceding volumes.

Vol. III is a book of about 900 pages and covers the subject in a manner highly creditable to the numerous contributors and the editor. While this and the previous volumes have been subjected to severe and adverse criticism by several prominent specialists, it must be borne in mind that the work of compiling such a volume is one that few men would care to undertake, and the promptness with which it is issued materially enhances its value. While there may be room for criticising comparatively slight errors in some of the statistics, the critics should bear in mind the fact that the volume gives practically correct figures *before* the official figures are obtainable from the statistical departments of the several governments. Again, the fact that the statistics are all grouped in one convenient volume, and those interested are thereby saved much vexatious and often fruitless labor in searching for desired information, makes the work one of great value.

U. S. GEOLOGICAL SURVEY REPORTS.—No reports issued by the National Government are of more practical value than those issued by the U. S. Geological Survey, under the direction of Major J. W. Powell. We have before us in two quarto volumes the Fourteenth Annual Report covering the operations during the year ending June 30, 1893. The first volume is the Report of the Director. It is accompanied by a map of the United States, showing, graphically, the work done during the year covered by the report, as well as the total area surveyed. Vol. II of the annual reports contains in detail the reports of a number of specialists on prominent geological features of various localities, illustrated with maps, sections and views.

Monograph XXIII is a profusely illustrated and instructive volume on the geology of the Green Mountains in Massachusetts by Raphael Pumpelly, J. E. Wolff and T. Nelson Dale.

Monograph XXIV, treats of the Mollusca and Crustacea of the Miocene formations of New Jersey, by Robert Parr Whitfield of the Geological Survey of New Jersey. It is illustrated by twenty-four fine plates showing a large number of fossils.

Bulletin No. 118 is a geographic dictionary of New Jersey by Henry Gannett, Chief Topographer of the U. S. Geological Survey.

Bulletin No. 119 is entitled A Geological Reconnaissance in Northwest Wyoming, by George Homans Eldridge, Geologist.

Bulletin No. 120 treats of the Devonian System of Eastern Pennsylvania and New York, and is by Charles S. Prosser.

Bulletin No. 121 is a bibliography of North American Paleontology from 1888 to 1892, by Charles Rollin Keyes.

Bulletin No. 122 is the results of primary triangulation, by H. M. Wilson, R. U. Goode and S. S. Gannett.

We have also received through Mr. Charles D. Walcott, present Director of the U. S. Geological Survey, "The Production of Tin in the Various Parts of the World" by Charles M. Rolker, which is an extract from the Sixteenth Annual Report of the Director, Part III., and "The Stone Industry in 1894" by Wm. C. Day, which is an extract from Part IV of the Sixteenth Annual Report of the Director.

REPORT ON THE "NEW RED" OF BUCKS AND MONTGOMERY COUNTIES, PENNSYLVANIA, by Benjamin Smith Lyman. This an author's edition, and is a reprint from the Pennsylvania State Geological Summary, Final Report, Vol. III, Part II. It is illustrated with maps, sections, fossils, etc., and treats the subject in a thorough and scholarly manner.

Self-Extinguishment of Fires.

The several kinds of automatic fire sprinklers now in use in many large establishments afford familiar examples of self-extinguishment of fires. There is, however, nothing unexpected about their action; they are designed specially to put out fires, and when the sprinkler heads of fusible metal let go, and the flames underneath are deluged with water, we have simply the legitimate outcome of what was figured upon when the sprinkler system was put in. But there are a number of instances on record where the means of fire extinguishment were wholly unlooked for and of purely accidental character. One of these was furnished several years ago in a large church where a fire, caused by spontaneous ignition in a storeroom, melted the lead water pipes, and the water issuing from them quenched the flames. A similar instance happened in a tinsmith's shop. Some sheet metal pails, which had been made there, were returned by the purchasers with the complaint that they were not tight. The maker resoldered them, and, in order to test his work, filled them with water and hung them upon hooks screwed into the shop ceiling. During the noon hour, a fire heated the upper part of the room so that the handle fastening became unsoldered, and the dropping of the pails of water put out the fire. Again, in the engine room of a certain factory some oily cotton waste, left on top of a steam pump, set fire to the wooden lagging around the steam cylinders and a part of the steam-supply pipe, where it melted the soldered attachment of an automatic oiling device. The steam from this pipe escaped through the small tubes formerly leading to the oiling apparatus, and speedily extinguished the flames.—*From Cassier's Magazine for October.*

Automatic Dump Litigation.

A suit is in progress, brought by the Sullivan Machinery Company of Chicago, against the Phillips Mine Supply Company, of Pittsburg, for infringement of the Mitchell and Wilson Automatic Dump Patents owned by the former company.

The Colliery Engineer

AND

METAL MINER.

ESTABLISHED 1881, INCORPORATED 1890.

PUBLISHED MONTHLY AT SCRANTON, PA.

WITH WHICH IS COMBINED THE MINING HERALD.

Entered at the Post-Office at Scranton, Pa., as second-class matter.

THOS. J. FOSTER,
RUFUS J. FOSTER, MINING ENGINEER, } EDITORS.

THE COLLIERY ENGINEER COMPANY, PUBLISHERS.

TERMS.

Subscription, (*Postage in the U.S., Canada, or Mexico, prepaid.*) **$2.00 a Year**

TO FOREIGN COUNTRIES IN THE UNIVERSAL POSTAL UNION $2.50.

Remit by P. O. Order, Express Money Order, Bank Check or Draft or Registered Letter.

P. O. Orders.—You can buy a Money Order at your Post-Office, payable at the Scranton Post-Office.

Express Money Orders can be obtained at any office of the American Express Company, the United States Express Company, and the Wells, Fargo & Co.'s Express Company.

Registered Letters.—If a Money-Order Post-Office or an Express Office is not within your reach, your Postmaster will register the letter you wish to send us on payment of eight cents.

We Cannot Be Responsible for money sent in letters in any other way than by one of the four ways mentioned above.

EXPIRATION OF SUBSCRIPTION.

The date after your name on the wrapper of THE COLLIERY ENGINEER AND METAL MINER shows to what time your subscription has been paid.

RENEWALS, ETC.

If you do not want THE COLLIERY ENGINEER AND METAL MINER continued for another year after your subscription has run out, you should notify us by postal card to discontinue it. The courts have decided that subscribers to newspapers who do not order their paper discontinued at the expiration of the time for which it has been paid, are held liable for the payment of their subscriptions up to the date when they order the paper discontinued.

NOTICE OF DISCONTINUANCE.

THE COLLIERY ENGINEER AND METAL MINER is sent to subscribers until an explicit order for its discontinuance is received by us, and all payment of arrearages is made, as required by law. *Papers returned are no notice of discontinuance, as we cannot tell where they are from.*

CHANGE OF ADDRESS.

A Subscriber wishing to have his address changed should be careful to give his *former* as well as his present address; otherwise we cannot find his name on our mailing list.

All communications should be addressed,

A MISTAKE IN AMERICAN COAL MINING LAWS.

PENNSYLVANIA was the first State in the Union to enact laws for the protection of life and property in coal mines. Her first laws on this subject were, naturally, crude, but they have been revised until now they are, in the main, excellent laws.

Other States, in framing mining laws, followed the example of Pennsylvania, and modelled their mining laws on hers.

Those States, which were progressive enough to realize the value of mine officials equipped with well digested theoretical as well as practical knowledge copied the Pennsylvania law in regard to certificated mine foremen and made the same mistake.

The Pennsylvania, Illinois and Alabama laws requiring the employment of certificated mine foremen are wise enactments in all particulars but one. That particular is the requirement that applicants for examination shall be citizens of, and shall have had a certain number of years practical mining experience in the particular State in which the examination is held. This restriction prevents the competent citizen of any other State securing employment as a mine foreman in either Pennsylvania, Illinois or Alabama. It also prevents a citizen of Pennsylvania securing employment as a mine foreman in Alabama or Illinois. The other coal mining States will, in time, enact similar laws, and in justice to their citizens they will place the same conditions in their laws. This will result in a great hardship to an intelligent, and valuable class of American citizens. It is, if not a violation of the letter of the Constitution of the United States, a violation of its spirit. It abridges the liberty of a citizen of the United States in plying an honest and useful vocation in any part of the nation. No other industry or profession is so handicapped.

It may be urged that a mine foreman from Pennsylvania is not familiar with the local conditions in Illinois or Alabama and *vice versa*. This reason is a weak one. If he is capable of passing a good examination, he will soon grasp the differences in the local conditions. It might as well be urged that the mine foreman from the Connellsville or Pittsburgh region would not be familiar with the local conditions existing in the mines of the Clearfield region. Or it might be still further narrowed down to the statement that the competent mine foreman in one mine would not be competent in the adjoining mine, for the local conditions are seldom the same in two mines.

Every coal mine foreman in the United States should be compelled to have a certificate of competency won by passing a thorough examination before a competent and fair board of examiners, and he should be compelled to show that he has had at least five years practical experience in coal mines, not of any one State, but in the United States.

The law should be so framed that a legal certificate of competency issued in one State should be good in another until the next succeeding examination in the district in which a foreman from the first State has secured employment. Then his worthiness for a certificate from the State in which he is working could be determined by admitting him to the examination and the acceptance of his first certificate as proof of character and practical experience in the mines. If he passes a successful examination he should be certificated. If he does not he should be removed from his position. In this way mine foremen will not be tied down to a residence for life in any one State, but like other American citizens, they will be at liberty to seek employment as mine foremen in any State they wish, or in which they think their chances for advancement are best. We do not advise that the question of practical experience in coal mines be left open to experience in foreign countries, but it should not specify experience in any one particular State of this Union.

We commend this subject to the attention of the mine inspectors and mine officials of Pennsylvania, Illinois and Alabama, and trust that they will see the wisdom of urging the amendment of the present laws on this subject.

LOSS OF GOLD IN REDUCING.

IN the processes of separating metals, ores and minerals from the particles of their associated gangue there is considerable trouble in getting the miners to know and understand that unless the crushed ore is first sized, and the slimes classified a considerable percentage of the metal will be carried off as loss in the tailings.

This statement is taken from the experience of the government of Victoria, one of the Australian Colonies of Great Britain; and to prevent the continued loss due to imperfect dressing, the government appointed Mr. Henry Rosales, M. E., F. G. S., to report on "the loss of gold in the reduction of auriferous veinstone in Victoria, and to make such recommendations as are necessary in the system of treatment, more especially relating to the dressing of slimes."

It appears Mr. Rosales has found that the Luhrig system gives satisfactory results, for the report says: "Consequent upon the continued investigations by this department, Mr. J. Cosmo Newbery visited Europe and reported favorably upon the methods of gold and ore saving known as the Luhrig system. Following upon this an inspection was made by Mr. Newbery and myself of the most advanced gold saving and treating plants on the principal gold fields, and we found that these appliances failed in all cases in one important point, namely, that no attempts were made to classify the material before concentration, and that the concentrates showed very large percentages of quartz grains, which were not only valueless in themselves, but hindered the proper working of the vanners." It was found that the loss due to the non-classification of the slimes was very considerable for "the estimate was made that the average tailings of the quartz mining districts of the colony might be considered as containing from 2 dwts. to 2½ dwts. of gold per ton, or an average annual loss at the present time, 1894, of $1,797,010 on the 898,506 tons of quartz crushed." The report next refers to improvements that have been as follows:

"The want of classification of material, to which I have time and again drawn attention as one principal cause of the loss of fine gold and mineral has been partially remedied in some cases. The Luhrig plant erected at Stawell, North German Mine at Maldon, and Long Tunnel Mine at Walhalla are object lessons of the highest value."

This report only amplifies the evidence, daily increasing, of the importance of practical miners having a better educational equipment to secure success for themselves and their employers. The merely practical man need not be jealous of the merely theoretical man, but both have good reasons to be jealous of the practical man with technical knowledge. The report next proceeds as follows: "To successfully reduce auriferous veinstone and extract the gold therefrom, *classification* should unquestionably commence from the begining of the trituration of the gangue, whether it be done by stamps, rollers, or a ball mill." Again we are told that the particles of the crushed gangue should not be smaller than the *natural* size of the particles of gold, or the grains of the contained sulphides, for it says: "To reduce the stone to a finer grade than required is a mistake that should be avoided. Elsewhere I have already uttered the same opinion, and further, I may quote an expression used by the late Sir Warrington W. Smyth, M. A., F. G. S. etc., to the effect that by crushing the stone unnecessarily fine, the gold is 'stamped dead' implying that the particles of gold would be carried off in the slimes as float gold." Altogether this report is suggestive of the steady progress that is being made in mining in every land and it is a significant fact in the whole matter that all the steps in this advance have been made with the indispensable help of technical allied with practical knowledge.

THE COOSA COAL FIELD OF ALABAMA.

THE report of Coosa Coal field of Alabama, by the State geologist Eugene Allen Smith, Ph. D., and illustrated by the sections made by his assistant Mr. A. M. Gibson, is at hand. It is a very satisfactory presentation of the facts available to the writer. But for the useful minerals obtained by mining, little would ever be known of the presence or absence of any series of rocks, in any locality, because the relative superposition is only found by such sections as we obtain by sinking and boring, and where this is not done, very little reliance can be placed on speculative opinions. This is especially so in coal bearing strata, because the existence and preservation of such a tender rock as a stratum or seam of coal is the result of it being protected from the effects of the denuding forces, by lying in the troughs or basins of crumpled and contorted strata, or sheltered in the depressions made by one, two, or more great faults.

We can therefore never determine the characteristics of a coal field until the area within the boundary lines of the outcrop has been pierced in all directions by many borings and sinkings, from which reliable sections can be made. Until, therefore, more sections of the Coosa coal-field are known, the comercial industrial, and state value of the mineral, will remain an unsolved problem, but we are happy to find that the people of the State of Alabama realize the importance of their first class resources in coking coal, iron ore, and lime, and that in the near future they will see that spending money is a good investment, when it is spent to furnish good reasons for commercial speculation.

The Coosa coal-field in its greatest length is 60 miles long. It extends 34 miles through St. Clair county and 24 miles into Shelby county where it terminates. Its breadth is nearly six miles, and it therefore has a mean area of 345 square miles. The coal is of a fine coking variety, with a small percentage of sulphur and it is therefore, adapted in a superlative degree for the manufacture of iron and steel. The seams vary in thicknes from 2.5 ft. to 4.5 ft. Like all the best varities of coking coal, the seams in the Coosa coal-field are soft and tender, and do not, therefore, command their true value when sold in the market for household fuel.

To make these seams reach their real value, the coke will have to be consumed in the smelting of Alabama ores, and in iron and steel manufacture. The field is in the shape of a long dish or basin-like trough on the south-east side of the terminus of the great Appalachian field. The report contains a number of tables of analyses of the coals of the different basins in the coal-field, but like all other tables of the kind, and we have English and Australian lying before us while we write, the solvents contained in the coal, such as nitre, common salt, sulphates of lime and magnesia, etc., are not given These solvents play an important part in the coking and combustion of the coal and should, therefore, be known and especially so when we are aware that some varieties of coal are more subject to spontaneous combustion than others.

LEGAL DECISIONS ON MINING QUESTIONS.

Reported for THE COLLIERY ENGINEER AND METAL MINER.

Insufficiency of Notice of Location of Claim.—Under the statutes, requiring a person making a location of a mining claim to file a declaratory statement thereof on oath, a statement which, on its face, appears to have been verified a year before the location of the mine, is insufficient, in the absence of proof that the affidavit was wrongly dated by mistake.

Berg v. Keogel, (Supreme Court of Montana,) 40 Pac. Rep. 605.

A Subscription by a City to the Capital Stock of a Corporation Invalid.—Chapter 114 of the Laws of 1887, entitled, "An act authorizing counties and incorporated cities of the second class to encourage the development of the coal, natural gas and other resources of their localities by subscribing to the stock of companies organized for such purposes," is unconstitutional and void. A subscription made by the city of Geneseo to the capital stock of a corporation organized for the purposes of prospecting for, developing, and operating natural gas, oil, coal, salt and other minerals, is invalid, and although bonds are issued, and accepted in payment for such capital stock, the Supreme court of Kansas holds, does not render the city a stockholder in the corporation. The city, having issued its bonds to the corporation, which it is alleged in the petition and admitted by the demurrer, are valid obligations of the city, may recover from the corporation the proceeds of such bonds illegally issued to pay the city's subscription to the capital stock of the company, and wrongfully converted by it to their own use.

City of Geneseo v. Geneseo Natural Gas, Coal, Oil, Salt & Mineral Co. 40 Pac. Rep. 655.

Valid Notice of Location.—A notice of location of a placer mining claim, which contains the name of the locators, the date of location, and a sufficient description all as required by the statute, is not invalidated by the fact that the date is preceded by the words "dated on the ground," and such words are to be regarded as mere surplusage.

Preston v. Hunter (Circuit Court of Appeals, Ninth Circuit.) 67 Fed. Rep. 996.

Right to make New Location.—A locator of a quartz mining claim, who has allowed his location to lapse and become subject to relocation, under the statutes providing for the relocation of claims on which the required annual amount of work has not been done, has the right to make a new location, covering the same ground.

Warnock v. DeWitt. (Supreme Court of Utah.) 40 Pac. Rep 205.

Sufficiency of Marking Claim.—A mining claim marked by a discovery monument, on which was placed the notice of location, and by a stake at each of three of the corners of the claim, and a monument at the center of each end line, leaving one corner of the claim unmarked, was sufficiently marked, under the statutes, providing that such a claim shall be "distinctly marked so that its boundaries can be readily traced."

Warnock v. DeWitt. (Supreme Court of Utah.) 40 Pac. Rep. 205.

Duties of the Mine Boss.—The mine boss is an individual so designated by the statute, who must be employed by the mine owner, and put in charge, with reference to its safety and its security. He has the entire supervision of the whole system of the ventilation of the mine, likewise of its entries, drifts, and rooms, and all machinery and appliances which are used in its operations. He is bound to make his reports regularly to to the mine inspector, and is subject to severe penalties for any violation of the statute. Of necessity, this would include any failure on his part in the supervision, inspection, and care which the statute requires. Miners are likewise given the right to inspect the mine and machinery, either in person or by committee, conjointly with the owner, or otherwise, as they may choose, and to take such steps as their prudence may dictate to secure their own safety and prevent accidents.

And a right of action is also given to certain designated parties in case they sustain damage by reason of any failure to comply with the provisions of the statute, or because of any violation of its requirements.

Colorado Coal & Mine Co. v. Lamb. (Court of Appeals of Colorado.) 40 Pac. Rep. 251.

Location of Mining Claim.—The act of congress provides that the locator take no more than 1,500 feet in length, nor more than 300 feet in width, on each side of the vein. This contemplates a location to be made parallel with the line of the vein, and if a locator, knowing the line and course of his vein, and willfully, and with a fraudulent purpose, locate his claim in disregard of such line and course of the vein, and establish its length, not along the vein, but across it, to an excess of several hundred feet or more beyond the 300 foot limit allowed by congress, for the fraudulent purpose of gaining and appropriating such excess surface ground as his mining claim, this would be in deliberate violation of the law, and a locator so acting could gain no rights whatever, but his location would be absolutely null and void, and he would be left in as bad a position as if one had never been attempted to be made.

Walsh v. Mueller, (Supreme Court of Montana.) 40 Pac. Rep. 292.

The Rule of Safe Place.—The doctrine that a mining company can send its employes into the bowels of the earth to conduct its mining operations without making any provision for the proper supervision and inspection of the mine for the security and protection of the miners and the mine is unsupported by authority, is opposed to sound public policy, and is cruel and inhuman. Miners do undoubtedly take upon themselves all the ordinary and usual risks of the business; but what are these ordinary risks? They are the risks incident to to the business when it is conducted by the mine owner according to the customary and approved methods and with due regard to the safety of the miners. The neglect of the mine owner to discharge his duty in this regard is not one of the risks assumed by the miner, but is a negligent act on the part of the mine owner which renders him liable in damages to any miner injured thereby. It is the duty of the mine owner to provide a competent foreman or inspector to superintend the working of the mine; it is the duty of this foreman to direct the miners when and where to work; and it is particularly his duty to make timely inspection of the timbers and walls and roof of the mine in order that no harm may come to the miners from causes which a capable and diligent inspector would discover, and when discovered, remove or cause to be removed. Where blasts are used in a mine, it is the imperative duty of the foreman to be diligent in discovering the effect of the blast upon the timbers, walls and roof of the mine, and to point out to the miners any dangerous conditions resulting from the blast, and to cause these conditions to be removed without delay, by proper appliances and with as little danger to the men as practicable. Mining is a necessary and permanent business, and must be conducted in an intelligent, orderly and systematic manner, not alone for the protection of the miners, but for the preservation of the mine itself. For these reasons, the business must have an intelligent and competent head. The necessity for this is imperative. When properly conducted, there is no pursuit in the country carried on with greater regularity, system and order, and with a stricter observance of rules intended to secure employes against accidents and property from loss or damage. The conditions confronting the miners from day to day, as a rule, are neither unexpected nor unusual. They are the common and expected incidents of mining, and when the foreman does his duty they are provided for and met without accident or any special danger. There is nothing hasty or haphazard about the business.

Finalyson v Utica Mining & Milling Co., (Circuit Court of Appeals, Eighth Circuit.) 67 Fed. Rep. 507.

Liability for Injury to Miner.—Where the superintendent of a mine, knowing that stones had been continually falling down the surface of the mine at a certain place, and that it was more dangerous than other parts of the mine, put a miner at work immediately under it without informing him of the danger, or without having the surface raked, the owner is liable for the resulting injury to such miner, who was ignorant of the danger.

De Weese v. Meramec Iron Mining Co. (Supreme Court of Missouri.) 31 S. W. Rep 110.

Duty and Liability of Mine Owner and Miner.—Under the Rev. St. section 6,871, which reads as follows: "The owner, agent, or operator of every coal mine shall keep a supply of timber constantly on hand, and shall deliver the same to the working place of the miner, and no miner shall be held responsible for accidents which may occur in mines where the provisions of this section have not been complied with by the owner, agent, or operator thereof." By another part of the same section it is made the duty of the miner "to securely prop the roof of any working place under his control," under a penalty of $50 fine or 30 days in jail or both, if he intentionally and willfully neglects or refuses to perform such duty. Under this section of the statute it is the duty of the owner, agent, or operator to keep a supply of timber constantly on hand, and to deliver the same to the working place of the miner, and it is the duty of the miner to securely prop the roof of any working place under his control. The duty of each party is clearly defined by the statue, and for a neglect of such duty by either, resulting in an injury to the person or property of the other, an action will lie. The statute makes it the duty of the agent, owner, or operator to have the timber constantly on hand, and to deliver it to the working place of the miner, and hence the miner is not concerned as to the manner in which the delivery is made. All he has to prove to make his case, as to that point, is that in fact the delivery was not made. He is not required to ask for the timber or give any notice. It is his right to have the timber delivered at his working place at all times without request on his part, and without notice to any one; and a failure on the part of the owner, agent, or operator to so deliver timber to the working place of the miner is negligence, and, if injury is thereby proximately caused to the miner, an action will lie therefor.

Coal Co. v. Estlevenard. (Supreme Court of Ohio.) 40 N. E Rep. 725.

Interpretation of Contract.—A coal dealer, entered into a contract with three coal companies, agreeing with each other as follows: The dealer agrees to represent the entire interests and sales of the other three parties in the Detroit trade; that he will confine himself to the use and handling of their coal alone, taking the same from them in equal quantities: that he will turn in all his present trade and orders, at the price of 70 cents per ton at the mines; that he will labor to improve the market, giving to said parties the advantage of whatever improvement may be made, asking no greater part of such increase than his fair proportion; and that he will keep his books, sales, and contracts open to their inspection. Said other parties agree to aid and encourage the trade of the dealer in all lawful ways. It was held, that such contract was several, and not joint, and that the parties contracting with the dealer, were bound to fill contracts made by him for future delivery, in accordance with a custom known to all the parties, at the market price of the coal at the time such contracts were made, and not at the market price at the time of actual delivery.

Shipman v. Straitsville Cent. Min. Co. 15 U. S. Sup. Court Rep. 886.

Grant of Mining Patent.—The grant of a patent to a mining claim from the United States to one who procured it for and assigned it to an alien is the judgment of a special tribunal and cannot be collaterally attacked. While it is true that the mineral lands of the government are open to location and purchase only by a citizen of the United States, or one who has declared his intention to become such, and the fact of alienage if raised at the proper time by any one adversely interested, will defeat the acquirement of title, yet the qualifications of an applicant for a patent, as well as the fact of discovery, and the compliance on his part with other requirements made essential by the act of congress to entitle him to purchase the mineral land of the government, being cognizable by the officers of the land department, when in the exercise of their jurisdiction, they approve the application, and allow an entry, the fact of citizenship, as well as all other questions of fact, is presumed to have been established, and is not open to review by the courts at the instance of third parties.

Justice Min. Co. v. Lee. (Supreme Court of Colorado.) 40 Pac. Rep. 199.

Liability for Injury to Employe in Mine.—Under the statutes, which require the operator of a coal mine to keep the same free from gas, and to have the the working places examined every morning with a safety lamp before workmen are allowed to enter, and give cause of action to a person injured for direct damage occasioned by any violation or willful failure to comply with the requirements of the statute, an employe cannot maintain an action against his employer for an injury following such violation, unless at the time he was injured he was in the exercise of due care.

Krause vs. Morgan, (Supreme Court of Ohio,) 40 N.E. Rep. 886.

Admissibility of Statements as to Dangerous Premises.—In an action for injuries to an employe caused by defects in the roof of a coal mine, statements as to the condition of the roof, made by persons not connected with the mining company are inadmissible.

Treager v. Jackson Coal & Mining Co., (Supreme Court of Indiana,) 40 N. E. Rep. 907.

Ordinary Care and Prudence.—The courts have very frequently, within the last few years, been called upon to define the meaning of "ordinary care and prudence."

New inventions in steam and electrical machinery have resulted in new occupations for men, and new mechanical appliances whereby their labor is employed, Thus, are unforseen and nice questions of the law of negligence constantly arising as the new relations of employes and employers are discussed and considered by the courts. Familiar underlying principles, evolved from generations of experience and thought, are to be applied to the peculiar phases presented by the facts and circumstances of the particular case under investigation. And so we find the opinions, in discussing the definition of "ordinary care," recognize that no fixed arbitrary rule can be laid down, but that the degree of care and vigilance required varies according to the exigencies which require attention and vigilance, conforming in amount and degree to the particular circumstances under which they are to be exercised. The care and attention necessary on an employer's part in furnishing a steam boiler is relative to the work to be done by the boiler, and the capacity of such instrument for harm as well as good. In a concentrating works, where three large boilers are needed, aggregating about 200 horse-power, it requires no technical knowledge to say that many men are necessarily employed about such machinery, and that the dangers and responsibilities of the owners and the men employed are great; hence ordinary care in furnishing suitable boilers for such works would be a much higher degree of care than, for instance, would be ordinary care in furnishing a wagon wherewith to haul the concentrates from the works to a railroad depot, or elsewhere. The Circuit Court of the United States for the Eastern district of Michigan charged a jury in relation to negligence and ordinary care as follows: "You fix the standard for reasonable, prudent and cautious men under the circumstances of the case as you find them, according to your judgment and experience of what that class of men do under these circumstances, and then test the conduct involved, and try it by that standard; and neither the judge who tries the case, nor any other person, can supply you with the criterion of judgment by any opinion he may have on that subject.

Johnson v. Boston & M. Consolidated Copper & Silver Min. Co., (Supreme Court of Montana,) 40 Pac. Rep. 298.

Liability to Accidents to Trains.—Where a rail way company delivers cars to a mining company by leaving them on a siding, it is bound to see that they are left and maintained in such a position as not to interfere with trains on the main track; and if the mining company negligently permits them to run down on the main track whereby a train is derailed and one is injured the railway company is liable.

Union Pac. Ry. Co. v. Harris. 15 U. S. Sup. Ct. Rep. 843.

THE PROGRESS IN MINING.

ABSTRACTS FROM THE PROCEEDINGS OF THE MINING SOCIETIES

And Journals of Europe and America, Illustrating the More Modern Developments in all Branches of the Mining Industry.

The Efficiencies of Mine Pumps.—Mr. Per Larsson recently read a paper on "Efficiencies of Some Pumping Plants on the Menominee Range," before the members of the Lake Superior Institute of Mining Engineers. This paper cannot be taken as even an approximate gauge of the efficiency of any of the classes of pumps tried, because many of the pumps or engines were either out of repair or subject to some needless resistance. For example, we are told that the main steam pipe of the Vulcan Cornish engine was too small, and as a consequence, the steam was vacillating in its flow of supply; and, says Mr. Larsson in reference to the matter: "The steam pipe leading from the boilers to the basement of the engine house is four inches in diameter and 250 feet long. This pipe is apparently too small, as shown by the sharp vacillation of the index of the steam gauge during each revolution of the engines." In reply to a question by Mr. W. J. Olcott, concerning the small result of the Worthington pump at the Aragon, compared to that of the Worthington pump at the Vulcan, Mr. Larsson said: "The pump at the Aragon has been working for four years, and the plungers are pretty well worn out, and it is a smaller pump than any of the others." Again, the quality of the coals used is an important factor in obtaining good results, and so are also the speeds and sizes of the pumps and engines. For, slow running large engines give better results, so far as economy in the consumption of coals is concerned, than small fast running engines and pumps; and in support of this conclusion Mr. W. C. Brown, during the discussion on Mr. Larsson's paper, said: "It is found in building pumping engines of that character that there is a very great increase of duty in the larger engines." This fact is exemplified in the case of the table of results given by Mr. Larsson. At Chapin a large new Cornish pump with plungers no less than 28 inches in diameter, and the engine making only 4.39 10 feet strokes per minute, the duty was no less than 63.715 000 foot pounds per 100 pounds of coal consumed. The results of two pumping plants that were tested by a mechanical engineer was sent in after the paper was read. "One plant consisted of a Cornish pump with fourteen inch poles, nine feet stroke, and geared with a single reduction of eight to one. The engine is of the Corliss type, 18″ x 60″, and is connected to a Bulkley condenser, which is supplied from the column pipe." The lift of this pump is 660 feet, the speed is 4 to 6 revolutions per minute, and the duty is 62,813,300 foot pounds per 100 pounds of coal consumed.

We cannot over-rate the value of such papers as Mr. Larsson's because the test always applies somehow; in this case we had perfection of repair, against those that were out of repair, local mistakes as in the case of the over small steam pipes, against ample provision for injection and emission. Bad coals against good ones, boilers of good types against old fashioned ones, and slow running engines, against fast running ones. Now, the results collected by the writer of the paper brought out in strong relief the peculiarities of the successes and defects of all the pumps and engines in the Menominee Range.

Perhaps one of the most remarkable tables of results sent in is that of "The New Pumping Plant of the Stirling Iron and Zinc Co., New Jersey."

It appears that after sinking a shaft through highly watered strata, the Cameron or sinking pumps were replaced by a Triple Expansion Duplex Worthington Pump, to force 800 gallons per minute against a 600 feet head. The total cost of this plant including pipes from the boilers and the preparation of the station was $10,000 and the estimated saving per day was $18.00 and the duty per 100 pounds of coal consumed was no less than the extraordinary figure of 69,502,506 foot pounds, and even this was excelled on May 3, 1895, when during a trial of 60 minutes duration the duty was 78,294,625 foot pounds.

The Mines of Elba.—Mr. Herbert Scott, a Fellow of the Geological Society of Italy, last May, read a paper on the above subject before the members of the "Iron and Steel Institute of Great Britain."

This island is deeply interesting not so much from a mining or metallurgical point of view as from its grand historical associations. It was to this small island that Napoleon was sent to govern in peace about 25,000 people, after he had tried and failed to conquer and govern the whole of Europe.

Iron mined and manufactured in this island was used as weapons at the siege of Troy, 1289 years B. C. The very name of the island, off the coast of Tuscany in the Mediterranean Sea, and consequently in ancient days accessible to the ships of Greece, is derived from a Greek word meaning "blazes of iron furnaces." Iron ore has been mined here for 40 centuries and it appears that after all the timber fuel was consumed on the island the ore was carried to the main land, where the supply of wood was inexhaustible, to be smelted.

From Mr. Scott we learn that in ancient days the processes of calcining and smelting were about the same as that practised by the Chinese and the natives of Hindustan, living on the slopes of the Himalaya Mountains now, that is, the furnace consisted of a rude hearth divided into pockets or cells, and in one the ore was roasted, and in the other the ore was smelted, and in another the front of the bottom of the pocket was open to the air, and in it logs of wood were kept burning with a fierceness proportionate to the speed of the wind blowing over the tops of the mountains, for the furnace was always set at a high elevation on the mountain slope.

In the ancient days, as the result of not understanding how to construct a reverberatory furnace with a chimney flue, the waste of fuel was enormous, for to make a ton of iron bloom, it required 9 tons of wood for fuel.

The ancients did not use the iron as castings, and therefore made it at once into true steel, or a kind of steely iron, and strange to say the ancient steel was more of the character of the latest steel, known as Siemen's or Bessemer. During the process of smelting cast iron is produced and contains a high percentage of carbon, to convert this into malleable iron the carbon must be burnt out as in the modern process of puddling, but the ancients burnt it out, by adding some calcined ore, the oxygen of which effected the purpose required, and they found that when different quantities of the ore were added to the metal in the furnace, they obtain malleable iron, or mild or hard steel according to the weight added, the result was with good ore they were able to produce the finest examples of steel, as the celebrated Damascus steel. The ancients did not used a flux for smelting their iron ores, the result was a high percentage of the metal combined with the silica of the ore to produce slag, or we may say they fluxed the iron ore with oxide of iron instead of oxide of calcium, or lime, and we find according to Mr. Scott, the slags contain no less than 60 per cent. of ferrous oxide and 12 per cent. of ferric oxide.

Through all the 40 centuries the mining of the ore has been most primitive, the deposits having only a relatively thin covering of earth, all that has been required and is now required, is to remove the overburden and mine the ore in the open.

Coal in Illinois.—The thirteenth annual report of the Illinois State Bureau of Labor Statistics is at hand, and contains valuable tables of numerical facts of great importance to all concerned in the commercial prosperity of the country, and to all who are anxious to promote the safety and happiness of their fellow creatures engaged in the hazardous pursuit of mining.

Every report contains the records of a cycle in human experience, for men continue to repeat their follies and mistakes and receive the rewards they do not want. The cycle of the year 1894 is remarkable for a triad of misadventures, namely, a strike, a depression in trade, and an alarming increase in the number of fatal and non-fatal accidents in the mines of the state.

The results of the strike were: First, an average loss of 70 days' employment by the miners, and a present and future loss of trade by the operators, a loss in the wealth of the state, and in a lesser, yet sure degree, an injury to the wealth and resources of the nation; second, after the strike a larger number of men were employed, and many of them not being practical miners, their inexperience was the cause of much of the increase in the number of fatal and non-fatal accidents that the Bureau records, and yet, notwithstanding all this, the miners of the United States have won the palm of victory for their hard-working industry, for the yearly output in tons of coals produced per man is greater than in any of the other coal-fields of the world, and we will show the proportions for the miners of six nations taking the miners of the United States as unity of tons of coals produced. The results are calculated from the tables given by the Bureau in their report, and the tables in question were copied from the tables of "The World's Production of Coal," published by the British Government.

Actual output of coals per person employed in the mines of six great nations. Year 1892.

Lake Superior Mining Institute. Address by the President, Mr. J. Park Channing.—It has seldom been our pleasure to read an address that was so suggestive of wise steps that ought to be taken to reduce and alleviate the suffering arising from mine accidents. The speech evidently was not made at short notice for a special occasion, for every paragraph indicates close, interested, sympathetic and prolonged observation in mastering all the important phases of the subject. Mr. Channing inspires confidence in his conclusions by first applying the gauge to himself that he uses in the measurement of others, and here is what he says:

"As Sir William Temple has said, 'The abilities of a man must fall short on one side or the other like a scanty blanket when you are abed, if you pull it upon your shoulders your feet are left bare; if you thrust it down to your feet, your shoulders are uncovered.'"

In one short paragraph he finds a place for the phase of mining experience on which he treats, and here it is.

"In selecting a subject for an address to the Institute, I have determined for the time to neglect the strictly economical side of mining and to call your attention to the ethical. Mining, like all other problems, is in the nature of a polyhedron; we must examine all the faces and angles to fully appreciate the crystal."

He commences his reference to mine accidents by confronting us with the awful, and oft repeated truth, namely, that many of the sorrows of humanity are self inflicted, and thus the president speaks.

"A large proportion of humanity will not take care of itself, will not follow the common laws of health or nature. I regret to say we must use force to compel them. Only a few days ago the press noted the closing down of a factory in the South where flints are ground, because of the enormous death rate among its employes due to inhaling dust. Masks and respirators were provided and yet the men persistently neglected to wear them."

He continues his remarks, however, and not with lamentation, but with a noble declaration of duty, for he says:

"While the natural carelessness of mankind is difficult to overcome, it does not excuse us who know better from continually exerting our influence for right."

Mr. Channing does not, in a cowardly spirit, heap reproach on the every day miner, but finds more to say about the want of oversight manifested by the mine inspectors or guardians for the execution of the law, and here is one, out of several given from the records of the State of Michigan.

"In Iron county, a careful examination of the records at Crystal Falls, shows a report, setting forth the death of nine men, but failing to give the year. Also a report for 1893, showing the death of two men, and a special report for 1893 on the Mansfield cave-in fail to record any fatal accidents.

"None of the reports except the last, give any statistics, and so the whole county has has been omitted in compiling tables.

"The reports for 1888 in Marquette county could not be found." Mr. Channing then gives the Prussian and British methods of classifying accidents in mines, and shows that they are worthy examples on which to base a classification of our own.

In short then, the President's address is so comprehensive in dealing with the laws that are required, and the steps that ought to be taken to enforce the execution of the laws, and the ethical principles, that should ensure respect for the laws, that we hope it will bear the fruit that has been nourished by a wise well meaning man.

The Lake Mine Hoisting Machinery, Cleveland Iron Company, Ishpeming, Michigan.—The engines for this hoisting plant, are of the cross-compound, condensing, steam-jacket type, with Corliss valves and an independent Deane condenser. This hoisting plant was made by the M. C. Bullock Manufacturing Co., Chicago.

The compounding cylinders are 20″ and 32″ in diameter, and have a 48″ stroke, and are constructed for a steam pressure of 125 pounds. The hoisting drums are so connected that changes in the length of rope for different depths can be adjusted with ease, expedition, and accuracy.

One drum we will call *A* is keyed or fastened onto the engine shaft, while the drum *B* when out of clutch is loose on the same shaft, and to enable the alteration in the lengths of the ropes to be made, the brake is caused to seize on *B* and hold it stationary and fast while the engine winds rope on or off the drum *A* for the necessary adjustment.

For hoisting, the drums *A* and *B* are bolted together by a quick connection, that takes the character of a fast clutch and secures both the drums and the engines under the control of the one brake on *B*.

The posing of the valves for reversing the engines, is done by turning through a portion of a revolution the shaft that synchronizes the valve movements, and this is done by a nut or helix that is pressed along the axis of the shaft by two steam cylinders that are provided for that purpose.

What is called an intercepting valve, is really a replenisher valve to restore a supply of steam to the low pressure cylinder, when the receiver from the high pressed cylinder is exhausted. The drums are 12 feet in diameter and the tread surface for the rope on each is 3.5 feet wide, making the tread surface of each drum sufficient for a rope 1¼ inches in diameter and 1256 feet in length. The following particulars are deeply interesting and worth careful thought: "The governor speed is thirty-five revolutions per minute, giving about 1320 feet of rope travel per minute.

No gates are used in the shaft.

The angle of the shaft is 50°.

The skip load is 3½ tons.

From the dump to 1st level is 310 feet.

From the dump to the 2nd level is 440 feet.

From the dump to the 3rd level is 570 feet.

Hoisting has been done from the 2nd and 3rd levels at the rate of twenty-six skips in twenty-five minutes.

With a pressure of 100 lbs. the following are the current results, but the engines are made for 125 pounds pressure. Total H. P. 263.58 with a credit to the condenser of 21 per cent.

These facts have been taken from a paper by Mr. J. M. Bickers, read before the members of The Lake Superior Mining Institute.

Open Pit Mining in the Mesabi Range.—A paper on the above subject was read by Mr F. W. Denton, before the last meeting of The Lake Superior Mining Institute. Mr. Denton's paper deals directly with a deposit of iron ore in the Mesabi Range, that lies under the cover of a small overburden, and here is his introduction of the subject.

"With the discovery on the Mesabi Range of large, more or less flattened masses of iron ore, with in many cases a shallow covering, interesting problems in mining have arisen, such as, how deep will it pay to strip? and after this is done, how shall the ore be mined?"

He shows there are two methods of mining ores with a small overburden, one is to strip a large area, and blast the ore, and fill it in the open; the other is to remove a limited portion of the overburden, and where the bed is of considerable thickness, to undercut it with levels and connect the surface and the levels with raises so that after the ore is blasted, it can be filled by the raises into the cars in the levels and then sent on to the shaft bottom to be hoisted. He discusses the advantages and disadvantages of the use of the steam shovel for lifting the ore and delivering it into the cars, and concludes that this device is not economical except when the work advances upgrade and the drainage takes place by gravitation and is therefore inexpensive, for he says: "It would seem, however, that the use of steam shovels has not the extended application of the milling system, but will be limited to the favorable conditions, such as easy grades of approach and easy drainage. The ideal conditions for steam shovel work would occur should the ore lie in a side hill and dip in the same direction as the hill, with its lowest point at or above the level of the adjoining country. Such occurrences of the ore unfortunately are rare. The steam shovel from a mechanical standpoint is a very uneconomical machine, and costs of repairs are high.

"Locomotive expenses are increased rapidly by adverse grade, for a locomotive can haul on a two per cent. grade only about one-eighth, and on a three per cent. grade only about one-twelfth of what it can haul on a level. The economy of steam shovel mining depends on keeping the shovel constantly at work, in order to maintain a large output. In the milling systems the work grows in depth, and after a given amount of stripping has been done, all of the ore uncovered may be removed before further stripping is necessary.

"When the block of ore has been mined, the pit thus may be used as a place of deposit for the next stripping. It ought to be possible to utilize this advantage to materially reduce the cost of subsequent stripping, for the haulage would be short, and by systematic methods, the bottom of the stripping could be dumped into the bottom of the pit, and gravity would thus be made to assist throughout the work."

The paper is an excellent one for reference and here are among many other valuable facts the advantages and disadvantages of the systems.

Comparison of Open-Pit with Underground Mining.

"1. There is less danger to the workman from falls of roof and blasting, and the chances of fire are less.

"2. Economy in mining due to the possibility of using large stopes and large blasts, and thus avoiding the narrow working places necessary in underground mining—an advantage which increases with the hardness of the ore. The easier and better superintendence: The saving of the cost of timbering: The saving of the cost of tramming: The small saving in the cost of lighting.

"3. All the ore can be mined with equal ease and absolute certainty, thus avoiding the loss of ore more or less great, which must always accompany underground work.

"4. Saving of the expense of making stock-piles and subsequent loading.

"5. As the output per man per day is increased anywhere from two to nine times, the increase in cost due to an increase in wages will be less.

"6. If the ore requires sorting it can be done cheaper and better in daylight. Or, if thorough mixing is desired it can be done better in open pit mining.

Chief Disadvantages of the Open-Pit Method.

"1. The necessity of providing a place for the waste material removed. This has been a chief source of difficulty elsewhere, and no doubt will often be so on the Mesabi.

"2. If masses of glacial drift; beds of sand, or quantities of unsaleable ore are met with they must be handled. In underground work these deads could be left in place, or at least would not have to be handled.

"3. The expenses of open-pit work increase rapidly with the depth of covering, while those accompanying underground work are independent of this depth, at least up to the point when stripping is no longer a possibility."

Korumburra Coal Fields, Victoria, Australia — *Intrusions of Volcanic Dykes.* In a government report of the coal fields of Victoria, we find that: "During a preliminary examination of the sections of a portion of a field visible in railway cuttings between Nyora and Korumburra, it was observed, that the sandstones, shales, and subordinate coal seams had been much disturbed by the intrusion of volcanic dykes. It was therefore with a view to prevent unnecessary expenditure in boring in disturbed and faulted strata that the area to the west of Korumburra was first surveyed.

A Singular Excavator for Coal.—"I have before," says Mr. James Stirling from whose report we quote, "drawn attention to certain organic agencies in the formation of soils, and special reference was made to the work performed by the land crab in bringing up pieces of the rock forming the sub-soil, and suggested that these diminutive excavators might prove useful in assisting the miner in finding coal seams in South Gippsland and Mr. Bellamy informs me that one of the young men working with him, has successfully utilized the hint, and by carefully observing the material brought up, and forming a small heap round the orifice made by the crab, he detected small pieces of coal and sank a shaft on the spot, and cut the coal seam 4 feet below the surface.

Origin of the Coal Seams.—"The coal deposits found in the Korumburra and Jumbunna coal fields are of Oolitic age and the coal is good, but there are only about three 3 feet seams that will probably yield 35,755,511 tons of coals, but the two things that are remarkable about these measures are, first, *coal* was not expected in Victoria, as the true carboniferous measures are absent, and, second, the origin of the seams appear doubtful according to the claims of the accepted theory that: "The coal seams consist of mineralized vegetation *in situ*." The result is Mr. Stirling thinks that the vegetation from which the seams are derived has been carried onto the sites of the beds by floods, for the coal seams consist of different varieties of coal more or less laminated with stony matter, and there is found in many cases within the pieces of coal, glassy like rounded pebbles, and Mr. Stirling thinks that all this is indicative of conditions that could not exist in the deposition of coals of uniform quality, and nearly uniform thickness. Here are Mr. Stirling's conclusions.

"The explanation offered by many eminent authorities that coal beds are formed by the growth and decay of plants which flourished *in situ* in marshes does not account for all the different conditions observed in studying the carboniferous deposits in South Gippsland, and the following facts present themselves to my mind as difficulties in accepting an otherwise plausible theory:—

"First. Although small bands occur in some of the beds, and underneath the seams as at Outtrim and furnishing an excellent holing,—yet there is nothing to show that such bands represent old soils in which the plants forming the vegetation of the coal beds grew.

"There is an absence of true 'seatstone' containing imprints of the rootlets of plants, such as the stigmaria, associated with the underclays of the true carboniferous beds elsewhere.

"Second. On the contrary, there is strong evidence that the vegetation has been transported from the localities in which it flourished.

"Third. Among other instances, I may refer to the existence of finely water-worn pebbles of glassy quartz in coal of the Korumburra mines, and also the occurrence of occasional lenticular-shaped deposits of clod or shaly matter associated with some of the seams.

"Fourth. The difference in the physical structure of the coal in the same bed, one portion consisting of a mass of charred material resembling an accumulation of charcoal, while another has alternating bright and dull bands or layers, one of which is highly bituminous and the other earthy."

"Fifth. The remarkable variation in the thickness of some of the seams, the false bedded nature of the strata above and below them, and the occurance of portions of the trunks, branches, and roots of trees, regularly deposited in the sandstone beds, all point to driftal agencies in the accumulation of the vegetation forming the coal seams."

Mr. Stirling does not allow or indorse the accepted theory, that the coal seams consist of the mineralized vegetatation that grew where the seams are found, but claims that the driftal theory alone can account for the existence of these coal deposits. The report however claims no finality in the matter, but furnishes facts that are also favorable to the *in situ* theory, and we find abundant evidence that the region of these coal fields was during the deposition of the seams and the immediately overlying and underlying strata subject to great storms and floods that washed off portions of the bog and washed in the roots, branches and trunks of trees already referred to, and in the action of moving water, we have sufficient to account for all the apparent divergence from the common origin of coal seams. The following is Mr. Stirling's statement of these facts:

"Referring to the genus Baleria and to the scarcity of coniferous plants, while there is a great abundance of ferns, cycads, and equisetacea, it is remarked that those plants grew near the shores of the lakes and in islands in them, and thus their remains were more readily preserved in the sediment accumulating in the still shallow waters. Whenever the strata was of such a character as to indicate the presence of water in motion, such as rivers or floods from the highlands, then we do find abundant traces of coniferous vegetation.

"Thus in the sandstones of the lower series we find coniferous wood usually silicified, but it is especially in the upper series—or that characterized by the large amount of granite sand that we find the greatest number of coniferous relics. Often isolated trees which must have been a foot or more in diameter, occur embedded in the sandstones and shales of the upper measures, but which are now flattened by pressure."

In conclusion it is interesting to know, and to notice, that the coal fields of Australia like those of India are not of the Carboniferous, but of the Triassic and Jurassic periods.

Mine Locomotives with Secondary Batteries B. F. Cambessedes in American Manufacturer.—At Amercœur, near Charleroi, in Belgium, electric traction has been applied in a gallery joining two pits, 1575 meters apart, in which, to avoid the cost of overhead conductors the principle of driving by secondary batteries carried on the locomotive is adopted. The gauge of the line, which is laid with fish-jointed flange rails weighing 12 kilograms per metre, is 500 millimetres, the minimum radius of curvature is 8 metres, and the average gradient (in favor of the load) 1 in 370. The first locomotive, built in 1893, resembles a low-sided goods-wagon, having a rectangular body 2.725 metres long and 1.2 metre broad, carried on two axles 1.1 metre apart, the length being further increased by a platform for driver and brakesman at either end to a total of 3.969 metres. The secondary batteries, on Julien's system, include 36 elements, each containing 12,300 by 200-millimetre lead plates, with an active weight of 31 out of a total of 40 kilograms. These are arranged in four groups of nine in covered ebonite boxes, two being placed at either end, leaving a space of 525 millimetres long in the centre for the motor. The boxes are connected by naked copper wire, and the main conductors to the motor are in tinned-copper, insulated with vulcanized rubber; their section is 28 square millimetres allowing the passage of a current of 100 amperes without being unduly heated. The total capacity of the battery is estimated at 465 ampere hours, or 15 ampere hours per kilogram of plate employed.

The motor is of the Lahmeyer type, with bipolar field-magnets of cast iron, series-wound, and Siemens' drum-armature, the core being built up of alternating thin disks of charcoal iron and vegetable parchment. The brushes of carbon, electro-coppered, maintain a fixed position on the commutator independent of the direction of rotation of the armature; and as the breadth of the pole pieces is limited to about half the circumference of the latter, a neutral zone is obtained of sufficient breadth to prevent danger from sparking. The armature makes 1020 revolutions per minute, which is reduced by two changes to 85 on the driving axle, the latter receiving motion from an intermediate blind axle by means of pitch chains. The wheels are 500 millimetres in diameter, giving a traveling speed about 2.4 metres per second, or 8 kilometres per hour.

The total weight of the locomotive is 3,200 kilograms, and that of the train drawn 9 750 kilograms, made up of 15 trams of 250 kilograms, each carrying a load of 400 kilograms of coal, giving, with the engine, a total load of 12,950 kilograms. The journey of 1,575 metres is performed in 11 minutes, giving a useful effect of about 150 kilogram-metres (two horse-power).

The mean potential at the terminals of the motor being 70 volts and the current 30 amperes, the energy consumed is 2,100 watts, or 214 kilogram-metres, giving an efficiency of 70 per cent. According to the calculation of the author, the disposable energy of the battery may be taken at 45.5 horse-power hour, to be expended during eight working hours in the shaft, equal to 5.7 horse-power gross exerted continuously, or 4 horse-power allowing 70 per cent. efficiency for the motor and transmission. This, however, is subject to some reduction, as it is necessary not to leave the batteries completely uncharged at the end of the day's work. What effect is realized from the batteries has not been determined, but experiments made with one of the same type under other circumstances showed, for 20 consecutive operations, charging and discharging, an average of 78.7 and maximum of 85 per cent. Allowing 80 per cent. and the same figure for the primary dynamo, the mechanical effect realized becomes .80 × .80 × .70 = 45 per cent of that of the driving engine at the surface. This is subject to a further deduction by the loss due to resistance in the cables connecting the dynamo with the charging station, which does not appear to have been determined experimentally, but is computed by the author to be equal to about 4.2 per cent., as the depth of the gallery below the surface is only 28 metres, and the length of conductor in the complete circuit not more than 150 metres. In a deep pit, say 500 metres, requiring about 1,100 metres of cables, this loss would be very much larger, and might amount to 25 per cent. of the energy of the primary dynamo. In the present case we obtain as a final result that 40 per cent. of the power expended at the surface is reproduced in the driving wheels of the locomotive, or about twice as much as can be obtained with compressed air, which rarely gives more than 20 per cent., except special means are adopted for supplying heat to the air during expansion.

The daily working cost of the locomotive is given as follows:

Driver's wages	$ .80
Motive power and charging cost, etc	.51
Maintenance of accumulators	1.00
Sinking fund and interest on capital	.59
Total	$ 2.80

This, upon the work done—300 tubs, with a net load of 120 tons, hauled 1,575 metres—corresponds to a cost of 7.4 centimes per kilometre (about 1.2d. per ton-mile), or rather less than half that of horse-traction, which is 16 centimes. In this estimate the duration of the positive plates of the accumulators is taken at a minimum of six months, but in actual work they have been found to be in perfectly good working order at the end of that time.

The locomotive described above has subsequently been supplemented by another of greater power, and differing in construction in several particulars, the most important of these being the substitution of two four-wheeled bogie for the two rigid axles of the first one, and the division of the power, each pair of axles having its own motor, with transmission by epicycloidal spur-gearing instead of a combination of spur and chain-gearing driven by a motor common to both.

The Prevention of Explosions in Mines.—The following is from the *Colliery Guardian*, and is a summary of a report that was recently published in the Austrian *Mining Journal*.

As the majority of colliery explosions are due either to blasting or to defective lamps, attention is naturally directed chiefly to these two points. The danger of an explosion being caused exists at the very moment a shot is fired. Despite the number and variety of the methods of detonation that have been proposed of late years, there is in Austria a marked tendency to return to the electric method and to use no other in fiery mines. The employment of the ordinary fuse, an appliance which on account of its cheapness is still largely used, is not unattended by danger. The dangers were well shown in some experiments made in the Ostrau Collieries, the fuse, being found to explode gas mixtures containing only 1½ per cent. of firedamp. At several collieries in the Ostrau-Karwin district, the use of this fuse is only permitted under certain conditions, whilst at others its use is absolutely forbidden. Some collieries that still use it employ only the gutta-perch pattern, as sparks are not so frequent. The Lauer friction igniter, an Austrian invention dating back to 1887, is now employed only to a limited extent in the Ostrau coalfield. At first its use led to numerous accidents caused by careless handling in transport, by tamping too vigorously, and by the wires becoming entangled. This instrument possessed, however, the advantages that when an accident did happen, as a rule only the person suffered to whose faulty manipulation the accident was due, and that no serious firedamp or dust explosion resulted. A more recent invention, the Tirmann percussion igniter, has not as yet come into any general use, although it has been tried in a number of collieries. It is quite as cheap as the Lauer igniter and it is easily handled. The number of of miss-fires is, however, considerable, and experiments prove that this is due to the want of strength in the spring which projects the bolt against the explosive. The electric method, which appears to be the surest, has hitherto been employed almost exclusively in shaft-sinking and in driving stone-drifts. It is now, however, coming into use for other purposes. Laying long lines of conductors in the workings is, however, a matter of difficulty; the method is uncertain in its action in wet places; and the work of a miner carrying some 20 lb. weight of electric firing apparatus is rendered difficult in steep workings. The danger of the ignition of firedamp in the colliery from sparks at the detonating machine and between badly-covered conductors is considerable.

The machine itself must be carefully attended to, and the insulation of conductors should be as nearly perfect as possible. Wherever practicable the wires should be placed on opposite sides of the roadway. At one of the collieries in the Ostrau district, it may be noted, an electric firing plant has been imported from England.

The current in this is so well regulated that the spark produced does not explode firedamp. One objection to the electric method is that when several shots are fired together, the various explosions are so nearly simultaneous that only one report is audible, and miss-fires consequently often pass unnoticed.

Adverting to the precautions taken in the Austrian collieries during shot-firing, Mr. Lamprecht refers especially to the employment of a special class of workmen to fire shots. Before firing the shots these men carefully examine the workings for gas. This practice is now general in Austria. Shot-firing is often very carelessly carried out, and it is quite out of the question to entrust the average coal-getter with a delicate instrument for gas testing.

Turning to explosives, it may be noticed that in Austria ordinary black powder is rarely used in mines that are at all fiery. Compressed black powder is frequently used. Although it is cheaper than ordinary powder and easier to handle, it is even more dangerous than black powder in the presence of gas. Dynamite is very largely used in the Austrian and Hungarian fiery mines, and the water cartridge, which is used only in rare instances, provides a certain method of obviating explosions. Of the explosives in which salts, containing water of crystallization, are added with a view to reduce the temperature of the gases produced on explosion by this water being converted into steam, soda flameless dynamite has found the most extended use in the Ostrau-Karwin district. Its deliquescence is, however, a great drawback. The use of explosives containing ammonium nitrate is attended by great safety in fiery mines. All the high explosives have, however, the disagreeable property of deflagrating instead of exploding. To this cause several of the most notable accidents of recent years must be ascribed. Lime cartridges were found quite unsuitable in the Austrian mines, and the methods of wedging down the coal advocated at various times have been found unable to compete with blasting powder.

Turning now to the methods in vogue for lighting the workings, it is found that in the Austrian and Hungarian collieries the Wolf benzene lamp is mostly preferred. It is undoubtedly a good gas-tester, and the device that enables the lamp to be relit without opening it presents many advantages. In the Ostrau pits the average velocity of the air-current is from 13 ft. to 16 ft. per second and the Wolf lamp is safe for such a velocity as that. The magnetic lock is not absolutely faultless, as after a lamp has been in use for some time unscrupulous miners easily find means of forcing it open without damaging it. The extent to which the recklessness in some miners may go is well shown by the fact that the period from October 29, 1894, when a serious colliery accident occurred at Anina, to November 20, in that district where 3,000 miners are at work, no less than three cases of unauthorized opening of Wolf benzene lamps were detected; in two of these the magnetic lock was uninjured. By swinging their lamps with both hands violently against the ground, the Roumanian miners in the Banat collieries succeed in forcing the benzene out on to the ground so as to light their cigarettes. The Mueseler lamp has been used for several years in the collieries of the Rossitz district and no accident has been traced to it. The Pieler lamp was largely used for gas testing, but in most of the Banat collieries its use has been discontinued.

Although stationary electric lights have been successfully introduced in the Austrian collieries, no portable electric lamp has yet been found to replace the safety lamp. The chief objection to such lamps is that they afforded no indication of the character of the surrounding atmosphere, and further that the length of time during which the light will last is uncertain. One of the best is the Bristol lamp, which is now used in the Karwin collieries in dangerous places.

Auriferous Deposits of New Zealand.—From a paper by Mr. Henry A. Gordon of Wellington, N. Z., and read before the members of The American Institute of Mining Engineers, the following extracts are taken:

In the Upper Taieri district, "wire gold" is occasionally met with in considerable quantities. It is always obtained at or near the surface, and was in the early days of the diggings considered by many of the miners to be petrified grass-roots. This form of gold is now less frequently met with; but in 1881 McKay, the mining geologist, saw a parcel of 40 oz. of gold of this character at Naseby, and purchased a few pennyweights of it, comprising most remarkable pieces, from the bank where it was sold. There were thin wires of gold straight or bent, one side of which was smooth or striated, the other side being covered with small cubical crystals of gold. This sample, or part of it, was taken to Sydney and exhibited at the first meeting of the Australian Association for the Advancement of Science. Last year Mr. McKay saw, in the possession of Mr. John McKersle, a fine specimen of the same character of gold, which was obtained somewhere in the neighborhood of the Carrick range. It was about 1½ in. in length and about 2 in. in diameter, and, like the specimens already mentioned, smooth on one side and covered with crystals on the other. Such gold might possibly be derived from the denudation of lodes, but the probabilities are against this view. It is to be noted that the samples hitherto found came from districts where the quartz drift deposits of cretaceo-tertiary age are auriferous, and as the strata are tilted to considerable angles, gold-bearing bands are thus exposed at the surface, where a partial solution of the gold might be again precipitated by organic matter and crystallized at the outcrops. Another possible instance of gold precipitated from solution is reported in the Macrewhenua field, but the occurrence requires verification. Last year Mr. McKay thought he detected minute crystals of gold which were supposed to be derived from a greensand band on that field. Samples of the greensand subsequently sent to Wellington yielded no gold, but the formation was declared by the miners to be gold-bearing. The greensand is a marine deposit, full of sharks' teeth and shells of various mollusks, and consists of glauconite and very fine quartz sand, that has evidently been deposited in comparatively deep and still water, and is therefore very unlikely to contain mechanical gold, however fine.

The underlying quartz drift has auriferous layers or bands through it, and extends over a very large area of Otago. Sloping as it does from higher to lower ground, as on the flanks of the Kakanui range, it would at the lower levels become saturated with water, possibly chlorinated water, which would dissolve a part of the gold in the lower drift, and, under pressure, would rise into and saturate the greensand band, while the organic matter in this band would be sufficient to effect the precipitation of the gold now present in the greensands.

Mechanical Deposits.—Recent and pleistocene gold deposits need not be adverted to in this paper, and, as many of the later pliocene gravel deposits are not readily distinguishable from those of still younger date, the most modern deposits that will be mentioned here are probably of older pliocene date.

Pliocene and Upper Miocene Deposits of the West Coast of the South Island.—The youngest of these are the gravels of the Humphrey's Gully range, on the southern side of the Arahura Valley. Similar gravels are noticeable at O'Donohue's Creek, five miles from Kumara, on the Kumara-Christchurch road. At the latter locality, though gold is present, and the bed of the creek has been worked, the gravels indicated have not as yet proved profitable. At Humphrey's Gully goldmining has been carried on in these gravels for a long series of years, and there is yet an unlimited supply of material to be operated upon. Auriferous gravels—it may be of a slightly greater age—are worked in the Totara district on the top of Mount Greenland, 3,000 ft. above the level of the sea; nearer the sea level in the Mount D'Or claim, near Ross, and in other claims in and along the eastern margin of Ross flat; while on Ross flat the same gravels are found 240 ft. below sea-level and contain large deposits of gold. The same beds have a very large development in the northwestern part of Westland, but, owing to the small percentage of gold yielded, they are not worked at the present time. They also have a large development along the east side of the Grey Valley, more especially in the valley of the Little Grey; and at the source of this stream they fill the valley between the Paparoa range and the hilly country to the southeast of Reefton. In the Inangahua Valley they have an important development between the north branch of the Inangahua River and Boatman's and Larry's Creeks; in the southwest part of the upper Buller Valley their distribution has been less definitely ascertained; but between the junction of the Owen and the outlets of Lakes Rotoroa and Rotoiti, north of the Devil's Grip, an enormous development of these gravels fills the northern slope, between the mountains to the east and west, to the shores of Blind Bay. The same gravels are largely developed along the east coast of the South Island, but neither in the Marlborough nor in the Canterbury district are they known to be gold-bearing. In the interior district of Otago they have again a large development, and are mined for gold at the Kyeburn, on the eastern side of the Maniototo Plain. They are largely developed in Ida Valley and in the Manuherikia Valley, and appear at several places in the Molyneux Valley below the junction of the Manuherikia River.

Meteorology and Mining.—"Meteorology and Mining" was the subject of a paper descriptive of a method of indicating meteorological conditions and changes in and about coal mines, which was read before the members of the South Wales Colliery Officials' Association, at Pontypridd, on Sept. 14th, by Mr. Joseph Thompson, M. E., of Cardiff. Mr. Thompson said there could be no question of the absolute unanimity of feeling that it was desirable that explosions of gas in coal mines should, if possible, be prevented, and the contingent loss of life, and destruction of property which occasionally occurred, be avoided. The axiom "Remove the cause and the effect will cease," was as true to-day as ever, and as applicable theoretically to the problem of how colliery explosions were caused as it was to any of the simpler problems of life. The ability to pass a quarter of a million cubic feet of air per minute through a main airway was one thing, but the advisability of doing it was another, for if it be possible for the seat of a explosion to be in the main intake airway where most of the air passes with the velocity of a gale, such velocity must necessarily preclude the possibility of searching with the safety lamp to ascertain the presence or otherwise of fire-damp. Making a passing reference to the coaldust theory, the speaker thought no one would venture to deny that these hurricane velocities were responsible for such large quantities of the dust being carried through long distances in suspension in the air-current, and deposited in considerable bulk at points where such might not otherwise have occurred. Further, it was clear that in the event of an explosion originating in such a current, impregnated with this inflammable dust, the tendency must be with such a high velocity to elongate the flame of the explosion, and thus not only most seriously increase the capacity for damage and destruction by burning, but intensify the violence of the explosion itself. The speaker then gave an interesting description of an instrument which he submitted to the meeting. It had been called a meteorograph, or a delineator of the atmosphere, and was intended to be hung against the wall; and when fixed up to represent any set of conditions or circumstances. It presented the account in bold text, and in popular phraseology, and entirely free from the ambiguous confusion of technical terms. In its scope for coal mining purposes it embraced the elements of pressure, temperature, moisture, and time of observation, together with a diagnosis stating whether the indications given by the diagram were "more," or "less," or "similarly" favorable (or unfavorable) as compared with what was indicated twenty-four hours previously, so that there should be little, if any, difficulty on the part of those using the apparatus keeping in constant touch with the operations of those physical laws and forces which admittedly exercised so powerful an influence for good or evil upon the manœuvres alike of exudations and accumulations of fire-damp in coal mines. Structurally, the apparatus was self-contained—when fixed it had no loose parts to become mislaid or lost. Dealing with pressure (barometer) he had made an entirely new departure by dividing the barometer scale into zones of high and low pressure.

He was as conscious as anyone could be of the seemingly inexplicable mystery which usually surrounded the problem, after an explosion, of how it was caused; but, so far from regarding it as one of the hidden things of nature, or accountable for only by some outside circumstance or combination of circumstances into which only experts might pry—circumstances such as are sometimes set up in connection with blown-out shots, coaldust, and such-like theories—he ventured the opinion which he had held and continued to strongly hold that, if fire-damp were prevented from coming into contact with open flame, there would be few or no explosions. He might go further, and say that it was not the gas we know of in the mine which gave rise to difficulty and danger, but that which we do not know of, which coroners' inquiries proved abundantly. The conclusion was thus forced upon them that it became an essential element of duty to make a special study of this gas "we do not know of," and it was at this point that meteorological knowledge came to their aid. In the days when the science of ventilating coal mines—if science it could be called—was in its rudest form, contemporary with and anterior to Sir Humphrey Davy, observant old colliers whose working places were often found to be foul with fire-damp were wont to associate that condition with the direction of the wind, probably due to the fact that certains directions of wind in the particular locality were associated with a lower or falling condition of atmospheric pressure as indicated by a falling barometer. It would thus be seen that the association between atmospheric conditions and the presence or absence of fire-damp in the workings of coal mines was not by any means novel. In those days meteorology was an insignificant branch of the science of astronomy. Meteorology—which, technically speaking, meant the science of the atmosphere—had, however, established for itself a worthy and honorable position in the mercantile world, and this comparatively young branch of science now speculated upon coal mines. Bearing in mind the settled views held by all intelligent and practical mining men of the present day, that atmospheric pressure and moisture were influences of great potency in connection with the ventilation of coal mines, he thought no greater absurdity could be conceived than that of neglecting to apply to the best purposes the useful information and suggestions which this branch of science placed within their reach. What were formerly speculative problems are now well established scientific truths, and in deciding what to accept or what to reject it was at least desirable not to err on the hazardous side. It was not to be implied that in the well conducted operations of coal mining this important branch of science was neglected for he knew that it secured in many places a very full share of study and consideration, and with useful results. He could not imagine how anyone, having seen the sound evidences of its utility in matters concerning atmospheric influence over ventilation, could ever think of relaxing his hold upon it enabling him, as it did, to settle many important points with certainty and which must otherwise have remained in the region of dangerous doubt. He must not overlook those who seemed to prefer to live entirely free from scientific considerations, and who were content to go just so far as was required by the provisions of the Coal Mines Regulation Act, which made the existence of a barometer and thermometer a statutory necessity at the entrance to each mine. The meteorological instruments useful in connection with coal mine ventilation were the barometer, thermometer, hygrometer and anemometer, which respectively indicated the condition and changes of pressure, temperature, moisture and volume of ventilating current. Although each element had an appreciable and important significance to the responsible officials of a mine in the economy of ventilation, the premier position must be accorded to the barometer, which indicated the condition and variations of pressure. Temperature played a less important part in these days of mechanical ventilation than was formly the case under the older *regime* of the furnace, though it was a condition which had to be carefully reckoned with as being liable to exercise its most deleterious influence concurrently with other adverse circumstances of the working of the mine. Moisture, as indicated by the difference between the readings of the wet and dry bulb thermometer (hygrometer), was said to be responsible for the variation of resistance to the passage of the current of air through the air passages or galleries of the mine, but of itself it was, in Mr. Thompson's opinion, only of material importance when its influence for evil operated concurrently with other adverse elements. With regard to the volume as ascertained by the anemometer, he confessed that his mind was not free from doubt as to the absolute or general utility of such enormous volumes of air as are frequently heard of in both in practice and in project.

Artesian Wells and Water Motors.

Among the most interesting water power installations now in existence are, without a question, the artesian well plants which, of late, have gone into operation at different places in the western part of the United States. Incidentally they have given prominence to the much-neglected water motor, which for years past has led a modest kind of existence, notwithstanding its very fair claims to consideration. As a matter of fact, it has many decided advantages as a means for supplying small power, and even for comparatively large quantities some of its various modifications have been found to give very good accounts of themselves. Practically, a water motor is as easily managed almost as a water faucet. Its cost for repairs is nominal, and its first cost is exceedingly small. With this in its favor, a pretty heavy bill for water power can be afforded, and yet a considerable profit be left over steam or compressed air.—*From Cassier's Magazine for October.*

EASY LESSONS ON MINING.

This Department contains articles to assist ambitious Miners to educate themselves, and obtain Certificates of Competency as Mine Foremen, or to become Mine Superintendents.

The articles are written to be understood by the unlearned and the learned alike. Plain language is used, no obscure terms are employed, and each subject treated, is made as clear and easy to understand as possible.

Further: The Questions asked at the different Examinations for Mine Foremen and Mine Inspectors, are printed and answered.

☞ The Series of Articles "Geology of Coal," "Chemistry of Mining," "Mining Methods" and "Mining Machinery" was commenced in the issue of March 1894. Back numbers can be obtained at twenty-five cents per single copy, $1.00 for six copies, and $2.00 for twelve copies.

MINING MACHINERY.

The Mode of Action of the Fan.—The Piston Analogous to the Fan Blades.—Velocities and Densities.—Balancing the Mine Resistance.—Velocity into a Vacuum.—Pressures and Squares.—An Example in Fan Calculation.—The Blowing Fan.—Pumps and the Velocities of Fluids.

65. **The Mode of Action of the Fan.**—In commencing to study the principle of action of the ventilating fan, we must at once dismiss from the mind the idea that the fan is either a puzzle or an enigma, that can only be solved by being immersed in the profundities of abstract mathematics, for all the haze and obscurity that envelopes the subject, is the result of believing that the mode of action of the ventilating fan is a riddle that can only be solved by special deeply learned experts, whereas any student in mining can, through the medium of ordinary arithmetic and the well known laws of mechanics, balance any equation relating to it. To make the mode of action of the ventilating fan quite understandable, let us proceed with the help of Fig. 112.

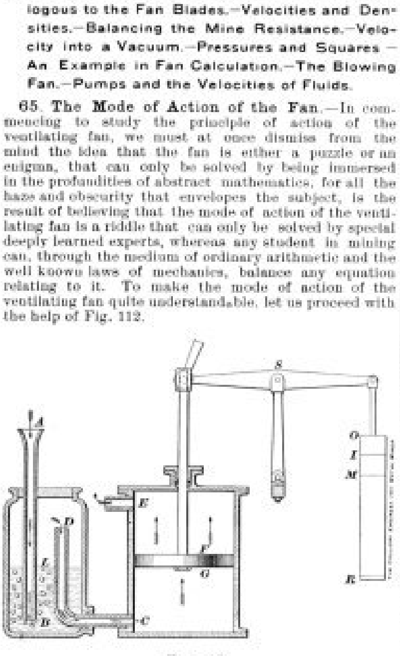

FIG. 112.

66. **The Piston Analogous to the Fan Blades.**—Here the case of the fan is substituted with a cylinder and the blades with a piston *F G*. The centrifugal machine is continuous in its action, but the piston and cylinder has an alternate action for intake and discharge, but so far as the pumping action is concerned, both are alike; and to make the piston and cylinder analogous to the fan, the port of entry on the upstroke is made to take place at *C* and the discharge at *E*. Now if the cylinder be disconnected with the vessel *A D B*, and if the ports *C* and *E* are equal, we may now proceed to try such experiments as will demonstrate the laws that govern the mode of action of such a pump. Let the area of the piston *F G*, be equal to one square foot and the area of the port of injection at *C*, 4 square inches, and let the area of the port of ejection at *E* be 4 square inches, or equal to *C*; further, let the piston be moved with an upward force of 2 pounds. Under the conditions given, the pump is similar to a fan, when situated in the open air and not subject to any mine resistance. The orifice of entry situated at the center of the fan, is the exact analogue of *C* under the piston, and the square of the velocity of the air entering the cylinder is increased or diminished directly as the depression under the piston is increased or diminished, and what is true in the principle of action, when air rushes into the depression under the piston in this case, is equally true of air entering through the central orifice into the depression in a fan. Let us here notice one thing however, and that is the ejection of the air above the piston at *F* will either be at a less velocity than that of the entry of air at *C*, or a greater pressure will be required for ejection, but if the mass of the air per cubic foot is the same at the discharge and entry of the pump, then no difference can arise, because the velocity of discharge cannot exceed the velocity of entry; therefore it follows that when the densities are equal, the pressures are equal and the velocities are are equal. In the case of an air pump or fan however, the densities of the injected and ejected air are never equal, consequently the pressures are different, and the velocities are different, but the masses of air entering and leaving a pump or fan in a given time are always equal. All these peculiar statements may seem very strange, but we cannot understand the action of a fan without being first made aware of how the elasticity of the air affects its mode of action; and further, if we refer to the figure we will see that when the piston moves upward the air above it is compressed while that beneath it is rarefied, with the result, that a pound of compressed air is smaller in volume than a pound of thin or rarefied air, consequently as we mean by mass, the quantity or weight of air, it is clear, that a greater or less weight of air cannot leave a pump or fan in a given time, than that which enters it, but a large volume of rarefied air, may be only equal in weight to a small volume of heavy air, and if the volumes are different the velocities must be different. For example, the density or weight of air varies directly as its pressure. Then take the pressure of air to be about 2,130 lbs. per square foot, and if the pressure be increased 1,000 pounds, and if the weight of 13 cubic feet of air is 1 pound, the same volume will now weigh $\frac{(2,130 + 1,000) \times 1}{2,130} = \frac{3,130 \times 1}{2,130} =$ 1.469 pounds, or let the pressure be reduced 1,000 pounds, then the weight per 13 cubic feet will be $\frac{(2,130 - 1,000) \times 1}{2,130} = \frac{1,130 \times 1}{2,130} = .5352$ pounds.

67. **Velocities and Densities.**—Here then we see clearly that to make the mass entering the pump equal to the mass discharged by it, the velocities will be inversely as the weights of the masses per cubic foot, or per 13 cubic feet. Then if we take the velocity of the heavy air to be one, that of the light will be $\frac{1.469}{.5352} = 2.744$.

Let the reader be careful to duly appreciate these fine points, and his progress will be quicker after. Now let us introduce the mine resistance that the fan must overcome and will we discover the great importance of the matters we have just discussed. Connect *A D B* with the port of entry at *C*, and let us observe that we are about to imitate the mine resistance by causing the incoming air to blow through a stratum of water 2 inches deep as at *L*, and when the piston ascends, it is clear that two things will occur. First, the mine resistance *M R* will require extra force like the weight *M R* to overcome it; and second, the increased mine resistance will reduce the atmospheric pressure, and hence the air will be rarefied. 2 inches of water-gauge being equal to 10.4 pounds per square foot, the weight of air must be reduced as $\frac{(2,130 - 10.4) \times 1}{2,130} = .995$ or from 1 to .995. This appears to be a small reduction, but when we notice that the mine resistance and the consequent rarefaction affect the result as a square, we can realize the importance of the matter, as $\frac{2,130}{(2,130 \times 10.4^2)} = \frac{2,130}{2238.16} = .951$. It will be shown further on, that the mine resistance alone gives to this class of centrifugal pump a diminishing ratio of exhausting efficiency, but there are other negative or antagonistic factors that convert a diminishing, into a vanishing efficiency.

We see that a centrifugal fan can only establish a perfect vacuum at its orifice of entry, by making an infinite number of revolutions in a limited time, but with a considerable mine resistance, the infinite number of revolutions would be reached long before a depression equal to half the pressure of the atmosphere was reached.

68. **Balancing the Mine Resistance.**—Refer again to the figure and notice that if the counterbalance weight *M R*, weighed exactly 10.4 pounds, or a weight equal to the current pressure due to 2 inches of water-gauge, no air would enter by *C* or leave the cylinder at *E*, because the piston would only rise until it had made a depression equal to a reduction of pressure of 10.4 pounds per square foot, and the air could not enter through *A* and blow through the water in bubbles, escaping at *L*. Here, then, we see clearly that neither a pump nor a fan has any spare energy for injection or ejection until the mine resistance is balanced. Set above the weight *M R*, the weight *M I*, and this will represent the force required for injection, and upon *M I* place *I O*, and this will represent the force required for ejection,

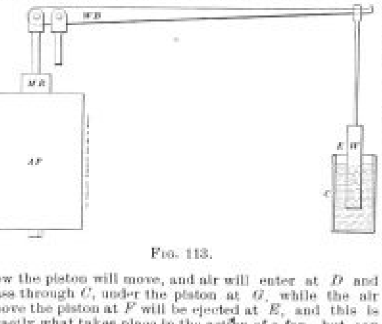

FIG. 113.

now the piston will move, and air will enter at *D* and pass through *C*, under the piston at *G*, while the air above the piston at *F* will be ejected at *E*, and this is exactly what takes place in the action of a fan; but, say you, rarefaction does not come in here. Pray look again, and you will find it does; and to assist the investigation, Fig. 113 is introduced. The figure is that of a lever balance. *A P* is a heavy weight to indicate the atmospheric pressure and *M R* is the mine resistance, *A P* + *M R* being the denominator of the fraction that will just now engage our attention. *A P* + *M R* are balanced by *E*. *E* is seen to be immersed in water *W*, in a cistern *C*, and the object of this arrangement is to illustrate the diminishing power of the fan as the result of the rarefaction due to the mine resistance, for just as the weight *E*, could not balance the weights *A P* and *M R* if it was entirely immersed, so the rarefaction of the air within a fan fixes an unalterable limit to the velocity of the air into it, that cannot be increased or diminished without increasing or diminishing the velocity of the fan. Consequently, to find the ventilation due to the action of a given ventilating fan, the factors required are:

1. The revolutions per minute.
2. The diameter.
3. The radial length of the blades.
4. The areas of the orifices of entry and discharge.
5. The mine resistance.
6. A fractional constant of efficiency.

Keeping in view the fact that Fig. 112 is a complete illustration of the mode of action of a fan, we will now proceed to still further establish that conclusion.

69. **Velocity into a Vacuum.**—At atmospheric pressure the velocity of air rushing into a vacuum is equal to 1341.+ feet per second, and the square of that velocity gives a number that we often require in fan calculations, namely, 1,800,000.

The reader will remember that *C* and *E* were supposed to have a sectional area of 4 square inches, and that after making *M R* = 10.4 pounds per square foot, *M I* for the depression was 1 pound and *I O* for the compression of ejection was 1 pound, therefore the total weight, or the analogue of the engine turning the fan was 10.4 + 1 + 1 = 12.4 pounds.

70. **Pressures and Squares.**—Again we noticed the effect of the rarefaction and resistance of the air, and to allow for these we proceed as follows: Call the mine resistance *M* and the calculated centrifugal force *T*, and the moving force remaining after the mine resistance has been deducted *F*, and the pressure of the atmosphere in pounds per square foot is 2,130 pounds, and remembering that the pressures that give motion to fluids are alway in the proportion of the squares of the velocities of the fluids, we can by an easy process in figures, determine the velocity of the air on entering *C* after passing through the resistance in the bottle *A D L*. For if the pressures and squares are directly proportionate to each other, which they are, then *T* — *M* is equal to the numerator of the fractional portion of 1,800,000, which is the equivalent of the square of the velocity of the air in feet per second. In the case before us $\frac{T - M}{(2130 + M)} \times 1,800,000 = \frac{2}{2238.16} \times 1,800,000 = 1608.46$, and the velocity is, therefore, in feet per minute $\sqrt{1608.46} \times 60 = 2,400$.

We can now see how to find the velocity of the air entering a fan, and we must be careful to notice two things in relation to this matter. First, by the water gauge we can find the velocity of the ventilating current in an air-course, but we *cannot* by the water gauge alone find the quantity of air passing through a fan.

All this appears plain enough, but there are other modifying factors that must be explained before calculations can be made that will give correct results.

For example, the relative areas of the orifices of intake and discharge seriously influence the results, but to keep the reader abreast of the subject so far as we have advanced with it, let us give an example to illustrate what has been learned; and let us further say that after the whole matter has received exhaustive treatment, numerous questions and answers will be given to show how the values in eace case are determined.

71. **An Example in Fan Calculation.**—A ventilating fan for a mine is 20 feet in diameter; makes 80 revolutions per minute; the radial length of the blades is 6 feet; the orifices of intake and discharge are equal; the mine resistance is equal to 12 pounds per square foot, and the reduction of flow due to the contraction at the orifice of entry, commonly called the *vena contracta*, is .6. What then is the quantity of air per minute passing through this fan?

ANS:—First find *T* the pressure due to the radial column. The radius of gyration is 4 + 3 = 7 or half the length of the blades added to the radius of the orifice of entry; and the mean diameter then is 14 feet. The mean velocity in feet per second is

$$\frac{14 \times 3.1416 \times 80}{60} = 58.6432.$$

Taking the average weight of a cubic foot of air to be .0766 the weight of the radial column will be 6 × .0766 = .4596, and as the tangential force varies as $\frac{V^2 W}{3.1416\, g} = F$, then *T* will be equal to $\frac{58.6432^2 \times .4596}{3.1416 \times 32.16} = 15.644$ pounds per square foot.

And the square of the velocity of the air entering the orifice of the fan will be

$\frac{(T-M)\times 1,800,000}{(2130+M^2)} = \frac{(15.644-12)\times 1,800,000}{(2130+12^2)} = \frac{3.644\times 1,800,000}{2274} = 2884.32$. The velocity into the orifice of entry will be in feet per minute $\sqrt{2884.32}\times 60 = 3222.415$. The area of the orifice of entry into the fan is $8^2\times .7854 = 50.2656$ and taking the co-efficient for the *vena contracta* at .6, the quantity of air passing through the fan per minute will be $50.2656\times .6\times 3222.415 = 97186$ cubic feet.

Let us not forget that for reasons that will afterward be given .6 has been found as low as .3 with the consequent bad results. The example just worked out demonstrates the accuracy of the process, and to still further sustain the conclusions arrived at, let us take the case of a fan set in the open air and therefore having no resistance at either intake or discharge, and to make the contrast show a marked difference, let us take all the values given for the last example except the mine resistance, which will not occur. We can see at once that the whole of T will be available for the injection of air into the orifice of entry and for discharge, and it is also clear that the pressure of the external air is not by any speed of the fan reduced at the entry, but the density and pressure of the air at the moment of discharge is increased, therefore the resistance set up is directly as the pressure or $\frac{T\times 1,800,000}{(2130+T)}$ = the square of the required velocity.

Carefully notice the T is not squared before being added as was the case with M, because there is no rarefaction due to T; then as we found in the last example that $T = 15.644$, it follows that the square of the velocity in this case is $\frac{15.644\times 1,800,000}{2130+15.644} = \frac{15.644\times 1,800,000}{2145.645} = 13,124$ and therefore the velocity per minute is $\sqrt{13,124}\times 60 = 6,873.574$ and the quantity in cubic feet per minute passing through the fans is $.6\times 8\times 8\times .7854\times 6,873.574 = 207,303$. From this example we learn an interesting fact, namely, that with the same velocity of the fan the value of T remains, but the mine resistance reduces the quantity from 207,303 to 97,186 cubic feet; or 12 pounds per square foot of mine resistance reduces the quantity in this case from 1 to $\frac{97,186}{207,303} = .4689$. After this the water gauge can only be taken as a negative and uncertain index of the quantity of air passing through a fan.

72. The Blowing Fan.—To still further make the the facts under discussion cohere we introduce Fig. 114

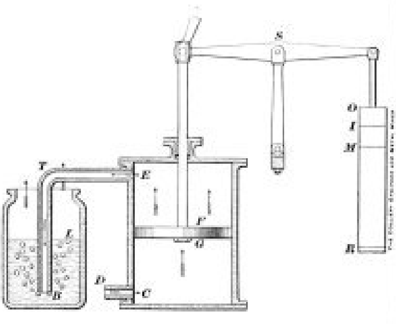

FIG. 114.

as an illustration of the mode of action of the blowing fan, and it will be seen that two things occur that set the blower in strong contrast with the exhauster, and the first is the pressure of the external air at the orifice of intake is invariably atmospheric pressure, and that the pressure at the orifice of discharge is always above atmospheric pressure. The second point of contrast is the pumping efficiency of the blower is greater than that of the exhauster, and the diminution of efficiency in the blower takes place more slowly than in the exhausting fan. For example, the atmospheric pressure at D, before the port of entry C, is uniform, whereas the compression at E increases; and to prove this, remove the weights MI and IO and RM will just balance the resistance in the bottle, for the water in the tube T will just reach the bottom without blowing through. Therefore MI and IO represent the depression within the fan and the compression at the exit from the fan as before, and to sustain the claim of the second point, let us first notice that instead of the denominator of the fraction for finding the square of the velocity being as before $(2130+M^2)$, it is now $(2130+M)$, and for illustration let us use the former values of the exhauster to find a result with the blower. T was 15.644 and M was 12; the square of the velocity will therefore be $\frac{(T-M)\times 1,800,000}{(2130+M)} = \frac{3.644\times 1,800,000}{2142} = 3,062.3$ and the velocity in feet per minute will be $\sqrt{3,062.3}\times 60 = 3320.3$, and the cubic feet per minute passing through the fan will be $.6\times 8\times 8\times .7854\times 3,320.3 = 100,138$. Then under the same conditions of mine resistance and velocity, the same fan exhausts 97,186 cubic feet and blows 100,138 or a difference in favor of the blower of $100,138 - 97,186 = 2,952$ or an advantage of a little over 3 per cent. At higher velocities the blower leaves the exhauster far behind; and when the reader has learned the lesson, as taught with the illustrations, he cannot fail to see the loss due to the rarefaction in the drift.

75. Pumps and the Velocities of Fluids.—Fig. 115 introduces another phase of the operation of the same law as illustrated with a piston moving in advance of the ascending water column.

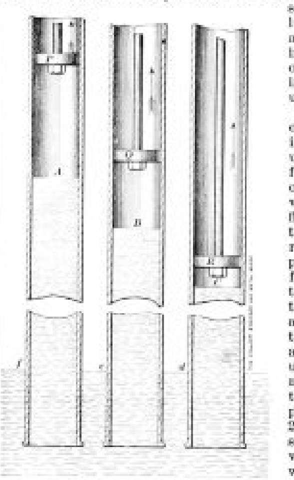

FIG. 115.

The velocity of water rushing into a vacuum is 46.819 feet per second, and as the velocities of fluids vary as the square roots of the pressures, it follows that the squares of the velocities are directly as the pressures, and the pressure of the atmosphere is, therefore, proportionate to 2192.2, the square of the velocity of water rushing into a vacuum. Water rises to an elevation of 34 feet in a vacuum, but it requires time to ascend to that height, because of its inertia and the friction of the sides of the chamber it moves in. 46.819 feet per second is equal to 2809.14 feet per minute, and as this velocity is calculated without allowing for frictional resistance, let us make it for illustration nearer what it should be, 2,400 feet per minute, or 40 feet per second, or the square of the velocity in feet per second is 1,600 when allowance is made for incidental resistance. To make the matter clear, let us begin with an example.

The piston of a pump is situated at an elevation of 16 feet above the ingoing water that is in course of being pumped, what should be the maximum velocity of the piston?

ANS:—Now as a 34 feet column of water will balance the pressure of the atmosphere, it might be thought that the velocity would be as follows $\sqrt{\frac{(34-16)\times 1,600}{34}}$ = the velocity per second, but before the column can move, the inertia of the 16 feet of column must be overcome, and the mass set in motion, therefore as in the case of the blowing fan the velocity will be found as follows:

$$\sqrt{\frac{(34-16)\times 1,600}{(34+16)}} = \sqrt{\frac{18\times 1,600}{50}} = 24 \text{ feet}$$

per second, or $24\times 60 = 1,440$ feet per minute, and as the valves require force to lift them, and a still further interference of the *vena contracta* takes place, it is probable that the velocity is still much less. We see then that the efficiency of a water pump is a vanishing ratio, for let us suppose the piston is to be situated at an elevation of 24 feet, then

$$\sqrt{\frac{(34-24)\times 1,600}{(34+24)}} = \sqrt{\frac{10\times 1,600}{58}} = 16.6 \text{ or}$$

996 feet per minute. A double acting pump then, with a 6 feet stroke and making 100 strokes per minute would lose the $\frac{(100-83)}{100} = .17$ of its stroke at every lift as shown at RC and at a higher piston speed the loss of water lift would become like QB or PA.

The *vena contracta* so powerfully interferes with the inflow at the orifice of entry, that the piston may be set to work below the level of the feed water and yet at a high speed it may outrun the column as at Rb and ag Fig. 116. C is the surface level of the feed water, and by a thoughtful inspection of the last two figures the causes of the diminishing efficiency of machines of the fan class can be so understood, that the succeeding lessons on the subject will heighten and deepen the interest called forth in the investigation of the matter.

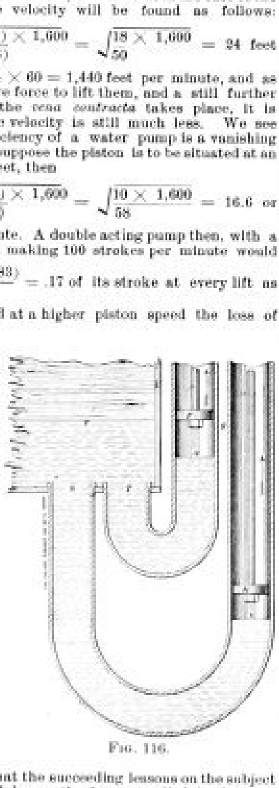

FIG. 116.

GEOLOGY OF COAL.

The Varieties of the Cephalopoda.—The Conifers of the Devonian Period.

51. The Varities of the Cephalopoda.—The recurrences of invariable law, make the past and the present one grand harmonic, and but for this concord in the pulse of life that beats true to the same time for ever, the past would be concealed in the impenetrable darkness of the infinite. We can therefore read the past by the present, because the biology of to-day, is only a reprint of that of all the ages that are gone, and knowing this, our faith is as satisfying as the evidence of a fact, and we can therefore with this assurance, dare to restore as a mental conception the life of former eons, and the fauna and flora of former lands.

From the standpoint just assumed let us then associate the present with the past by finding examples of progression in succession arising from the altered and improved life conditions of each succeeding vast period of time, and where can we look for a better example of these progressive and successive changes, than that which characterizes the most highly organized mollusks the cephalopods. They first appeared in rocks of the Cambrian age as the orthoceras and persisted into the Carboniferous period when the orthoceras vanished forever. Fig.

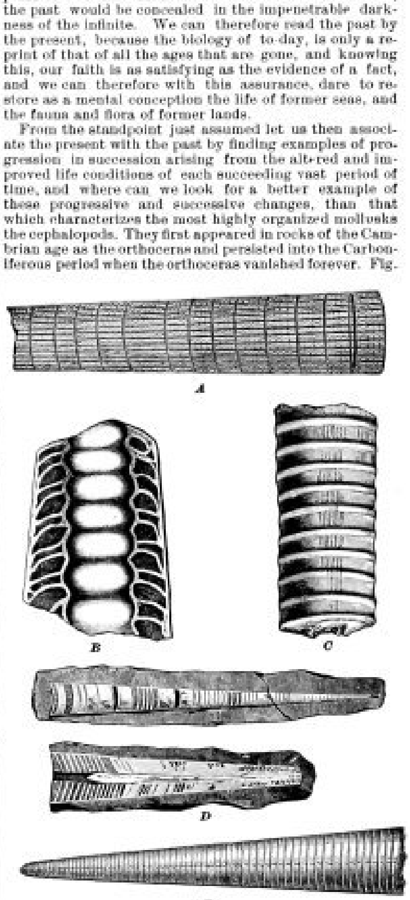

FIG. 85.

85, A, B, C, D and E, are Silurian examples of the straight shells or long-horns or orthocerites. This singular mollusk lived in a shell divided by septa or transverse plates or partitions into chambers, through the whole of which passed the siphon or siphuncle, and the head with its beaked mouth was set in the midst of the roots of its tentacles, or arms for seizing its prey, hence it was head footed, or was a cephalopod. The tentacles were and still are covered with vacuum discs or suckers, hence the danger of being attacked by the living cephalopod or cuttle fish.

By Fig. 86, it will be seen that the orthoceras became early in the Silurian period an open coiled "ram's horn" or a modified orthoceras, as *Lituites cornu arietis*, at D, and this change continued until the coils of the shell became close, and then we had examples of the beautiful ammonites, where the junctions of the septa with the hornlike shell cause these pretty curling ridges such as are seen on B as lines, and on A as indicating the boundary lines of the septa where they are joined to the

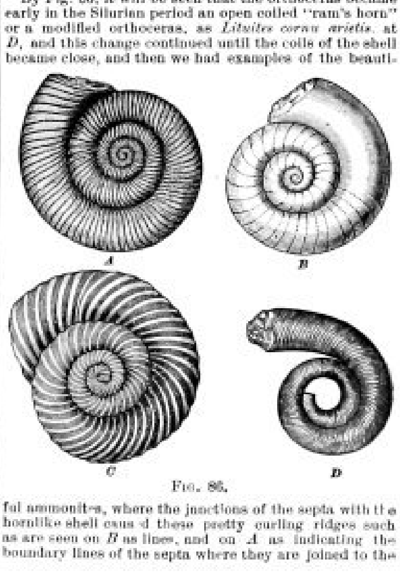

FIG. 86.

shell; but these ridges are still more developed on *C*, and are the embryo of the spinelike processes of the magnificent shells of the ammonites of the Cretaceous period. The cephalopods are found as long horns in the early Cambrian, and continued right on into the Carboniferous period. During the Silurian period some varieties became curled as open coils, and others became close coiled as ammonites and the true ammonites are only now represented in our seas by the pearly nautilus, but the cephalopods as naked or shell-less cuttle fishes swarm in our seas to-day, and they are distinguished from the shelled variety by being Dibranchs, the other being Tetrabranchs, that is the naked present day cephalopods, are more highly organized than their predecessors being Dibranchs, or two gilled, the shell varieties being Tetrabranchs, or four gilled. The gills of a fish are the substitutes for the lungs of the higher orders of animals, it is by the gills that oxygen is collected from the water to aerate the blood of the fish. Now as the cephalopods of all the ages, have been strongly characteristic and distinctively different, they furnish unsurpassed indices of the periods, and therefore are worthy of the closest attention.

52. The Conifers of the Devonian Periods.—Fig. 87 is an illustration of the cell walls of the woody fibre of the fir or conifer. These lines or vesicles and

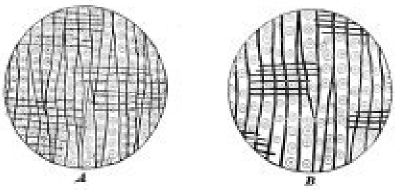

Fig. 87.

discs have given distinctive character to the wood of the conifer from Devonian to the latest times, *A* is an example of the fossil wood, *B* is an example of the latest firs. Perhaps none of our forest trees have altered so little during the mighty march of time, as the fir. They are first found as gymnosperms, and they are gymnosperms still, that is their ovules or seeds are matured in nakedness. The conifer of the Devonian period then is of great interest as proving that the dry land and climate of that time was the beginning of the morning of the period wherein all the life forces made their strongest manifestation in the production of the prodigious plant growth of the Carboniferous period.

CHEMISTRY OF MINING.

Units of Electrical Measure—Correct Ideas of Electrical Terms—High and Low Tension—Amperes and Volts—Volume and Intensity—The Coulomb and Heat Units—Electric Resistance—The Transmission of Energy.

62. Units of Electrical Measure.—The basis of all knowledge and civilization is found in units of extension, volume, energy, weight, measure and value, and the difference between ignorance and knowledge can be discovered on hearing men speak. The ignorant man says, "there was such a tremendous lot of people there," the educated man says "he estimated the crowd at 360 persons." Fancy men saying, "it is *such a strong* current of electricity," by this statement we have no idea whatever of true value.

We clearly see then that units of measure for estimating the value of energy are indispensably necessary, and further, as electricity is a mode of molecular motion the units of its measure must be of a like character to those used in other branches of mechanics such as time, mass and velocity. And such is actually the case for we have the Coulomb for time *one second*, the ampere for mass or flow and the volt for velocity or pressure. 1 volt multiplied by 1 ampere gives .7373 of a mechanical unit of work per second, and what is called a Watt consists of 746 of these .7373 of a foot pound units per second. This makes the electrical mechanical units harmonize with those of steam.

For example, a horse power per minute consists of 33,000 units of work, as established by Watt, or $\frac{33,000}{60} =$ 550 units of work per second, and $\frac{550}{.7373} = 746$, or $746 \times .7373 = 550$, then as an electrical unit of work is only .7373 of a foot pound, 746 of these are equal to 550 foot pounds done per second, a true Watt.

63. Correct Ideas of Electrical Terms.—As our fore-fathers called electricity a fluid, we continue even yet to speak of it as *flowing*, and no doubt this mode of speaking will continue until our children and successors have found out all the possible uses and the machines requisite for the application of electricity, when those that follow will reform the terms, and introduce others that will correctly express what is meant. In the meantime we have to say much to make the terms understandable, for example, a foot pound is either the equivalent of one pound being lifted one foot high, or that of a force of one pound being exerted through the space of one foot, in overcoming a resistance of one pound, so the electric .7373 of a foot pound, is the unit of work done, when a force of one volt lifts one ampere through the length or resistance of one Ohm.

Fig. 106 is to explain the relationship of the volt to the ampere, or the velocity to the mass. At *B* we see a small weight shown as 1 *A*, that is 1 ampere, at an elevation of 10 *V*, or ten times that of 1 *V*, now $10 \times 1 = 10$, that is 10 of the 746 units of a Watt, again $10\ A \times 1\ V = 10$ Joules.

64. High and Low Tension.—From the standpoint, however, of heat, the voltage is sometimes spoken of as high and low tension, or of greater and lesser intensity, and as the necessary explanation of the relationship of mass and intensity as found, say in different volumes of water, will aptly illustrate the uses of the electric units. We will now consider the matter through the medium of light and heat. Let the circu-

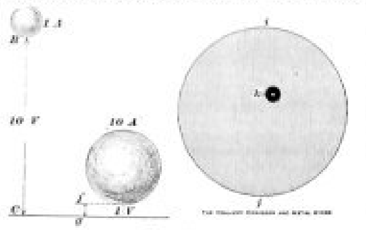

Fig. 106.

lar disc *i j*, represent the face of the full moon, and we can realize the fulness of the volume of pale soft light that illuminates at once, half the surface of the earth, and although the intensity of the light is low, yet the quantity of that feeble light is enormous, or it would be said in electric terms, the amperage is very great but the voltage is very small. On the disc is seen a white spot in the middle of a black one at *k*; this small white spot is to show that the intensity or tension of the light of a candle very far exceeds the reflected light of the moon, yet it is so small in quantity, that at a distance of 20 feet, the more intense, and yet infinitely smaller volume of the candle light is drowned in the ocean of moon light. The voltage then of the candle flame is very high, while the volume or amperage is very small, on the principle just explained, of 1 *A* falling 10 feet being equal in work to 10 *A* falling 1 foot. Now the area of the illuminated hemisphere of the moon is so vast compared to the surface of a candle flame that to make their illuminating powers equal, notwithstanding the high intensity of the candle light, the latter would have to be so increased in intensity that the light of every sun in the universe would be darkness compared to it.

64. Amperes and Volts.—Fig. 107 furnishes an example in contrast, of a great intensity accompanying a great volume, and a moderate intensity associated with an exceedingly small volume, the former is that of the sun at *S* and the latter is that of a candle at *C*. Now the sun not only illuminates the earth, but all the

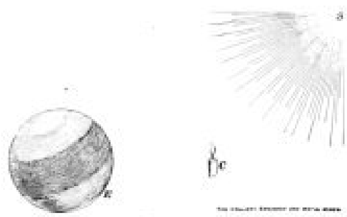

Fig. 107.

planets in the solar system, and while the light of the candle would be washedout by the vapor in the air at a distance of a few feet, the light of the sun penetrates the measureless depth of space. The candle would illuminate a few feet, while the sun covers one-half of the earth with a vastly more intense light.

65. Volume and Intensity.—The electric light can be made equal in intensity to the sunlight, but the volume of the electric arc is not larger than the flame of a small candle; so intense is the light of the arc, however, that if it is thrown on a screen, and a burning candle is interposed, the light of the candle appears in the disc as a shadow, as shown at *S* Fig. 108. *E* and

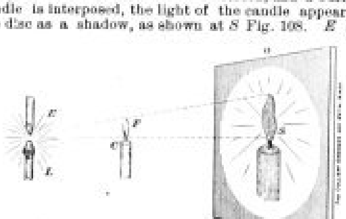

Fig. 108.

L are the carbon pencils of the electric lamp. Here then we find very high tension of light in the electric arc, accompanied with a very small volume, and therefore a relatively small area is illuminated. and we now can show that if all the electric lights in the world were located in one small space, they would conjointly only make a small fraction of the illuminating power of the moon. The electric light then is high in intensity, but very small in quantity, while the moon's light is low in intensity but very large in quantity compared with artificial lights.

66. The Coulomb and Heat Units.—Water furnishes some excellent illustrations of the volt, ampere, and coulomb; for example, suppose the temperature of a pound of water is raised from 87° to 212° or boiling point, and that the temperature of 100 pounds of water is raised from 87° to 89°, to which of the two masses of water has the most heat been given? Here it is again a question of volume and tension, the boiling water is very hot, its temperature has been raised from 87° to 212° or increased by 125°. Now if the one pound is taken as the unit volume for measuring quantities of heat, then $100 \times 2 = 200$, that is to say we have imparted to the one pound of water 125 heat units, whereas we have given to the 100 pounds of water 200 heat units, or we may say the heat units in the one pound of water are 212, whereas the heat units in the 100 pounds of water are $89 \times 100 = 8,900$; or we may say the intensity or voltage of the heat in the one pound is equal to 212 volts and the volume or amperes are equal to 1 or $212 \times 1 = 212$ joules, and the intensity or voltage in the 100 pounds is 89, and the volume or amperes are 100, therefore $89 \times 100 = 8,900$ joules. The common illustration is that of comparing the energy due to moving fluids, with that manifested by electric action, and to make this mode of presenting the case clear Fig. 109 is introduced. Here

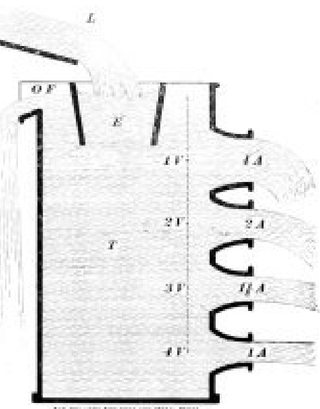

Fig. 109.

a vessel is contrived in such a way that water is made to pour out of four orifices all of different sizes and subject to different pressures, now the pressures are taken to represent volts, and the quantities per second as amperes, and to secure continuity in the pressures or volts, the water level in the tank *T* is kept uniform by making an excessive inflow from the spout *L*, and an overflow as as at *O F*; further to keep a steady level the inflow is into a funnel *E*, where the movement of the agitated water at the foot of the fall is prevented from disturbing the level. Now the pressure at 1 *V* is intended for one volt, while the outflow being 4 unit volumes, is made to represent 4 amperes, then $4 \times 1 = 4$ joules, then at 2 *V* we have double the depth made to represent 2 volts, and the outflow is 2 unit volumes, then $2 \times 2 = 4$ joules as before. Again, $3 \times 1\frac{1}{3} = 4$ joules, and $4 \times 1 = 4$ joules. Now the pressure or volts is greater for 2 *V* than 1 *V*, but 2 *A* is contracted so that the outflow is only ½ that of 4 *A* but as ½ the volume or amperes is subject to twice the pressure voltage, then the joules remain the same for 2 *A* as for 4 *A*, and the same reasoning applies to the others.

67. Electric Resistance.—The electric current when transmitted through a cable, furnishes the same mode of action as gases and liquids transmitted through pipes, and the liquid, say water, may be taken illustratively to represent amperes and the pressure, volts; and if the same volume, or amperes is passed through a pipe at double the pressure but with the same velocity, then the same flow will do double the number of units of work. The same characteristic is found in steam, but perhaps the most peculiar phase of the matter is this: If you double the velocity of water through pipes you very much increase the friction, so that to double the units of work in a limited time, by doubling the volume or flow without increasing the area of section, a great loss of useful effect is the sure result. The same law is found in the transmission of steam, when the steam pipes are too small in transverse section, the velocity of steam on its way to a fast running engine is retarded by greatly increased friction and consequent loss of energy; and stranger still, electricity behaves in its transmission through a cable like liquids and gases through pipes, so that if you increase the amperes or flow to increase the work done, the chances are that you may fuse the cable, or destroy the solenoids of the motor; because when an electric current meets with resistance in its path, the electric, is at once converted into heat energy. But if you double the volts or pressure of the current, you double the work done without increasing very much, the resistance and loss.

Miners are apt to confound current pressure with the total pressure of, say air, and conclude that the velocities of the air through the pipes will vary as the square roots of the *total* pressures. This not being so, let us at once set the matter right by saying that if we double the total pressure of the air we double its weight and therefore, double its current friction, but we still obtain twice the effective work done because we have not altered the percentage of loss due to current friction, the speed of the air in the pipes being still the same, and two per cent. of thin air has exactly half the resistance due to 2 per cent. of air twice as heavy, and the heavy air does twice the work for twice the friction. Total pressure and current pressure are therefore very different things.

As it is such a difficult matter to increase the amperage of an electric current beyond the conducting capacity of the wire, you will hear people speak more of increasing volts than amperes.

68. The Transmission of Energy.—Fig. 110, is given to illustrate the laws of the transmission of energy by gases and liquids through pipes; and to correlate this fluid transmission with that of electricity through cables, we should keep in mind the fact that the rate of speed or rate of flow is a matter that must be considered as well as the area of the transverse section of the pipe, for through a large area the volume, say 1,000 gals. per minute, may flow at a much lower velocity than the same volume through a small area, and here again, we find the same fact exemplified in the electric cable, but the same quantity flowing through the small pipe can only do so at an increased pressure because it offers a greater resistance, and thus introduces the electric unit of resistance the Ohm. Through the sections shown in the figure, at Q, R, T the quantities are 49 A, but the pressures are different, because the currents are supposed to have shorter and longer lines of resistance, thus teaching the lesson that the amperage being the same, the Ohms of resistance are proportionate to the voltage of the current. To obtain the passage of the same quantities through W and X as through U, it is seen that the voltage has been increased to 40 and 100.

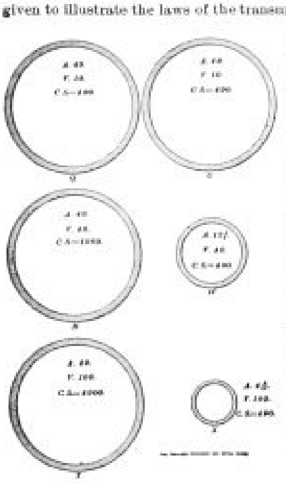

Fig. 110.

[TO BE CONTINUED.]

MINING METHODS.

Mechanics of Fluids in Motion—The Water-Gauge—The Difference of Potential—Static Air Pipes.

62. Mechanics of Fluids in Motion.—The water-gauge does not only measure current pressure, but inferentially it also measures current speed, and really, in mining the use of the gauge lies chiefly in the direction of determining the current speed, because in the mine itself, the pressure producing the ventilation is directly proportionate to the current resistance. Fig. 110 illustrates the use of the gauge for three purposes. First, to determine the value of the pressure producing the draught through the furnace; second, to determine the quantity of air used in the combustion of the fuel, and third, to ascertain the temperature of the hot gases in the chimney. It is true, the gauge measures directly, pressure only, but from the pressure can be deduced the velocity, because the current pressure varies directly as the resistance, and from the current pressure gauge the motive column can be found, and from the motive column the temperature can be calculated, so we see the gauge $W G$, connected at P with the chimney flue C, is of great value in gauging the efficiency of a furnace, and the waste or otherwise of heat that is allowed to escape with the products of combustion into the chimney flue.

Now, if all these facts can be determined by finding the motive column $M C$, who can underrate the economic use of this instrument?

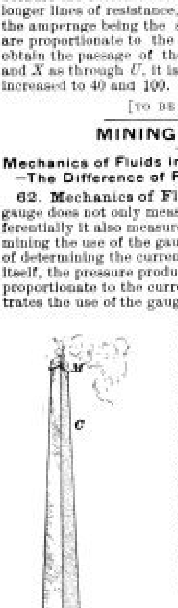

Fig. 110.

63. The Water-Gauge.—Fig. 111 is another modification of the water-gauge for determining the current *potential* between two points in an air circuit; for example, the ordinary gauge can be, and is used for this purpose, but there are conditions under which it cannot be so used. When the ordinary gauge is connected with the fan drift it measures the potential or total pressure of the ventilating current from surface back to surface, but when the water gauge is fixed at the bottom of a downcast shaft, and there connected with the return air current, before entering the upcast shaft, the gauge now only measures the potential of the current between shaft bottom and shaft bottom, and if the pressure or potential due to the underground galleries is subtracted from the fan drift reading, the difference is the potential of the shafts.

Fig. 111.

Suppose, however, we require to know the current pressure at the working face, then with the ordinary gauge, that could only be done by carrying a small pipe from the bottom of the downcast shaft to the face, and screwing on the gauge, when the *static* pressure in the tube would be that at the downcast shaft and the reading would be the potential between the two points. Now if the face was distant from the bottom of the downcast shaft one-third, and from the bottom of the upcast shaft two-thirds of the entire length of the current circuit, then the potential between the working face and the bottom of the upcast shaft would be twice that between the face and the bottom of the downcast shaft. By potential is meant possible power, but as the velocity is supposed to be the same throughout the circuit, then the potentials and pressures will be directly proportionate.

64. The Difference of Potential.—The instrument before us is used then to determine the difference of potential between the bottom of the downcast shaft, or the fan drift at the surface, or between any required points in the workings, and before explaining its mode of action, let us explain its principle of construction. It first consists of a glass jar, or white glass bottle, the mouth of which is closed with an india rubber bung B, through which a small glass tube is made to fit tight, and the lower end of the tube is made to dip into the water W. A thermometer T is placed within the bottle, and is seen to be also dipping into the water. The principle of action is as follows: First, the small glass tube is drawn up a little, so as to allow air to enter the bottle at the point of maximum or minimum pressure, or the bottle may be so canted that the water will uncover the bottom of the tube and allow the air to enter or leave the instrument, and so equalize the pressure within and without. When the pressure is balanced the thermometer is carefully read and the temperature recorded.

The gauge is now carried to the point in the workings where it is required to know the difference in potential, when if the water rises up the tube A, to an elevation $b\ a$, we know the pressure of the air within the bottle is greater than the pressure of the air without, and if $b\ a$ reads 5.38 inches, then the difference of potential would be 5.38 inches but for the interference of the altered temperature of the air within the bottle, and for this, a correction must be made. Suppose the temperature when the balance was made was 65° F, and now it is 70° F at the working face, let us find how high a rise of temperature of 5° would raise the column within the tube, if a column of 408 inches of water balances the pressure of the atmosphere.

By Boyle's law

$$\frac{(460 + 70)}{(460 + 65)} \times 408 = \frac{530}{525} \times 408 = 411.88.$$

That is, the pressure of the atmosphere would be increased by a rise of 5 degrees of temperature, in a *confined* space, from 408 to 411.88 or 3.88 inches, but the gauge reads 5.38 inches, therefore $5.38 - 3.88 = 1.5$ inches. The difference of potential then is in the proportion of 1.5 inches of water gauge.

65. Static Air Pipes.—Having made quite clear the meaning of a "difference in potential," we can now apply the principle in elucidating other practical applications of it; for example, at the Seaham and Silksworth collieries, England, static pressure pipes are carried from the junction of the return airway with the upcast shaft, as at RP, Fig. 112, up the upcast shaft and to some point on the surface as at G. The course of the static air pipe is up the dumb drift DD, and onward up the shaft.

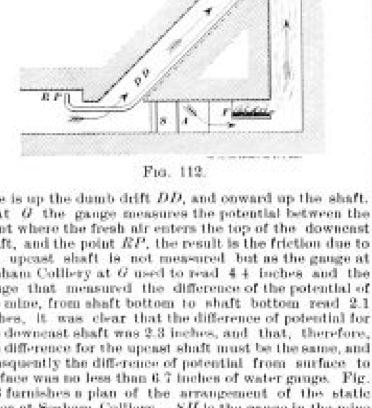

Fig. 112.

At G the gauge measures the potential between the point where the fresh air enters the top of the downcast shaft, and the point RP, the result is the friction due to the upcast shaft is not measured but as the gauge at Seaham Colliery at G used to read 4.4 inches and the gauge that measured the difference of the potential of the mine, from shaft bottom to shaft bottom read 2.1 inches, it was clear that the difference of potential for the downcast shaft was 2.3 inches, and that, therefore, the difference for the upcast shaft must be the same, and consequently the difference of potential from surface to surface was no less than 6.7 inches of water gauge. Fig. 113 furnishes a plan of the arrangement of the static pipes at Seaham Colliery. SH is the gauge in the mine superintendent's office at home. U is the top of the upcast shaft, and D is the top of the downcast shaft. G 2.1 is the reading of the water gauge at the bottom of downcast shaft or B of P. FH is the mine foreman's office at home where the second gauge is fixed, and O is the colliery office where the third gauge is fixed.

At each of these three stations the gauges read alike excepting during stormy weather, when difference of one or two-tenths often occur, nor need this be wondered

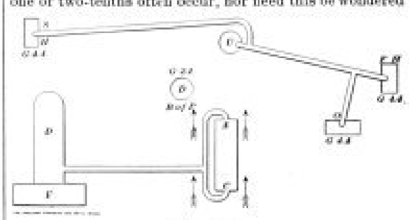

Fig. 113.

at when when we notice that a velocity of the wind of 14 miles per hour is equal to a pressure of one-tenth of an inch of water gauge, and that a velocity of nearly 20 miles an hour produces a pressure of two-tenths of an inch of water gauge.

Here is another illustration of the care required in looking for causes of error in water gauge reading. If a house A, and one C, at opposite ends of a block are connected with gauges and static pipes to a fan drift D, when the wind is blowing as indicated by the arrows, the gauge at C always reads higher than the gauge at A. Now as we have shown a small velocity of the wind will produce a pressure equal to $\frac{1}{4080}$ of the pressure of the atmosphere, that is to say $\frac{1}{10}$-inch of water gauge is equal to $\frac{1}{4080}$ of the total pressure of the atmosphere and therefore the readings of the gauge are very susceptible to false indications. Fig. 114 is an illustration of the water gauge in common use, and it will be seen that the syphon tube has one limb open to the external air at C where it is somewhat contracted to exclude dust, the other limb is connected by a static pipe A passing to the fan drift; a movable scale is seen at $D\ E$, and this scale is movable and adjustable by the screw G that is turned by the milled head T.

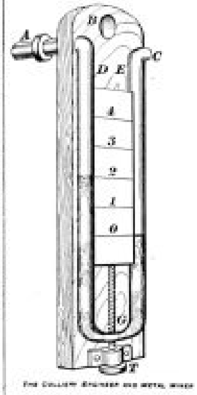

Fig. 114.

To read the gauge, turn the knob T until the zero of the scale O, is level with the water in the limb C, then read off at the high level in the limb A, and in this case the reading is two inches of water gauge or a pressure of $2 \times 5.2 = 10.4$ pounds on the square foot.

[TO BE CONTINUED.]

THE CAPELL FAN.

In response to a personal letter from the editor regarding the Capell fan, erected at the Youghiogheny Coal Co's. No. 1 Mine, Scott Haven Pa. Mr. W. S. Gresley, General Manager of the company, writes as follows:—

Scott Haven, Pa., Aug. 26, 1895.

"Regarding our Capell fan at our No. 1 Mine, I would say: It is a single 8 ft. fan. It runs at about 208 revolutions per minute (exhausting), and at 1 in. W. G. it is passing about 85,000 cu. ft. of air per minute through the mine. The air traverses about 2 miles of entries and workings before arriving at the fan. This fan was guaranteed by Mr. Clifford to pass 65,000 cu. ft. at 325 revolutions, and you see we get 20,000 cu. ft. more than the guarantee at ⅔ speed. We are driving the fan with a General Electric Co's, 25 H. P. 500 volt multipolar motor, belt connected, and the entire outfit is giving great satisfaction. I have known the Capell fan for about nine years and can honestly and very strongly recommend it. It is, I think, especially adapted to comparatively high speed motors. We are now putting in 2 more of these fans, one an 8 ft. same as No. 1 Mine fan, and the other a 12½ ft.—also single inlet machine. Both of these fans are intended to be operated by electric motors, the smaller one being close upon 3 miles away from the generating or central station.

"Mr. Clifford is also building me, for No. 1 Shaft at Spring Valley, Illinois, a 12½ ft. Capell fan, to force air through the very extensive longwall workings under high water gauges. This fan however is being constructed to exhaust instead of blow, when necessary.

"Mr. Clifford's fans are the strongest built machines of the kind I ever saw.

Very truly yours,

W. S. GRESLEY,

Gen. Mngr. Youghiogheny River Coal Company, and Con. Mining Engineer, Spring Valley Coal Co., Ill."

Mr. Wm. Clifford, M. E., Westinghouse Building, Pittsburgh, Pa., is the sole licensee and manufacturer of Capell fans in America. There have been so-called Capell fans erected in this country in the past, which while equal to the duty they were called on to perform, were not an unqualified success, as they were not constructed exactly on Dr. Capell's lines. They were purposely made different in several essential points so as not to infringe on the Capell patents. As a result the excellent results obtained at Scott Haven were not obtained with the so-called Capell fans.

MISCELLANEOUS.

LIVING AND LEARNING IN OLDEN TIMES.

A man, who spoke from experience, thus discribes the manner of students living 40 years ago. He began his experience at Williston Seminary. He said: "The students worked as hard and fared as cheaply as the men and women employed in the big factory of the place, and I know that I pored over my books of Greek, Latin, and mathematics for for hours of the night after the factory people were asleep.

"Our seminary fees were not more than $20 a term, and the payment was not required in the case of a student who confessed inability to meet them, while President Clark was especially gracious to such a student, of whose impecuniosity no one else was ever made aware. The rent of my room in the seminary was, if I remember correctly, $1 a month; and every room was good enough for its purpose. As for the price of table board in the houses in which the students boarded, it ranged from $1.25 a week up to perhaps twice that amount, for all I know. I paid $1.25 a week for victuals thrice a day. A lot of us formed ourselves into a club, one of the members of which went out into the town and negotiated for rates of payment with some housekeeper of economical mind who could accommodate perhaps twenty or thirty of us at a long table in her house. There were other clubs at which the prices were higher than at ours; but we were the Spartans, and did not care for that. Plenty of the students boarded at the houses of factory workers, whose wives prepared the meals. As for the dearer places, I doubt if there was any of them at which the charge was over $3 a week. At our club we had enough of that nourishing provender which is the very best thing for young students who mean to apply their whole mind to their studies without distractions. We had good mush, with maple molasses; we had corn bread and milk; we had fish; we had hash, and other things. Every day of the week we had a change; and Sunday was the best day of the week. There was not a scrap of waste at our table in our club, which was for those of the students who had no coin to waste. I remember how proud we were of our scholastic poverty.

"I am sure that the cost for me of living and learning at Williston Seminary, in Massachusetts, forty years ago, was less than $100 a year, and I earned that sum by my work during vacation. It was far easier then than it is now for a young man of narrow means to get a classical education. The training at the seminary was of the very best kind and fitted a student for any college.

"As it was necessary for me to count my dollars after I left the seminary, I visited both Yale and Amherst for the purpose of finding out the cost of living and learning at each of these collegiate institutions. The cost at Yale was less than half as much as it is now; but that at Amherst was yet less. I found I could get as good board for $2 a week when there as I had got for $1.25 a week when at the seminary; and I found that the tuition fees were within my narrow means. Everything there then was for the sons of ordinary folks, and I was told by Prof. Tyler that plenty of the students earned during the months of vacation a part, if not all, the money which they needed for college expenses. Forty years ago Amherst was a good place for an aspiring youth not overburdened with filthy lucre who wanted to get a classical education; and it had a faculty the members of which encouraged a student of that kind. One of the very best of the professors there then was Dr. Edward Hitchcock, the distinguished American geologist.

"I think it is to be regretted that the cheap old times at our American educational institutions have departed, and that the chances for the poor young aspirant are not as good as they used to be. The amount it would cost one of my sons to go through seminary and college in these days would be at least twice or thrice the amount it cost me. When I told my oldest boy about my expenditures as a student, and how I earned them, and how I studied day and night, he smiled.

"I read in *Macmillan's Magazine* a while ago an account of the meagre living of many of the students at the old Scotch universities forty or fifty years ago, when the writer of the article was a freshman at one of them. He told of farmers' boys trudging afoot over the mountains from their homes to the college, carrying on their backs a sack of oatmeal, out of which they would make their own porridge for a month or longer, till they went home and got another sack, besides, perhaps, a string of red herrings. Ashamed of their poverty? Not a bit. They were going to be great scholars, and the thought of that made the porridge and buttermilk the pride of their life. It was learning they were after, and happy they were to cultivate on oatmeal. I did not suffer any such pressure in my college years in Massachusetts, but the reading of that essay in *Macmillan's Magazine* brought back those happy years to my mind and taught me that even our board at $1.25 a week at Williston Seminary was living fit for a lord."—*N. Y. Sun.*

THE USEFUL MICROBES.

There has been so much written for some time past about the microbes of disease that, to most persons, the very name of microbe suggests poison, pestilence and death. It is therefore well to notice that these dreaded organisms are just as closely connected to the means of protecting health, and that, upon the principle of the old adage "set a thief to catch a thief," they furnish the most efficient means of combatting all sorts of infections as well as being the foundations of many valuable processes such as bread making and brewing. Some experiments have recently been made in England with large filters for filtering the sewage of cities, in which it has been conclusively shown that to make such operations a success, the microbe is indispensable and must be treated with most distinguished consideration. In the first experiment a filter, made of coke breeze, an acre in extent, was used, and the sewage allowed to run continually through it. In less than three months it clogged and became putrid.

In the second experiment the filter was merely filled and emptied twice daily, with such satisfactory results that fish placed in the filtrate were kept alive many weeks. A published report of these experiments states: "The conclusions arrived at in regard to these experiments are of considerable importance from a practical standpoint. 'The action of a filter is two-fold. In the first place, it separates mechanically all gross particles of suspended matter and thereby renders the effluent clear and bright. But the second consideration is the more striking. It is the action of the filter in effecting the oxidation of organic matters, both those in suspension and those in solution, through the agency of living organisms. It is the preliminary establishment and subsequent cultivation of these organisms which is to be aimed at in the scientific process of purification by filtration. The ordinary putrefactive and other similar organisms commence the work by breaking down the organic compounds and converting them into less complex forms—principally water, carbonic acid, and ammonia.

"The nitrifying organism then acts upon the ammonia, the nitrogen being converted into nitric acid. For this process to go on, three conditions are declared to be essential. First, the organisms must be supplied with plenty of air; secondly, there must be present a base—such as lime—with which the nitric acid can combine; and thirdly, the biological action must take place in the dark." Filtration on biological lines is further explained, followed by the statement that "the life of a coke filter worked in the manner is practically without a limit." We are assured that "there is no difficulty in obtaining any desired degree of purification by means of a system of filtration conducted on biological principles." One single sentence places the whole subject in a very different light from that which has generally appertained to it. The announcement is made that by the system now propounded, and already exemplified, "the necessity for costly farms is entirely obviated."

The experiments made in this country at Lawrence, by the Massachusetts State Board of Health, give similar results with sand filters, and show that purification by precipitation and filtration solves question of sewerage disposal by large cities.

These experiments show how by the use of the microbes on a large scale one of the most difficult problems in sanitary engineering may be accomplished which would be very costly if not impossible without them. This is only one example however, and it is probable that on the whole we receive more of good from the microbes than of harm, and those nervous people to whom these useful organisms are such a terror should take courage and learn to cultivate those that are of use, and remember in regard to those that are harmful, that

> "Fleas have other fleas to bite 'em,
> And so on ad infinitum,"

and that microbes are no exception to this rule.

ARABIA AND ITS PEOPLE.

Arabia comprises a wide region, which in its southern and central portions abounds with tracts of quite fertile country, extending inwards to a great table-land, which can also sustain a large population, and which possesses one of the healthiest climates in the world. It is fringed, however, all around its long coasts with stretches of sand, which at irregular intervals pass deep inland, until the great Dahna, or desert, is reached, which separates the fertile southern district of Yemen, the ancient Sheba, from the table-land, above mentioned, of the Nejd. Then to the north mountainous and stony deserts, with other stretches of sand, and occasionally fine oases here and there, extend likewise far to the east over to the valley of the Euphrates. This extensive country, therefore, has always afforded opportunities for settlements, with large towns and rich productions, separated, however, by open, treeless, and often rugged wastes, where none but nomads can live. A natural result of such a combination of physical elements has been that its people have been divided up into numerous distinct communities, inhabiting cities, with both trade and agriculture, while between them have roamed great numbers of tent-dwelling tribes, who, besides living on their flocks and herds, have always regarded it as their hereditary privilege to raid the caravans of the city dwellers. Moreover, the cities have never been really united under one government, but are from their position inclined to an independence and jealousy of each other, which, likely as it is from their physical conditions, yet for Arabs is well-nigh inevitable under all circumstances. Real Arabs are congenitally disposed to disagree. One of their famed poets, Ibn el Werdi, says, "No man can fail to have his enemy, though he should try living on a mountain-top." Another, El Tugraki, equally distinguished, uttered words often quoted both for their beautiful rhyme in the original and for their sentiment: "Love of peace takes all the life out of a man. If you incline thereto, set up a ladder to heaven and scramble thence, or find where you can mope in some underground cellar." The Arab disposition in fact is at bottom not unlike their great national animal the camel's. When you bid a camel to get up he objects, when you order him to start he objects, and when you order him to halt he again objects, showing that he really objects on principle.

As might be expected, these national traits show themselves in that faithful mirror of a people's true life, its language. A richer language does not exist for the names of external objects in nature, showing that its people are the children of the open air as no other race is. There is a quaintness and vivacity of expression in it which no other tongue can excel, and in its grammatical structure it can be made the vehicle of the most compressed utterance that can be imagined. But when the words are put to use you are struck with the inexhaustible richness of idioms expressive of a taunting, sarcastic, ironical, and mocking nature. That was a true Arab's answer which Job gave to his lecturing friends: "No doubt but ye are the people, and wisdom shall die with you!" So the Bedouin when he meet a stranger in the desert addresses his hapless victim, "My dear nephew, your aunt [*i. e.*, my wife] wants your garment, for her aged limbs are cold." When an Arab wishes to express dissatisfaction with you, he simply says, "*Subhan Allah*"—"God is to be glorified"—but the verb is in the Arabic subjunctive, and hence means that God is to be glorified although—The ellipsis to be supplied, of course, is, although He made you! So when a man returns from a journey his friends meet him with the salutation, "*El hamdulillah bis selame*,"—"Praise to God, we see your face in peace." But often the same greeting awaits a servant who has been too long on an errand.—*From "Arabia—Islam and the Eastern Question," by Dr. William H. Thomson, in Harper's Magazine for September.*

COMMERCIAL PRODUCTS FROM ACETYLENE.

It occasionally happens that the easy synthesis of one chemical compound will unlock the door to the cheap commercial production of a room full of others. It is declared that calcium carbide (with water power to run the dynamos) may be made for less than twenty dollars per ton. Now, from one ton of calcium we may obtain 812 pounds of acetylene gas, costing less than two cents and a half per pound. This means with certainty, the cheaper manufacture of innumerable substances used in the arts which may be made from acetylene by processes which, up to this time, have been matters of pure chemistry, but which, on account of the lessened cost of acetylene, will now wage war with the older methods.

Acetylene, on being passed through an iron tube heated to dull redness, goes rapidly and completely into benzine, without the formation of any other product. Benzine is a product of prime importance, and is the base of thousands of organic substances, known as the benzine series of compounds. If the resulting benzine vapor be passed into strong nitric acid it is transformed into the oily nitro-benzine, and this, on treatment with hydrochloric acid and iron filings, goes easily into aniline. The ton of calcium carbide, or the 812 pounds of acetylene, results thus in somewhat less than 956 pounds of aniline. With the formation of aniline the road is now clear for the production of the innumerable dye substances whose varied hues have adorned the sisters and wives of the last twenty years, and whose discovery and preparation absorb the energies of an army of chemists.

Instead of passing into the dye substances, however, we may transform our aniline into carbolic acid. Thence it is but a step to picric acid, the foundation substance of many modern explosives. Or again, we may boil the aniline with acetic acid and we have transformed it into acetanilide or anti-febrin, the well known fever specific.

Our protean acetylene, however, is capable of undergoing other changes just as startling. For instance, if it be passed through a tube heated to bright redness, it is changed to naphthalene, and naphthalene again will pass into a multitude of other valuable products. Or again, starting with acetylene, by the action of nascent hydrogen, we may change it into ethylene and finally into ethane. Ethylene, on being boiled with sulphuric acid and water successively passes into alcohol, which is absolutely necessary to the production of an enormous number of economic substances. Ethylene on treatment with permanganate of potash readily oxidizes, first into oxalic acid, and then into formic acid. If the formic acid so obtained be treated with ammonia, and the resulting product heated to 180 degrees C., it is transformed into the deadly prussic acid. Acetylene in the mere presence of salts of mercury unites readily with the elements of water to form aldehyde, so much used to-day in the production of essences and the manufacture of mirrors.

Starting with acetylene, by the agency of such cheap commercial products as muriatic acid, sulphuric acid, potash, ammonia, and a few others, it is possible to build up whole systems of dyes, medicines, essences, perfumes, poisons and explosives. The methods by which this may be accomplished are known matters of pure chemistry. They become commercially and economically practicable with the cheap synthesis of acetylene. Since this has been accomplished by the aid of the electric furnace and a mixture of lime and coal, we may expect to see the influence of acetylene ramifying throughout all organic chemistry. It has a utility out of all proportion greater than that derived from its peculiar light-giving powers.—*R. K. Duncan in Electrical Engineer.*

AMONG THE BASKET MAKERS.

In the stony valleys among the hills of Connecticut, where the bowlders lie too thickly for the plowman ever to disturb the soil, one will occasionally run across a little hamlet, where the basket makers spend their quiet but useful lives. It would seem that it must be a poor and barren part of New England that cannot be turned to some account. In these little communities the craft of basket making has passed from father to son for many generations, and doubtless will for many more, for, in spite of modern invention, the good white-oak basket promises to be as much in demand in the 20th century as now. Sheet iron or aluminum, paper or tropical fibre may do some part in solving the basket problem of the future, but alongside of these modern makeshifts will be found the tough products of the almost irreclaimable stony forests of the mountain regions.

Sometimes there will be a large, rude shop, surrounded by one-story gray cottages of the basket makers. In the shop they will carry on work in common, saving expense for fuel in winter. Other families will have a shop by themselves. Outside the door one will see frequently a pair of oxen hitched to a heavy wood sled with a load of basket timber, logs cut about nine feet in length. On the walls inside one sees an assortment of drawing knives, some of them polished, worn and ground down to a narrow strip of steel, ready to break after many years of use. There are wooden bench vises where the men sit to shave off the splints, and overhead one will see rows of bent white hickory handles, looking like rows of horseshoes in a blacksmith's shop.

No little skill is required to split up the wood so as to waste scarcely any, to shave out the tough, upright strips and to bend them into proper shape, to split out the "filling" and deftly weave it in. The black oak is fortunately so put together by nature that when a split stick of it is skilfully hammered across a large flat stone the different layers made by each year's growth will separate and lie all ready for the basket makers to use. White oak, black oak, pin oak, hickory, white walnut, pignut, white ash and black ash all enter into basket making more or less but white oak is the standard wood.

The basket makers who prepare their own material look with contempt on the baskets made in factories, where the splints are cut out by machinery. The machine necessarily often cuts across the grain of the wood, causing a weak place in the basket. The factory baskets are much cheaper, or course. One can buy a bushel basket of this kind for 35 cents when a hand-made basket, strengthened and bound with hoop iron, may cost $2, yet one of the latter will outwear 10 of the former; the one may weigh five pounds, the other 10 to 12. Sometimes an order will come for a big wool basket, to hold 12 to 25 bushels, or a dealer may want a few hundred of the conical bushel baskets used by the market gardeners of Long Island and New Jersey. The favorite basket for picking apples is the round half bushel with hickory bale, as it fits in nicely between the rungs of a ladder.

It is an exciting day in the basket village when one of the big rick wagons is loaded up with baskets to go to the steamboat landing or railroad station. There may be consignments in it from half a dozen families to half a dozen dealers. And there follows an interesting suspense as the wagon rolls out of sight till the check comes back from the New York merchant through the mail.

If the basket makers could always have steady work they could accumulate snug little fortunes, but the trade is a precarious one, and its followers generally make only a bare living. However, one will find the people hospitable and kindly. Although hands may become callous in wrestling with hickory and hoop iron, the workingmen's hearts are as open as any. There is no more cheerful blaze than that made in a shop stove out of hickory shavings, and your hosts are not only generally glad to welcome a visitor, warm him and chat with him, but will, if he likes, give him a big armful of shavings to start his own fire.—*New York Tribune.*

OAT MEAL DRINK.

Those who work in hot places must drink large amounts of water. This is especially true of the firemen on the steamboats that ply the waters of our rivers, lakes and oceans. The drinking of clear water under these circumstances appears not to answer the wants of the system. It passes through the circulation of the skin, as through a seive, and flows over the surface of the body in streams. A large drink of cold or even cool water, under these circumstances on an empty stomach is very dangerous and may produce death. Great practical advantage has been obtained by mixing farinaceous substances, particularly oatmeal, with the water to be used by the men employed at this labor.

The oatmeal is mixed in the proportion of a quarter of a pound to the gallon of water, and used according to inclination by the firemen and coal-heavers. It would be difficult to determine why oatmeal, for this purpose, should be better than corn meal, buck-wheat, rye, wheat, millet, etc., but the firemen seem to think it has the effect of making them strong. We may safely allow something for this sort of prejudice, which we know to be very potent among the influences on health and disease. The peculiar odor of the oats is associated with a pleasant degree of stimulation of the alimentary mucous surfaces, in such a way as to promote its complete digestion. It seems to fill the blood vessel without increasing the amount of cutaneous exhalations. The men occasionally try acid, saccharine and alcoholic drinks as substitutes but always with unsatisfactory results, except that they find molasses and water better than clear water, and those who are disposed to insist on the excellence of rum and whiskey under all circumstances, petition for these, and experience a momentary relief, followed by additional profuseness of perspiration and additional exhaustion.

The attoley of our Indians is a nutritive beverage similar to oatmeal drink used principally at the South and throughout Mexico. It is made by parching their corn (maize) or other grain, pounding it to meal in a suitable cavity of rock, with a smooth stone, and mixing it with a little sugar if they have it. About a tablespoonful of this is stirred with a pint of water from the spring and swallowed at two or three drinks, according to inclination. An Indian, provided with about two pounds of attoley in a little bag, is prepared to perform the most fatiguing and dangerous journey of two or three weeks, without expecting assistance or supplies by the way except water from the spring or brook twice a day. He appropriates, of course, any little food which comes in his way, but when this amounts to next to nothing he comes out of such an expedition without much apparent suffering or inconvenience. Nearly any other grain or grass seed seems to answer the purpose, though the Indian corn is generally preferred. A very small quantity of food, fully digested and assimilated, is capable of supplying the waste of the system even through extraordinary labor and fatigue.—*Dr. Joseph Wilson, in the Journal of Hygiene.*

THE PEDANTRY OF SPECIALISTS.

Of coining many words in the scientific world there has of late years been no end. This is the age of specialists, and of particular, accurate, and even hair-splitting knowledge. And of course refinement of knowledge must be crystalized in diversified nomenclatures. Sometimes, it is true, it has seemed as if the terminologies were likely to outstrip the knowledge, names being fairly spawned on the world in certain departments of science without corresponding increase of actual discoveries. To conservative persons it has seemed as if the word forming habit has become almost a disease in certain circles, and more than one protest has been lodged against allowing this scientific logomania to become epidemic.

It would seem, however, that there are certain departments of research where the opposite fault of undue abstemiousness in the coining of names is to be observed. In a recent number of the *Auk*, Mr. William T. Hornaday, the famous taxidermist, lodges a complaint of this kind against American naturalists. The particular sin of omission against which he protests is the failure of working naturalists to supply newly discovered animals with English names. It appears that in the last decade something like three hundred new species and sub-species of mammals have been discovered in this country. Each one of these has been at once supplied with a Latinized name long enough to more or less nearly approximate the length of the animal itself, but about half of them have been given no English name whatever. The result is that for all but the select few of the inner circle of naturalists these animals are practically nameless.

Mr. Hornaday urges that this is all wrong. He calls attention to the very pertinent fact that unscientific persons for the most part furnish the money with which scientific researches are carried on—with which, for example, museums are founded and developed—and thinks that for this reason, if no other, the untechnical masses are entitled to some consideration at the hands of the technologists. He urges the naturalists, therefore, to make amends for their shortcomings, and christen the neglected animals.

There is certainly a large mass of intelligent readers who will feel that Mr. Hornaday's protest is timely and important, and who would go a step further, and request that naturalists not only supply English names for animals, but that they also use these names in referring to the animals. All technical publications fall more or less commonly under the eye of untechnical readers, who would like to glean something from them, but who are often repulsed by finding only Latin names, so that they are unable to readily discover whether the creature they are reading about is a beast, bird, or fish.—*From Harper's Weekly.*

THE ART OF BREATHING.

It is perhaps one of the signs of the times, to those alert for indications, that the art of breathing has become more and more a subject of attention. Oculists as well as physiologists go deeply into its study in a way hardly to be touched upon here. Physicians have cured aggravated cases of insomnia by long-drawn regular breaths, fever-striken patients have been quieted, stubborn forms of indigestion made to disappear. A tendency to consumption may be entirely overcome, as some authority has within the last few years clearly demonstrated, by exercises in breathing. Seasickness, too, may be surmounted, and the victim of hypnotic influence taught to withstand the force of any energy directed against him.

There is a famous physician of Munich, who has written an extensive work upon the subject of breathing. He has, besides, formulated a system by which asthmatic patients are made to walk without losing breath, while sufferers from weaknesses of the heart are cured. At Meran, in the Austrian Tyrol, his patients (almost every royal house of Europe is represented) are put through a certain system of breathing and walking. The mountain paths are all marked off with stakes of different colors, each indicating the number of minutes in which a patient must walk the given distance, the breathing and walking being in time together. As the cure progresses the ascents are made steeper and steeper.—*From Harper's Bazar.*

ONTARIO'S MOVING HILLS.

An interesting and wonderful feature of the natural scenery of Lake Erie shores are two immense conically shaped sand formations, in the township of Houghton, Norfolk county, Ontario, just west of Long Point.

These hills are composed of the light silvery sand peculiar to the shores of the lake, with the one dissimilarity, that it appears lighter in bulk than the shore sand and drifts more readily with the wind. They are situated about a mile apart, the one to the east being the larger. It measures about 200 feet in height from the water level, 1,000 feet in length, and 300 feet in width. When viewed from the surrounding country it appears like a vast symmetrically formed giant's grave, erected on the lofty promontory, which lies high above and whose precipitous cliffs wall in the lake for miles.

These hills, besides their present interest, have a strange evolutionary history ascribed to them, as recorded by some of the early settlers in the vicinity. At one time the summit of the large hill presented a circular plateau with a crater opening into a vast funnel-shaped chasm, with sides nearly vertical, which extended down to a great depth. The bottom of this great amphitheater was eighty feet in diameter, and upon this natural arena the pioneer youths of many years ago played the game of baseball with the advantage of requiring no fielders, for, no matter where the ball was thrown or batted, upon striking the sides it would fall to the feet of e players. No trace whatever is now left of the crater. Many are the forms the hill has assumed since then.

If it is the action of the strong southwesterly gales, which for 150 miles have an uninterrupted swoop down the lake, upon the loose sand of the cliff, why are other hills not thus formed by the same force all along the shore in this locality, where the sand appears the same as here? There is a sand mound close to the large hill nearly forty feet high, which has the appearance of growing similar to the others. It is enclosed on three sides with a thick growth of large trees which it is gradually covering up.

These hills slowly but really change their positions, ever retaining some graceful and strange shape. The old trees that form a dense growth near by are gradually swept over and completely buried in sand. In many places their utmost branches only protrude above the surface of the sides of the ruthless sand monster that smothered and settled upon them. In time, as the hill moves on, these trees are again revealed, broken and dead, of course, with whitened trunks and maimed limbs.

Some twenty years ago the summit of the large hill was crowned by the observatory of the United States Lake Survey. From the observatory, one in the highlands of Pennsylvania, and another on Long Point, a triangle was formed, and the most accurate chart of the lake at that time was issued. At present a beacon is the only structure on the hill, having been erected in connection with the survey now being made of the lake by the Canadian Government.—*From the Buffalo Express.*

TISSUE STARVATION.

Strictly speaking, starvation is "an insufficient supply of the nutrition which is necessary for the proper support of the body." In the light of this definition it becomes evident at once that there is a condition of bodily famine which is not due to financial stringencies, and which is outside the pale of charity, since it belongs to the category of disease.

Man has a very complex nature, of which it is necessary to meet the requirements as exactly as possible if its different parts are to work harmoniously and in perfect health.

For instance, the disease which sometimes attacks children in their infancy, and which is perhaps better known as marasmus than by any other name, is a lack of nutrition, or a mal-nutrition pure and simple. Food, no matter how rich in nutrients, is useless if the system is unable to draw out these nutrients on their way through the digestive canal. A marasmic baby dies from starvation as surely as though he had suffered the sharpest pangs of hunger.

Rickets is another condition due to systemic starvation, and is closely allied to the preceding. The patient is unable to assimilate, or take into the system for its nourishment, the particles of fat in food.

Many diseases, more especially those of a "germ" origin, feed upon the tissues of the body. In these instances a greater part of the food taken into the body is seized upon by the disease or germ for its own nourishment. This process is called pathological starvation, or starvation due to disease. The various tuberculous conditions are examples.

Extremes of cold or heat also interfere with the nutrition of the body, cold by lowering the vitality of the body, and heat by raising the combustion of food to such a point that the demand is greater than the supply.

The direct result of systemic starvation is of course a lowering of vitality, by which the body becomes not only less able to perform the work required of it, but is more or less open to the ravages of disease of every form.

Many nervous disturbances and diseases, like nervous prostration, can be traced directly to a disturbance of nutrition. Indeed, it is doubtful if a condition of nervous weakness is not synonymous with tissue starvation.—*Youth's Companion.*

A CHILD'S GENIUS FOR ASKING QUESTIONS.

Child instruction should in the first instance proceed upon the principle that the young mind is an incalculable possibility, and that schooling should be of a character to carry that possibility just as far as may be toward its realization. The child's mind is as thickly studded with interrogation points as the sky is with stars. The primary genius of a child is the genius for asking questions. There is a natural affinity between the mind and the truth. Inquisitiveness is as natural to intelligence as hunger is to the stomach. One of the most common effects of current schooling is to destroy that affinity. Intellectual stuffing in the nursery or in the schoolroom is worse and more wicked than gluttony in the dining-room. Children who commence going to school when they are six and continue at it till they are sixteen hate knowledge a good deal worse than they do sin, and if they had the courage of their impulses would assassinate their instructors and practice nihilism on their schoolrooms and text-books. The distinct symptoms of nihilism are discernible in every schoolroom that has been used for educational purposes more than six months. This intellectual demoritization of the schoolroom will pursue its present course till teachers are selected who have enough of the genius of Froebel to understand that the mental constitution of the child is itself prescriptive of the course to be followed in its development, and that the proper office of school commissioners and school committees is to help the teacher to carry out the intentions of nature rather than to compel him to embarrass and controvert those intentions.—*Rev. Charles H. Parkhurst, D. D., in Ladies' Home Journal.*

THE FIRST COWBOYS.

The cow-puncher's play-ground in those first glorious days of his prosperity included battle and murder and sudden death as every-day matters. From 1865 to 1878 in Texas he fought his way with knife and gun, and any hour of the twenty-four might see him flattened behind the rocks among the whiz of bullets and the flight of arrows, or dragged bloody and folded together from some adobe hovel. Seventy-five dollars a month and absolute health and strength were his wages; and when the news of all this excellence drifted from Texas eastward, they came in shoals—Saxon boys of picked courage (none but plucky ones could survive) from South and North, from every town and country. Every sort and degree of home tradition came with them from their far birthplaces. Some had known the evening hymn at one time, others could remember no parent or teacher earlier than the street; some spoke with the gentle accent of Virginia, others in the dialect of baked beans and codfish; here and there was the baccalaureate, already beginning to forget his Greek alphabet, but still able to repeat the two notable words with which Xenophon always marches upon the next stage of his journey. Hither to the cattle country they flocked from forty kinds of home, each bringing a deadly weapon.

And then, the same stress of shifting for self, the same vigorous habits of life, were forced upon each one: watching for Indians, guarding huge herds at night, chasing cattle, wild as deer, over rocks and counties, sleeping in the dust and waking in the snow, cooking in the open, swimming the swollen rivers. Such gymnasium for mind and body develops a like pattern in the unlike. Thus, late in the nineteenth century, was the race once again subjected to battles and darkness, rain and shine, to the fierceness and generosity of the desert. Destiny tried her latest experiment upon the Saxon, and plucking him from the library, the haystack and the gutter, set him upon his horse; then it was that face to face with the eternal simplicity of death, his modern guise fell away and showed once again the medieval man. It was no new type, no product of the frontier, but just the original kernel of the nut with the shell broken.—*From "The Evolution of the Cow-Puncher," by Owen Wister, in Harper's Magazine for September.*

HOW MINERAL WOOL IS MADE.

Of those who know what mineral wool is, or silicate cotton, as it is sometimes called, probably only a small number are familiar with the simple process by which it is made. The wool itself, serving a variety of useful purposes, as a non-conducting covering against heat and cold alike, for steam pipes and cold storage room walls, as a sound "deadener" in floors of buildings and as a means of fireproofing, among many others, is, as its name implies a soft and woolly substance, consisting of a mass of very fine mineral fibers interlacing one another in every direction, and thus forming an endless number of minute air cells. The wool appears on the market in a variety of colors, principally white, but often yellow or gray, and occasionally quite dark, and is made by converting scorial and certain rocks while in a molten state into a fibrous condition by a steam blast directed against the liquid material. Blast furnace slag forms the raw material for one variety of the wool, and sandstone for another, yielding, respectively, slag wool and rock wool, the latter being preferable for pipe covering because of the absence from it of sulphur, which, with moisture present, bebecomes an active corroding agent. The furnace slag or the rock, as the case may be, is melted in a large cupola, and as it trickles out at the tap hole in a somewhat sluggish stream it meets a high-pressure steam jet which atomizes the woolen mineral, if it may be so termed, blowing it in fleecy clouds into the storage room provided for it. Soft and downy, the stuff settles wherever a resting place affords itself, the heavier and coarser wool coming down first, while the lighter portions are blown further along by the force of the steam and settle in the more distant parts of the room, the material thus naturally grading itself into varieties of different quality. A thousands pounds of wool per hour are turned out by one of the cupolas, and after the storage room has been blown full the flocculent mass is pushed into bags, ready for the market. The whole process affords an admirable and interesting illustration of the utilization of an utterly waste product.—*Cassier's Magazine* for September.

NO BOOK TYPOGRAPHICALLY CORRECT.

I remember once of a publisher in London who made up his mind to publish a book that should have no typographical errors whatever. He had his proofs corrected by his own proof-readers, until they all assured him that there were no longer any errors in the text. Then he sent proofs to the universities and to other publishing houses offering a prize of several pounds sterling in cash for every typographical mistake that could be found. Hundreds of proofs were sent out in this way, and many skilled proof-readers examined the pages in the hope of earning a prize. A few errors were discovered. Then all the proof-sheets having been heard from, the publisher felt assured that his book would appear before the public an absolutely perfect piece of composition. He had the plate cast, the edition printed and bound between expensive covers—because as a perfect specimen of the printers' art it was of course unique in literature, and exceedingly valuable to bibliophiles. The edition sold well and was spread all over the country. The publisher was very much pleased with himself for having done something that had hitherto been considered an impossibility. Then his pride had a fall, for six or eight months later he received a letter calling his attention to an error in a certain line on a certain page. Then came another letter announcing the discovery of a second error in this perfect book. I believe before the year was up four or five mistakes were found.—*From Harper's Round Table.*

THE MOON AND THE WEATHER.

In an address of more than usual interest, delivered at the the Meteorological Society by Mr. Richard Inwards, the president, the numerous fallacies which prevail with respect to the weather were exposed. The moon is very generally supposed to have a direct influence upon the weather; but, as Mr. Inwards shows, the influence is merely suppositious. As long ago as 1774, Dr. Horsley examined the weather tables of that year as furnished by the Royal Society, and out of 46 changes of weather only ten occurred on days of lunar influence, only two of them being at the new moon, and none at all at the full. As a result of twenty year's observation, M. Flarguergues, of Viviers, found that the barometer readings taken when the moon was farthest from the earth averaged 755 millimeters, and when nearest, 754 millimeters, showing a difference of 1 millimeter, or .04 inch, and this in a direction against the theory, the pressure being greater by that amount when the moon was farthest from the earth. The cycle theory, such as that advocated by Mr. MacKenzie and more recently by Mr. Hugh Clements, has, we are told, broken down, and there is no definite period after which the weather changes repeat themselves. The moon's influence on the weather is negligible, M. Flammarion, tells us, and the ideas that the full moon clears away clouds, that beans should not be sown or trees cut down on the wane of the moon, that two full moons in a month will cause a flood, or that to see the old moon in the arms of the new one brings rain, are all, to use an expressive phrase, mere moonshine. They are not only not supported by scientific observation, but are opposed to observed facts. The heat reaching us from the moon would only affect our temperature by 12 millionths of a degree, and the atmospheric tides caused by the moon would only affect the barometric pressure by a few hundredths of an inch—a quantity far less than the changes which are always taking place from other causes. Even the influence of the halo round the moon has been discredited, for observation shows that it is as often followed by fine weather as by rain. Altogether, the influence of the moon may be summed up in the words of the old rhyme—

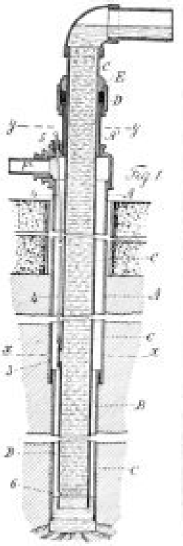
The moon and the weather
May change together;
But change of moon
Does not change the weather.

Newcastle, Eng. Chronicle.

NEW INVENTIONS

PNEUMATIC WATER ELEVATOR.

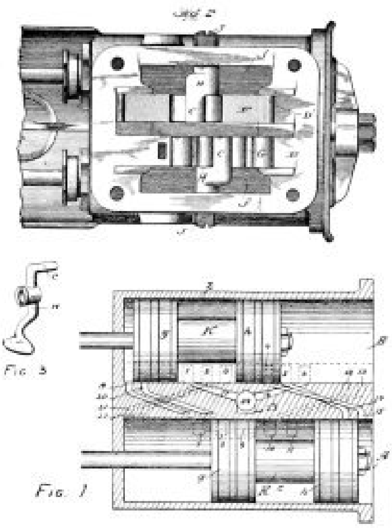
No. 542,620. James E. Bacon, Richmond, Va. *Patented July 16, 1895.* This apparatus operates upon the principle that a column of mixed air and water, is lighter than a column of solid water, in proportion to the amount of air bubbles contained in the mixture. The rising pipe *C* extends nearly to the bottom of the well, and is perforated with holes 6, a few inches above the end. The casing is closed at the top and is provided with a stuffing box *D*, through which the pipe *C* passes. Compressed air is admitted through the pipe *F*, to the space between the casing and the pipe *C*. It drives the water down to the level of the holes 6, and then escapes up the pipe in the form of bubbles. The air pressure has only to lift the water above the level to which it would naturally rise in the well. The space between the casing and pipe *C* forms an air reservoir of sufficient capacity, so that the compressor may be connected directly to the pipe *F*, and no other reservoir is needed. The air passing in at the lower



part of the uptake-pipe is usually sufficient in volume to lighten the column; but with deep wells or with considerable lift for the water above the water level in the well, it is sometimes advantageous to employ an auxiliary lift by providing a second air-supply higher up in the uptake pipe to still further lessen the weight of the column of liquid. To effect this object the slide-valve 3 may be provided over an opening in the uptake-pipe at any desired level, and a rod 4 extending from this valve up through a stuffing-box 5 allows it to be opened by hand more or less, and thus to admit the volume of air required for operating the auxiliary lift to the best advantage.

DUPLEX STEAM PUMP

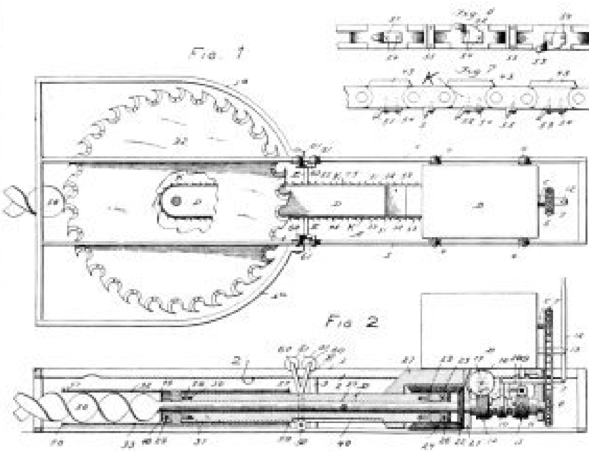
No. 542,342. Cassius M. and Edgar E. Miller, Canton, Ohio. *Patented July 9th, 1895.* Fig. 1 is a horizontal section through the cylinders; Fig. 2 is a top view showing the steam valves; and Fig. 3 is a perspective view of the lever which is used to move the valves. Each piston is double headed



as shown, and the enlarged end of the levers *H* play between these heads. The steam chest contains two slide valves *F* and *G*; *F* serving the cylinder *A*, and *G* controlling the cylinder *B*. The ports necessary to conduct the steam to the cylinders cross each other as shown in Fig. 1. The valves are moved by means of the arms *C* on the upper end of the levers *H*, which are pivoted upon the pins *J*. Thus the piston in cylinder *A* operates the valve *G* which controls the admission of steam to *B*, and the piston in *B* moves the valve *F* which controls the supply of steam to cylinder *A*.

MINING MACHINE.

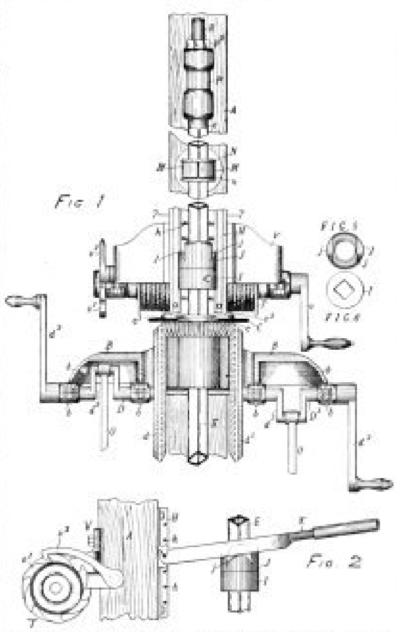
No. 544,424. Joseph L. Beury and John T. Cressey, Beury, W. Va. *Patented Aug. 13th, 1895.* Fig. 1 is a top view of the machine; Fig. 2 is a lengthways vertical section; Figs. 6 and 7 are side and top views of the center cutting chain. The cutting is done principally by two circular saws 32 and 33, which run in opposite directions. The saws are rotated by means of the chains *K* which connect the sprocket wheels 28, 29 to the drivers 25, 26. These are driven in opposite directions by means of the bevel gears 22, 23, 24. Power is furnished by a motor *B*, through the sprockets 5, 6, and chain 7. The machine is moved forward and back by means of the right and left worms 14, 15, the gears 17, 18, and small pinions which engage the racks 2, upon the under side of the frame bars 1. The saws are mounted in the end of the beam *D*, which is supported by a truck *E*, running upon the frame 1. The space between the saws is made large, so that the coal which is broken out from between them is of marketable size, and is not wasted by being ground into slack. The slab of coal which is left standing between the two saws, is divided by means of the auger 56, and is thus



made easy of removal. The chains *K*, which are armed with suitable cutters, enter the auger hole and carve a passage way for the beam *D*. When the slab between the saw cuts is removed, the hole thus formed is so large, that the hanging coal will be properly thrown forward when shot down.

CORE DRILLING MACHINE.

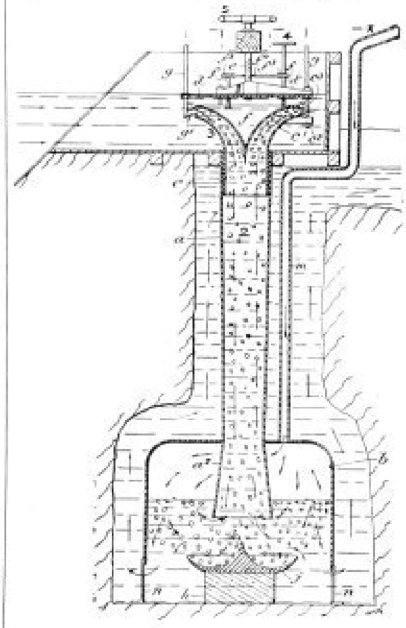
No. 543,227. Moses Beal, Elyria, Ohio. *Patented July 23rd, 1895.* Fig. 1 is a front view of the working parts of the machine; Fig. 2 is a side view of the feed lever; Figs. 5 and 6 are top views of the collars *I* and *J*. This machine is



intended for hand power, and for use in places where larger machines could not be taken. The driving gear and cranks are mounted in a bracket *B*; the windlass *T* is mounted in another bracket *V* at the rear of the post *A*. The drill tube is guided at the top by a collar *N* which turns in a bracket *M*. All these brackets are made to be bolted to a wooden post *A*, which may be cut in the locality where the drilling is to be done. The main tube *E* is made of square pipes which slides through square holes in the hub of the gear *C*, and guide collar *N*. The pipe is swaged round at each end and is threaded to suit ordinary pipe fittings. The drill tube is supplied with water by two pumps which are operated by the rods *O* and cranks *D*, and which are connected by hose to the swivel *P*, at the top of the tube. The feeding is performed by hand, by means of the lever *K*, which hooks under the pins *h*, in the rack *H*, and bears upon the shoulders of the collar *J*. The square tube *E*, having no keyways in it to wear out, is very durable and strong.

HYDRAULIC AIR COMPRESSOR.

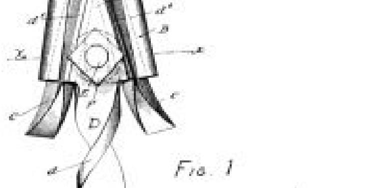
No 543,411. Charles H. Taylor, Montreal, Canada. *Patented July 23rd, 1895.* The degree of compression which can be obtained with this apparatus depends upon the difference in level of the water in the head and tail races. The chamber *b* must also be sunk below the water in the tail race to a distance equal to the working head. The water enters the stand pipes 2 through a conical funnel 3, and descends to the air box *b*, from which it escapes through holes *n*, and passes up the well *m* to the tail race. The funnel is covered by a conical cap *f*, which can be adjusted up or down, by means of the screws and hand wheel 4, to regulate the quantity of water flowing into the funnel. A large number of air tubes *g*, having several small jets each, are arranged in a circle around the rim of the funnel, and these



can be submerged to any extent desired by means of the screw and hand wheel 5. As the water rushes into the funnel, a stream of air bubbles is drawn out from each of the small air jets on the tubes *g*, and these bubbles are carried down by the water into the pipe 2. They are gradually compressed as they descend until they reach the box *b*. Here the water is given a rotary motion by suitable deflecting plates, and the bubbles rise to the surface and separate from the water. The compressed air which accumulates in the box *b* is conducted away, for use, by the pipe *m*. Although the air box is shown as though located in a well, that construction is not necessary. It is only necessary that a sufficient head of water be maintained above it to prevent the air from escaping through the holes *n*.

COAL DRILL.

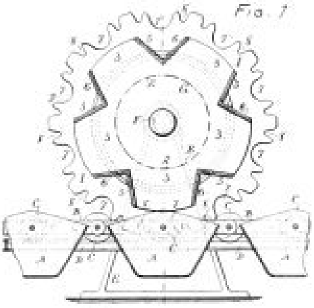
No. 544,206. George H. Bittenbender, Plymouth, Penna. *Patented Aug. 6th, 1895.* Fig. 1 is a side view of the drill head; and Fig. 2 is a cross section at the line *X* of Fig. 1. The end of the auger *A* is formed into a socket *B*, having in-

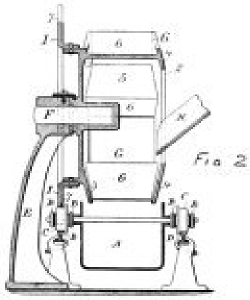


clined side flanges *b*. The central bit *D* has a tapering flat shank with beveled edges. Two side cutters *C*, which are made from triangular steel, are gripped between the center bit *D* and the flanges *b* of the main socket. The single clamping bolt *E* serves to secure all three bits firmly into place. The bits *C* may be shoved forward in their sockets, when desired, to enable them to cut a larger hole; and when they become dulled they can be very quickly replaced with sharp ones.

LOADING CONVEYOR BUCKETS.

No. 541,614. Charles W. Hunt and Charles C. King, West Brighton, N. Y. *Patented June 25th*, 1895. Fig. 1 is a sectional side view, and Fig. 2 is a vertical cross section of the apparatus. The conveyor is composed of an endless series of buckets *A*, which are carried by suitable chains *B*, and rollers *C*. *H* is the loading spout. In ordinary practice, the coal would fall through between the buckets *A*, and be wasted, unless the buckets were made to lap. To prevent all waste, and permit of the separation of the buckets, the wheel

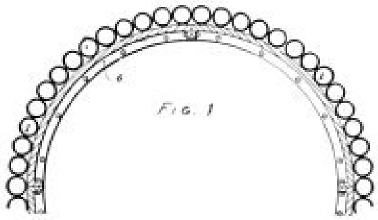


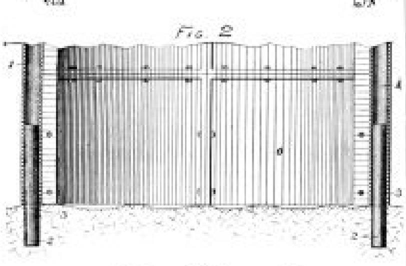


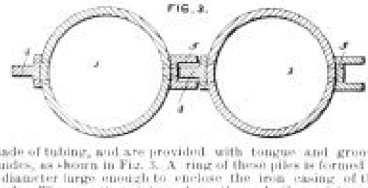
G is employed. This is formed with a number of spouts 3, through which the coal from *H* must pass to reach the buckets. The wheel turns on a pin *F*, upon the standard *E*, being rotated by the engagement of the teeth 7 and 8 with pins upon the chain links, and with the rollers *C*. As the buckets move along, one of the spouts 3, turns squarely down over the center of each bucket, and if any coal should pass out either of the other spouts, it would fall fairly into one of the buckets. Thus all spilling and waste is prevented.

METHOD OF SINKING SHAFT.

No. 543,230. Jesse A. Dubbs, Pittsburgh, Pa. *Patented July 23rd*, 1895. Fig. 1 is a partial top view of a shaft sunk by this process; Fig. 2 is a vertical section near the bottom of the shaft; and Fig. 3 is a cross section, on a larger scale, of the piles employed to enclose the shaft. The piles 1 are



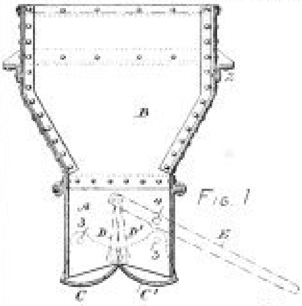


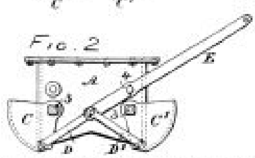


made of tubing, and are provided with tongue and groove guides, as shown in Fig. 3. A ring of these piles is formed of a diameter large enough to enclose the iron casing of the shaft. They are then driven down through the quicksands to the rock. The earth is then cleaned out of the tubes, and a drill is lowered down through them. Holes about four feet deep are drilled beneath each tube, or every alternate one, and an iron pin 3 is driven into each hole. The pins project about four feet up into the tubes and thus prevent them from being pushed out of place when the sand and water are removed from the central part of the shaft. In many cases the piles will form a sufficient lining for the shaft and the sectional casing 6 may be omitted. While not necessary it is generally preferable, to remove the material from the interior of the pile while it is being driven down, so as to permit examination as the direction of movement of of the pile, whether it is being shifted laterally or not, and affording opportunity of correcting any lateral deviation.

GATE FOR COAL CHUTES.

No. 543,182. Charles W. Hunt, West New Brighton, N. Y. *Patented July 23rd*, 1895. Fig. 1 is a vertical section of a coal hopper or chute, showing the gates closed; Fig. 2 shows the position of the gates when open. The gates *C*, *C'* are hung upon pivots 3, which are attached to the sides of the hopper. They are connected by means of links *D*, *D'* to a hand lever *E*, by which they may be operated. The surfaces of the gates are cylindrical, being curved to a circle

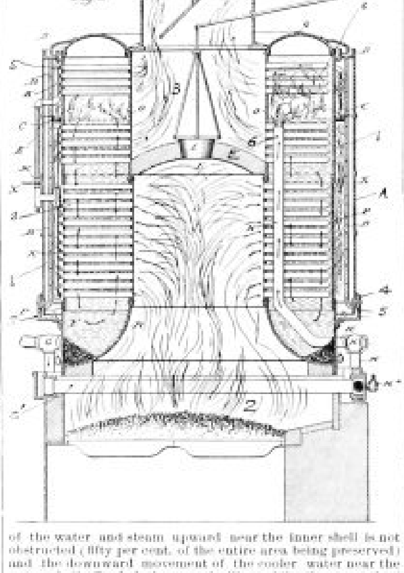




having its center at the pivot 3. The pivots are located nearly midway between the outer edge of the hopper and the middle, so that the effort required to open or close the gates, is about the same. There is no tendency to lift the coal while the gates are closing, consequently they move easily; and when shut, the coal has no tendency to push them open.

STEAM BOILER.

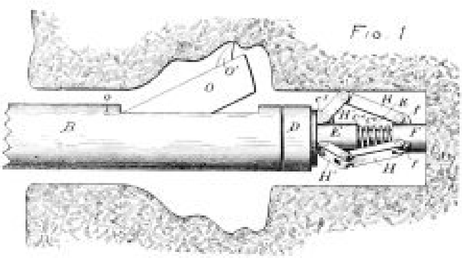
No. 542,674. William H. Berry, Hoosick Falls, N. Y. *Patented July 16th*, 1895. The boiler consists of two vertical cylindrical shells *O* and *P*, one within the other, united at the top by a crowned ring *Q* and at the bottom by a cone-shaped ring or crown-sheet *R*. Since these heads cover a comparatively narrow space they are of thin steel, and do not require bracing, and are threfore sufficiently flexible to accommodate any inequality of expansion in the two shells. Tubes *S S*, of small diameter, radiate from the inner to the outer shell, forming braces for each. These tubes are placed in vertical rows in the inner shell *O*, and are "staggered" in the outer one *P*. By this arrangement the rapid circulation

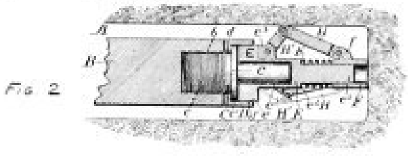


of the water and steam upward near the inner shell is not obstructed (fifty per cent. of the entire area being preserved) and the downward movement of the cooler water near the outer shell afforded the same facility, while the strength of the outer shell is not reduced below the percentage of that of the seams. The fire box is closed by a dome *E*, of fire brick, having a stopper *I* which is opened when cleaning the tubes. The hot gases pass through the tubes to the inside of the smoke jacket *A*, part of them return through the tubes just below the water line, to the smoke box 3; and the remainder pass upward through holes in the check ring *C*, and escape through the tubes which pass through the steam space. The smoke jacket is lined with fire-clay tiles *B*, and it rests on rollers 4, upon the edge of the ring or trough 5, which is filled with sand. A similar sand joint is provided at the top, at *D*. The smoke jacket may be revolved around the boiler, to bring the cleaning doors and flue cleaning pipes into range with any of the tubes. A steam blow pipe *K*, having jets which range with every row of tubes, is attached to the inside of the smoke jacket, and when in use is supplied with steam by a hose. Thus the tubes may be cleaned at any point without stopping the boiler. The furnace 2 is square. The feed water is introduced at *G* where it meets hot water descending from the mud chamber *F* into the flat coil *G'*. The water circulates swiftly through this coil (which is of large pipe) and is delivered close to the water line by the pipe 6. The sediment is swept out of the coil, and is thrown down into the quietest part of the boiler at *F*, from whence it is easily removed.

MINING REAMER.

No. 542,152. Robert H. Elliott and John B. Carrington, Birmingham, Ala. *Patented July 2nd*, 1895. Fig. 1 shows the reamer as at work, enlarging the inner end of a bore hole, to form a powder chamber. Fig. 2 is a sectional

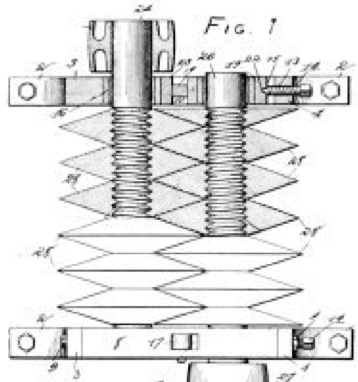


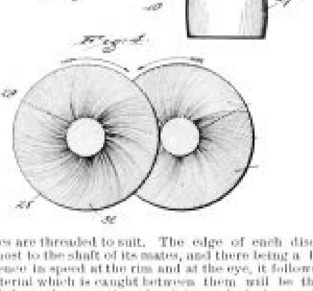


view showing the construction. The object of this improvement is to center the end of the reamer in the hole, and compel the cutter *O* to cut equally on all sides of the bore. The centering device consists of three pairs of toggle links *H H'*, which are jointed to sleeves *F* and *E*. When the reamer is thrust into the hole, the sleeve *F* strikes the bottom, and the links are forced outward against the sides of the hole, thus centering the main spindle. The parts then become stationary, and the plug *C* which is screwed into the end of the spindle, turns within the collar *D*, forming a swivel joint, the thrust being borne upon the enlarged head of the sleeve *E*. As soon as the pressure is removed, the spiral spring *K* will operate to draw in the toggle links, so that the tool may be readily removed from the hole.

GRINDING MILL.

No. 544,294. John D. Evans, St. Louis, Mo. *Patented Aug. 13th*, 1895. Fig. 1 is a top view of the grinding machine partly in section; Fig. 4 is a cross section of the same showing the grinding discs. The discs are thick at the center and taper toward the rim, and the beveled faces are corrugated to suit the material to be ground. They run in the direction of the arrows in Fig. 4. Both shafts are screw threaded, one being right handed, and the other a left handed screw. The





discs are threaded to suit. The edge of each disc reaches almost to the shaft of its mates, and there being a large difference in speed at the rim and at the eye, it follows that the material which is caught between them will be thoroughly rolled at the same time that it is crushed, thus making very effective grinding. It is claimed that the discs will automatically lock themselves in position upon their respective shafts, while the mill is in operation.

The Colliery Engineer

AND

METAL MINER.

VOL. XVI.—NO. 4. SCRANTON, PA., NOVEMBER, 1895. WITH WHICH IS COMBINED THE MINING HERALD.

Written for THE COLLIERY ENGINEER AND METAL MINER.

PROSPECTING FOR PLACER GOLD.

A NOVEL AND GIGANTIC SCHEME IN CLEAR CREEK CANYON, COLORADO.

Showing how Gold is Obtained on a Large Scale from Gold Bearing Gravels under Favorable Conditions.

(By Prof. Arthur Lakes, Golden, Colo.)

In our last, we gave an account of the arrangement of pipes, flumes, etc., and of the general plan of the enterprise. In Fig. 1 we give a skeleton sketch showing in detail how the works will appear when all is completed and bedrock reached. Fig. 11 also shows a panoramic view of the works from the intake flume far up the canyon to the penstock and from the penstock the big pipes to their final connection at the lower end of the placer with the giant nozzles, and on the opposite side the river, the big flume carrying the water of the river out of its natural course and leaving its bed dry for operations. We see by Fig. 1, that since our former article a deep wide pit has been dug 30 feet deep just above the stone dam, that giant nozzles are playing against the sides and into the bottom of this pit, washing down the debris of the banks and excavating the bottom, and that gravel elevator pipes and water lifters are forcing up the material as excavated to an elevated sluice to be winnowed of its coarser gold and thence the gravel to pass over a finer gathering broad undercurrent sluice and thence again by a narrow flume winding amongst queer crevices in the rocks (See Fig. 3) to a final long undercurrent where the finest material is collected on "Burlap" a species of rough sacking material well known to the trade.

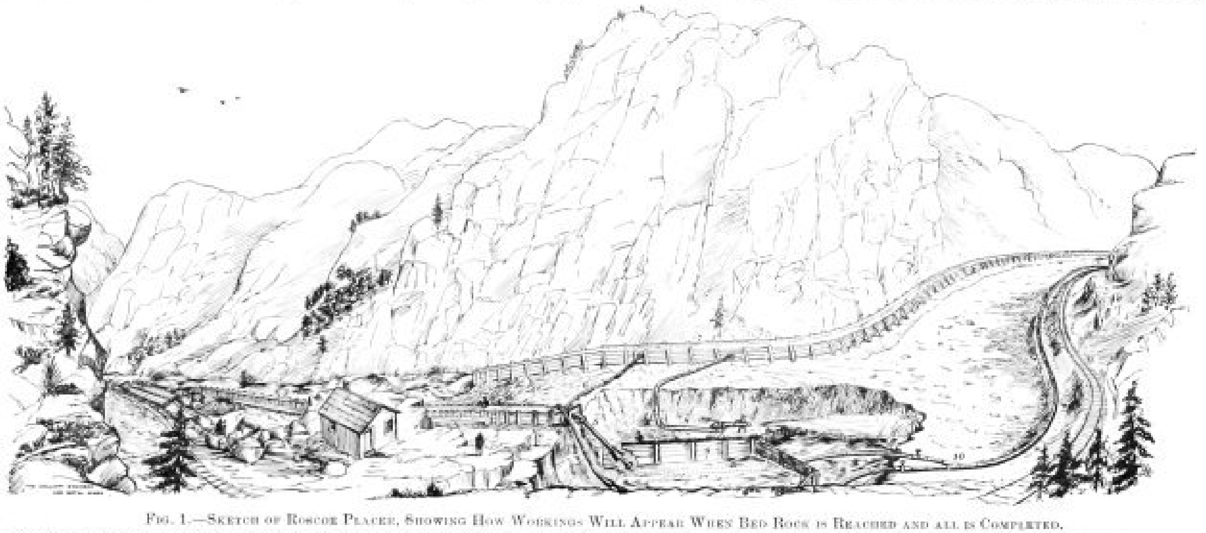


FIG. 1.—SKETCH OF ROSCOE PLACER, SHOWING HOW WORKINGS WILL APPEAR WHEN BED ROCK IS REACHED AND ALL IS COMPLETED.

1, LONG LOWER UNDERCURRENT SLUICE; 2, SMALLER UPPER UNDERCURRENT SLUICE; 3, GRAVEL SLUICES; 4, LUDLUM'S WATER LIFTER; 5, LUDLUM'S GRAVEL ELEVATOR, NOZZLE JUST APPEARS ABOVE BED ROCK, IN WHICH A PORTION OF PIPE IS EMBEDDED, AS SHOWN BY DOTTED LINE; 6, PIPE FROM MAIN FLUME TO CARRY WATER TO GRAVEL SLUICES; 7, THE FLUME; 8, GIANT; 9, WOODEN BOX FOR KEEPING IN MATERIAL FOR ELEVATORS; 10, PIPES.

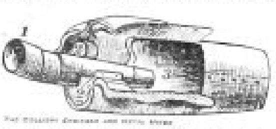

FIG. 2.—INSERTION OF NOZZLE INTO LUDLUM'S WATER LIFTER.

1, GIANT NOZZLE; 2, WOODEN BLOCKS; 3, WATER LIFTER PIPE OPENED, SHOWING NOZZLE.

We will now describe this latter and most important portion of the works in detail. It will be rembered that the general plan of the enterprise is to ransack the contents of the creek bed, down to bedrock and when needed a little below bedrock, all along and up the course of the bed of the creek from which the stream has been removed. After all the machinery, flumes, sluices, pipes and giants were in place, the next thing to be done was to excavate a pit down to bedrock at the stone dam at the extreme lower end of the workings. This is being done by help of giant nozzles and elevators. The plan is to keep working up stream making one long continuous and deep trench the full width of the river bed and the full length of the portion laid bare. The debris of the advancing excavation is thrown back into the portion worked out and abandoned behind.

In commencing the excavation, the giant nozzles were brought to play with their tremendous force and the material as the pit deepened was forced up through the elevator gravel pipe into the elevated gravel sluice (See Figs. 4 and 5). This Ludlum elevator gravel pipe, invented by Mr. Ludlum, is simply a big steel pipe somewhat funnel-shaped and towards the bottom this comes right down into the bottom of the pit where both water and gravel are accumulating under the work of the giants.

Right underneath the open end of the elevator pipe, at a distance of 16 inches below it, is a nozzle imbedded in the bed-rock together with a portion of pipe, as shown by dotted lines in Fig. 1, receiving a powerful pressure of water from one of the main pipes on the bank. As the gravel and stones keep rolling down and by a box are directed in upon this nozzle, the lower portion of which will be sunk in bed-rock when bed-rock is attained, it drives the debris and smaller boulders up the funnel of the elevator and into the flume, where a pipe (See 6, Fig. 1) communicating with the main great flume sends a flood of water into the gravel sluice to help push along the boulders and gravel that have thus come up. The other pipe that is also seen entering the end of the box of the sluice and passing down in a steep slanting direction into the pit, is a Ludlum water lifter sometimes called an elevator pump. It works somewhat like the gravel elevator only a vacuum is caused in the lower portion which causes the water in the pit to ascend into it. The power pressure nozzle is inserted in about a foot into the pipe. (See Fig. 2.) Its purpose is to drain the pit of water, accumulating from the giants and in other ways, so the giants tear down the banks and the elevators carry the water and gravels and gold up into the gravel sluice.

The main gravel sluice (See Figs. 6 and 7) is a narrow

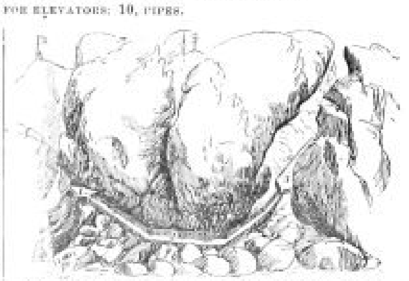

FIG. 3—ADAPTING NATURE TO CIRCUMSTANCES, ROSCOE PLACER.

1 AND 3, UNDERCURRENT SLUICES, 2, FLUME FROM THE -S.

trough or box 208 feet long by 48 inches wide and 3 feet high, laid down at a gentle inclination on the top surface of the creek bed from the lower end of the excavation. It is made of strong, inch thick boards and paved on the bottom with square 8 inch blocks of pine wood set on end so that the grain is uppermost. These block riffles are laid in rows quite close together across the bottom of the sluice from side to side. Between each set or row of blocks is laid a narrow strip of wood 3 inches high by ½ an inch thick. This is laid on the bottom between the riffles as shown in Fig. 7.

In laying in these block riffles the first row of blocks divided into a series of compartments or boxes set longitudinally. The divisions are by long boards about a foot deep, at the bottom of these boards a narrow strip of wood is laid and battened down on the burlap or sacking material which lines the bottom of the box and receives the gold. These burlap carpets are drawn off by rollers on swivels and transported to a wooden tank where they pass over a series of rollers which lays them conveniently open for inspection: every visible particle of gold is collected and the rest drops into the water in the tank.

Through the middle of this undercurrent sluice passes pit to a depth of 30 feet, shows a peculiar section. The great loose rocks, by forming the so-called stone dam across the stream, produced a natural gathering place for all the boulders and rubbish coming down stream from above. Here we may expect at this point the greatest depth that will be encountered before bed rock is reached. Some of the boulders are several feet in diameter and of great size and weight, see Fig. 9. Some of these have to be blasted out, whilst others, later, will be hoisted out by a derrick worked by a dynamo. Mixed with these boulders are a great number of stumps and

Lower Sluice. *Elevated Sluice.*

FIG. 5.—PLAN LUDLUM'S GRAVEL LIFTER.

are placed closely side by side. Then the strip of wood is nailed along the lower part of them with headless nails not driven home but protruding a little so that when the next row of riffles is laid down they are driven up against the points of the protruding headless nails and made fast whilst a strip in being laid against them.

The gravel, as it is being borne along in the sluice, drops its gold which is collected in these cracks or gaps prepared to receive it between the riffles.

On the side of this main sluice, and connected with it at the head, are two smaller side sluices a little below it and running parallel with it. These are lined with Brussels carpet instead of with riffle blocks. This carpet collects the finer gold whilst the main flume usually collects the coarser material both boulders gravel and gold.

Nearly towards the end of the main sluice a few of the block riffles are omitted and a grating put in their place (See Fig. 7) made the full width of the box with a space between bars of ¾ inch and bevelled on the bottom. This grating only allows stones or gravel of a certain size to pass together with finer material into the next sluice called an "undercurrent." This is a broad

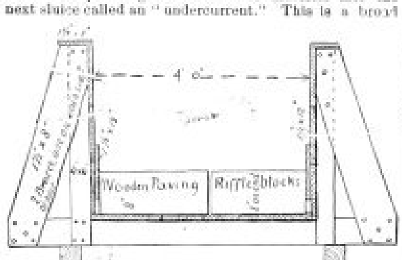

FIG. 6.—CROSS SECTION OF SLUICE.

THE LOWER STRING OF SLUICES ARE THE SAME EXCEPTING THAT THE SIDES ARE BUT 2 FEET HIGH AND 3 FEET APART.

shallow box, as shown in the cut (Fig. 10) dipping at an inclination of 16 inches in 24 feet which is the length of of the undercurrent, its width being 12 feet. In our sketch the box may appear to have a much steeper inclination than this but such is not the case and is a fault in the perspective or foreshortening.

The bottom of this box is lined with a peculiar kind of riffle. These riffles consist of narrow slats or strips of wood laid down on the bottom across the width of the box and on top of each slat is a piece of strap iron nailed flat, whose edge overlaps the slat on both sides on the lower side only ⅜ of an inch. The water passing through these, passes to and fro like an endless pulley and from riffle to riffle, dropping its gold amongst them by the eddies so caused. Still there is a certain amount of finer material carrying still finer gold which escapes this first undercurrent and must not be lost, so from this a narrow flume winding through a curious passage and crevices in the rocks (See Fig. 3) passes out into a still larger and longer undercurrent which catches the finest material, in the present case very largely composed of fine silt and tailings from the stamp mills. The long wide lower undercurrent 48 feet long by 24 feet wide is a small flume with perforated plates at the upper end. This flume is intended to catch and dispose of some of the coarser material that may have passed through the upper undercurrent, and what finer gold there may be in it drops through the perforated plates into the general undercurrent, the coarse rubbish being carried out to the river. When cleaning up day comes, which may occur at uncertain intervals, the block riffles are taken up and carefully inspected for gold. This leaves the bottom of the sluice uncovered, and on this a good deal of gravel and gold and quicksilver has collected. This is carefully shoveled into buckets and examined, the gold laid apart and the quicksilver containing gold placed in retorts. Similarly in the first undercurrent the riffles are taken up and gold and quicksilver collected, also the Brussels carpets in the side sluices and the burlap, as we have described in the lower undercurrent.

The bed of the stream as at present excavated by the

pieces of driftwood, some of which show the marks of the teeth of some ancient beavers. About half way up the side of the section is a thin bed of peaty earth, relics, doubtless, of an old surface soil. Above this are belts of coarse and fine sand, which, by their uneven bedding, show the action of torrents and rapidly changing currents. Gold has been found all the way down from surface to bottom for 30 feet, but they expect the most and coarsest gold when they reach bed rock, which they expect to do daily. They are obliged to wall up with cobble stones portions of the loose sides of the pit, as the jarring of a passing train is liable to shake down boulders and endanger the workmen below.

[TO BE CONTINUED.]

Combine Boilers.

Mr. L. M. Moyes, the patentee and manufacturer of the "Combine Water Tube Boilers" informs us that he has leased the factory premises 1434-36 Randolph St., Philadelphia, Pa., where the manufacturing and assembling of his boiler will be carried on, and where the general offices will be maintained.

He is at present arranging for the incorporating of his business with a view to the developing of the manufacturing department. The "Combine Boiler" is in successful operation, and a series of tests have shown gratifying results.

Mr. Moyes is at present erecting boiler plants at various points, and mentions 200 H. P. for Thos. Kelley, Esq., Phila., Pa.; 100 H. P. for St. Ann's Catholic Schools, Phila.; 125 H. P. for the Marietta Electric Light Co., Marietta Pa.; 130 H. P. Washington Agricultural College, Pullman, Washington.

Mr. Moyes is about to issue the second edition of his catalogue on "Steam Boilers" which will be sent on application, and will contain some interesting reading for steam users.

ELECTRICITY IN BITUMINOUS COAL MINING.

THE EVOLUTION AND DEVELOPMENT OF MINING MACHINES.

Practical Tests Made in Various Ohio Mines with the Principal Electrical Mining Machines, with a tabulated Statement of the Results.

By R. M. Haseltine, Mining Engineer, Chief Inspector of Mines of Ohio.

(From advance sheets of his Annual Report.)

The subject of mining coal by the aid of machinery has received renewed consideration each year, as its importance has become more apparent to the industry. This is especially true since the recent industrial depression has fallen upon the commercial world. Coal has been mined in Ohio in this way to a greater or less extent during the past seventeen or eighteen years, but not until within the past two years has it become plainly manifest that, upon the present basis governing the relations of pick to machine mining, the latter has such a decided advantage. It is believed that within this period the subject has received more attention than during any other period since its inception. While this is true, the subject of mining coal by the aid of machinery is by no means of recent birth. The records in the U. S. Patent Office show that as early as 1858 it had materialized to such a point as to be considered patentable. The first claim filed in this country and the first patent ganted on a mining machine was No. 19,545. It was issued to C. A. Chamberlain, of Allegheny City, Pa., on March 9, 1858. This pioneer inventor conceived the idea of attacking the coal by means of a horizontal wheel in the perimeter of which he inserted cutters. On October 23, 1858, seven months later, Mr. E. Simpkins of the same place filed a claim upon which patent No. 21,918 was issued. The inventive genius of this man led him to conceive the idea of imitating the miner with his pick. This claim stands to-day as the only application ever having been filed for protection on a pick machine.

Grier and Boyd, of Hatton, Pa., secured a patent July 12, 1864, on a machine which consisted of a series of augers working in unison in the same plane. Their patent number was 43,493. This would be classed as an end cutting machine, and was the first "auger machine" upon which a claim was presented at the Patent Office. A number of machines of this type have recently been designed to be driven by electricity. It has been found that the bit being in constant contact with the coal becomes heated, which removes the temper. It has also been discovered that as the augers advance while displacing the coal they become less rigid and have a tendency to become tangled. The circular saw has suggested one of the popular ideas among inventors as to the suitable device by which to reclaim the coal from nature's store house. This plan was first made public in this connection by J. S. Frisk and James Westerman, of Meadville, Pa., who filed a claim on a device which consisted of two parallel saws so arranged that the hub was between them. It was claimed that by this means a cut could be made as deep as desired. They were granted a patent covering their claim on January 17, 1865. It was numbered 45,917. The first claim on a reciprocating machine was made by G. E. Donesthorpe, of Leeds, England, on which patent No. 76,417 was issued, on April 2, 1868. Whitcomb's first patent on a reciprocating machine was issued January 18, 1876, and Harrison's first patent on the same pattern of machine was issued on September 2, 1879. J. Alexander, of Girtsherrie, Scotland, entered the first claim on a "chain machine" which was designed as a side cutter and on which patent No. 135,874 was issued to him on February 18, 1873. A patent for a double chain machine constructed so that they moved in opposite directions was issued to C. S. Lechner, of Ohio, on October 23, 1883, and in 1886 a patent for a single chain end cutting machine was issued to V. & C. S. Lechner. On October 6, 1874, a patent for a rotary bar machine to which was attached an air blast for removing the slack was issued to P. Sheldon. This is the first record of a machine of this type. The patent number is 155,593. During January and August, 1879, patents on the details in cutters were issued to F. M. Lechner, of Columbus, Ohio, to whom, during January and September, 1880, patents were issued on an end cutting rotary bar machine. B. A. Legg also secured a patent on a rotary bar machine on January 3, 1884. This by no means embraces the list of claims that have been filed or of the patents that have been allowed upon mining machines in this country. It however gives those which were first to exhibit principles of merit as well as those which contained principles of mechanics that are now being used in the construction of machines that are regarded as having passed the experimental point. These patents also exhibit the range of thought over which inventors have gone in their endeavor to produce coal by the aid of mechanics, and with what eagerness they have tried to solve a problem that even to-day retains many mysteries. To those who are familiar with the progress made in this branch of industry, the small percentage of the claims which have been found to possess merit will appear quite startling. It is possible that the machines of many of the early inventors fell short of success for want of suitable power with which to operate them, the science of electricity being in a primitive condition and the air compressors being very imperfectly understood. For this and reasons hereinafter considered, it is doubtful if the number of economic mining machines on the market at the present time will exceed a half dozen.

There are many reasons why the energy of so many inventors has not been crowned with greater success. One is that mining machines are operated in caverns of Egyptian darkness into which even inventors who have this problem under consideration rarely enter, hence the machine escapes the gaze of the inquisitive mechanic who is constantly prying into ingenious devices which are exposed to the light of day. This results in the skilled mechanic and the inventor having little or no knowledge as to the requirements of a successful mining machine or to the amount of labor that it must perform. They are equally ignorant as to the rough usage that it must withstand in order to reclaim a ton of coal with economy to the mine operator. Although the most intelligent and skilled miners, thoroughly versed in their vocation, are usually selected to operate the mining machines, as miners they are entirely wanting in the knowledge of mechanics and are therefore unable to calculate as to the amount of additional strength required or of the form or place to apply it in order that the machine may withstand the resistance offered by the coal. It will be readily seen that the mining machine is thus deprived of suggestions, alterations and improvements that would be offered by both mechanics and inventors, were it operated where it would be exposed to the public eye as are other labor saving devices. Even since the introduction of the first economic machine, which was about 1876 or 1877, there have been scores of machines patented and placed on the market, many of them possessing features that would have been of great value to the mining industry had they been fully developed, but upon trial they were found to be too frail, and after a number of vexatious delays, caused by breakage, the were consigned to the scrap pile and the disheartened inventor found himself forced to abandon his hope of reward, and return to his former vocation. Had he been possessed of a knowledge as to the units of work that are required to undercut the coal, he would have increased the factor of safety in his calculations and the result might have been more satisfactory.

But few coal veins are adapted to machine mining at all and in a still smaller number can the present type of standard machine be used with economy. For profitable mining the roof must be strong and free from slips or bell shaped balls. Especially is this true of the rotary bar or of the end cutting chain machine, either of which cannot be well operated if the props are set less than twelve feet from the coal face. The floor of the coal vein must be nearly if not quite level to admit of the successful working of machines. There is no instance within the writer's knowledge where the mining machines have given satisfaction when operated on an uneven floor. The thickness of the vein has been considered as the index by which its adaptability for the introduction of mining machines is to be determined, and with but few exceptions, no attempt at any installation has been made except in the very thickest of the veins, and so machine builders have designed only for the mining of high coal. For this reason the practicability of using machines in reclaiming the coal in thin veins still remains undecided. This is largely owing to the fact that the fiber of the coal is as firm in the thin veins as in the thick, so that the power required to undermine the coal remains the same, hence the weight of the machine must be as great for one as for the other. The diminished space in which to use the bars by which the machine is moved, also the necessity of using a shorter bar, thus diminishing the leverage, makes the moving of the machine very laborious and slow and thus diminishes the opportunity of profit that might be derived from their installation. With a view of widening the field of machine mining, some manufacturers have turned their attention to the designing of a machine that would be of such a height as to not come in contact with the roof while being moved, but the weight of the machine was so great that it offered no encouragement to the operators in thin veins. The mere fact that a machine is of a height that will permit of its being readily moved is no guarantee that it can be profitably used in that vein. It is an old rule in mining to make the undercutting the same depth as the coal vein is thick. If a proper amount of powder is then judiciously used, the coal will be liberated in its best possible form.

The present type of bar or chain machine is designed to undercut from six to seven feet and where the vein is from eight to twelve feet in thickness, this is of course much less than than the rule would require. In such an instance great difficulty has been experienced in producing merchantable coal, owing to its flaking off in thin slabs so shattered as to not stand handling.

It has been found that a seven-foot machine must be much heavier than one that is designed to undercut but six feet, hence it is the writer's belief that if in these veins the machines were designed to undercut from three and one-half to four and one-half feet, as the thickness of the vein would demand, it could be so reduced in weight as to be readily moved into position. Such a machine would be designed to undercut the full thickness of the vein and the coal thus produced will enter the markets in as good form as if it were the product of pick mining.

In making installations, operators have generally adopted one of the three types of machine. These are the rotary bar, the chain and the reciprocating patterns, and in these investigations only the two former have been considered, for the reason that they received the greater consideration among the operators, presumably from the fact that they have been regarded as the most profitable to operate. The manufacturers of the reciprocating machine lay claim to holding a priority in

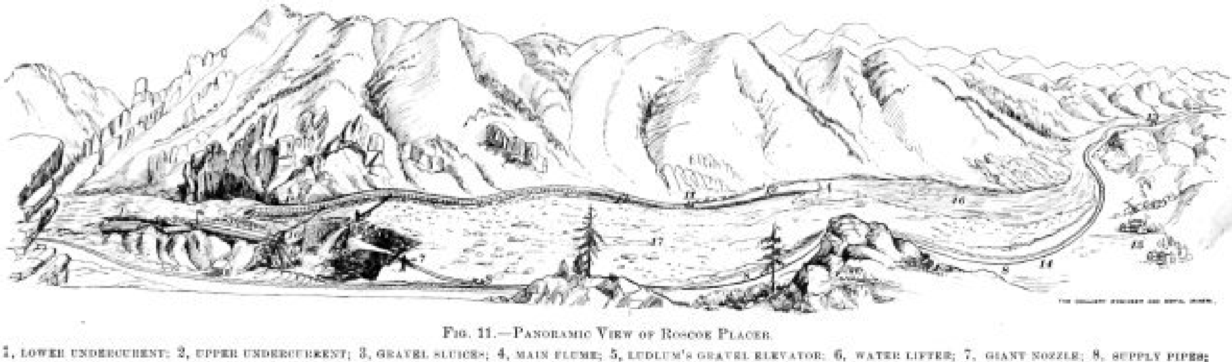

FIG. 11.—PANORAMIC VIEW OF ROSCOE PLACER.

entering the field. The age in this case cannot be definitely settled without first knowing which was the first to pass the experimental point. This type of machine, however, holds a very important part in the industry and is indispensable in a mine where machines of the other types are installed. In such cases it is used to do the cutting near faults where the coal contains balls of iron pyrites, etc., or other foreign matter. It is a machine that can be employed advantageously in driving narrow entries or in mining under tender roof. This type of machine is also regarded with much favor by the operators in the thin veins, owing to the ease with which it can be transported about the mine. It is designed to undercut a depth of four and one-half feet, which in many of the thin veins is ample to insure the production of a merchantable coal.

The early installations of mining machines, beginning about 1877, were confined to the use of compressed air as a motive power. This continued until early in the year of 1889, when electricity was first successfully applied to a rotary bar machine by the Jeffrey Manufacturing Co., of Columbus, Ohio. This machine is still in use in the mine in which it was first installed. The ease and economy with which this new power could be conducted about the mine commanded for it at once the attention of the inventor and operator. It placed the employment of the mining machine within the reach of a greater number of operators, and the development of machine mining has gone forward rapidly since that date.

The question of operating mines by electricity has received more discussion during the past six years than any subject before the mining public. And the few years elapsing since the first introduction of electricity has witnessed its successful application to every labor saving device in the industry in which compressed air had formerly been utilized. Furthermore, it has been known that the amount of power required to operate the mining machines has been reduced; also that the construction of the mining machine has been improved and that new and improved machinery has been designed to attack the coal in a more advantageous manner. Still there has been no careful investigation of this progress or no published information for which the public has been the wiser. It would seem that the efficiency of the power, its adaptability to the uses of the mine, the amount of it required to do a given amount of work, the loss in transmission, etc., were questions which should have received ere this the most careful investigation and the results placed before the mining public. The absence of this information can only be accounted for on the assumption that the persons who desire it dislike to undergo the necessary hardships and inconveniences, much less to perform the labor, whereby it can be acquired.

By reason of the scarcity and incompleteness of this information, which is absolutely necessary in order to intelligently discuss the subject, the writer has devoted several weeks to the making of practical tests as to the relative efficiency of the labor saving machines in the mines of Ohio. In order to set forth the results of this labor in a compact and lucid form, they are here presented in the accompanying table. It will be seen that visits were made to seven mines located in various parts of three of the most important coal fields of the State. Tests were made of twelve mining machines of the several types that are now regarded as standard machines. In securing these results the circuit was opened near the machine and meters registering potential and current were inserted. Simultaneous readings were taken every fifteen seconds while seventy-three cuts were being made. It will thus be seen that the results as they appear in the table embody the averages of over 1,400 readings, all of which were taken and reduced with the utmost possible precision.

In arranging this table it was thought desirable to show the comparative efficiency of the various types of mining machines while at work under the circumstances which the ordinary daily routine presents. It was also the purpose of the designer to exhibit the results of the tests made and the deductions drawn therefrom, as well as such other circumstances as would bear upon their value.

In the first column have been placed the names of the mines, and in the next the names of the operators, the county in which the mine is located and the character and capacity of the power plant. In the next column is represented the name of the machine, which also indicates its maker, and in the next the type of the machine. The fifth column exhibits the number of cuts that the machine made while being tested. It will be noticed that the number of cuts varies with the different machines. This was caused by a series of uncontrollable exigencies, which are liable to arise at any moment during the progress of such an investigation. For instance, on several occasions it was found that the machine had but few cuts to make before a change to another part of the mine, perhaps for want of a place in which to cut; and several times the testing was interrupted by the stopping of the generator and by breakages of the machine. On one or two other occasions the work was stopped to allow the experimenting party to catch a train. Thus it will be seen that it was almost impossible to secure an equal number of trials to each machine. In the next two columns appear the average depth and breadth of each cut. The former was obtained by measuring the depth of the undercut in several places and striking an average. These figures should not be considered as representing the depth which the machine is capable of cutting, as often the contour of the coal face is such that the machine is prevented from getting into a position that will permit it to make its full cut. The average width of the cut, as made during the trial, which appears in the next column, does not represent the capabilities of the machine with regard to the width of the cut. The reason why the machines are seldom set to make their full cut arises from the fact that a bar machine, so set, by reason of the impossibility of making the two adjoining cuts parallel invariably leaves a "stump" in the undercut, while in the case of the chain machine, when the cuts are made the full width, there is left a projecting angle, at the back where the two cuts adjoin. In either case the shooting down of the coal is seriously interfered with. For these and other reasons it has been found economical with the present type of chain or bar machine to cut less than the width of the machine. The next column represents the number of square feet undermined at each cut, and the next the time occupied by the machine in making the cut. By this is meant the period elapsing from the time the machine first caught the coal until the desired distance under was attained and the machine reversed. In the next column is registered the average gross horse-power consumed in making the various cuts. The instruments were read every fifteen seconds during the time occupied in cutting and the first two sub-columns give the maximum and minimum readings, respectively, while the third gives the average horse-power for the cut. In the next column is given the fractional load, which was obtained by running the machine light, with and without the feed. The next column exhibits the average net horse-power used in cutting, which embraces the average horse-power minus the frictional load. In the next column is represented the average horse-power required by the machine to undercut one square foot of coal in one minute of time. This is designed to reduce the efficiency of each machine to a common standard for comparison. In the last columns appears the average voltage for each cut, which has been introduced to show whether or not the machine worked under any disadvantage from this source.

By referring to the average of each machine tested as they exhibit the different factors considered, it will be seen that the average maximum horse-power of the five bar machines is eighteen and one-half, nineteen and four-tenths, twenty-two and nine-tenths, twenty-six and nine-tenths and twenty-six and eight-tenths, while the chain machine shows twenty-one and six-tenths, fourteen and seven-tenths, nineteen and six-tenths, nine and eight-tenths, seventeen and two-tenths, twenty-two and twenty and one-half horse-power, respectively. These results are of the highest value to persons who contemplate the installing of mining machines. They should use the highest power exhibited under the type of machine selected as the multiple by which to determine the power of the generator necessary to insure satisfactory results. Neglect in following this rule is a very common error practiced among the manufacturers of machines. They appear timid in presenting proper estimates of cost lest they discourage the operator and thereby lose the installing of a plant. Hence they take the chances of the maximum power not being required, or of being able to reinforce the power plant after the operator has discovered that a mistake has been made. Thus it is that at many plants the limit of power demanded is so close to the capacity of the plant. The minimum horse-power in the next column is of no particular value, beyond giving the amount of power required to undercut the coal under the most favorable circumstances. In the next column will be found the average horse-power required to make each cut, also the average horse-power required at each machine during the time that it was tested. It conveys the amount of power that must be ready at all times in order to operate the plant with any success. From this column there can be obtained a general knowledge of the resistance offered by the coal in different portions of the State as well as a general knowledge as to the relative efficiency of the several types of machines that are in use in the industry. It will be observed that in the column of averages for machines, the horse-power consumed by the rotary bar machine appears as sixteen and one-half, seventeen, eighteen and nine-tenths, and twenty-two and seven-tenths, while the chain machines show eight and six-tenths, twelve and five-tenths, fourteen and five-tenths, fifteen and three-tenths, sixteen, sixteen and three-tenths and eighteen and one-tenth. If the number of cuts are taken into consideration, it is found that the general average horse-power required by the bar machine is eighteen and seven-tenths, while for the chain machine the average is fourteen and four-tenths horse power. This shows by a comparison of all the coal cut during this inquiry, that the chain machine required four and three-tenths horse-power less than the rotary bar machine. The required power to overcome this frictional load of a machine is of vital importance, as it is so much power wasted to the operator. Under this heading in the subdivision of "Feed on" will be found the amount of power required to set each machine in motion, entirely apart from that used in cutting coal. This column shows that one chain machine required three and sixteen one-hundreths horse-power; one, three and fifty-one one-hundredths horse-power; one, three and seventy-seven one-hundredths horse-power; two, four and twenty-seven one-hundredths horse-power; one, four and thirty-four one-hundredths horse-power and one, six and three-tenths horse-power. The first mentioned was a new machine of the most approved workmanship, and was doing its second day's work. With the rotary bar machine the horse-power was five and thirty-one one-hundredths, one other was six and three-fourths horse-power, while three were between seven and one-tenth and seven and seven-tenths horse-power. It is obvious that each horse-power saved in the frictional load is a clear profit to the operator. If from the average horse-power required to make each cut, is deducted the horse-power required to overcome the frictional load, the result is the net horse-power consumed in cutting the coal. This average will be found to vary as does that of each cut. We again find the lowest powers indicated to be that of the chain machine which were five and four-tenths horse-power and eight and two-tenths horse-power. Then two show ten and two-tenths and ten and three-tenths respectively, then one eleven and eight-tenths, one twelve and two-tenths and one thirteen and eight-tenths. The lowest average for the rotary bar machine appears at nine and three-tenths and the highest at sixteen horse-power.

The average, as seen in the foregoing columns of the table, will convey to the reader a very concise idea of the elements which are important to consider in machine mining. It will be observed that each average considered is in a measure dependent upon the others, also that they vary with each machine whether compared in distant mines or in the same one. The relative efficiency of the several machines being under consideration, it was therefore desirable to compare them by a common standard, which is attempted in the column headed "H. P. Required to Undercut One Sq. Ft. of Coal in One Minute." It will be observed that the results include the frictional load. This was necessary, as the resistance offered varies with each machine, hence the power here indicated represents both that required to displace the coal and that required to overcome the friction of machinery. If the trials here considered had all been made in the same piece of coal, the results would give an absolute comparative efficiency for the machines here considered, but for obvious reasons this was impracticable, hence the comparative efficiency will differ in so far as the amount of resistance offered by the coal in one mine is greater or less than that encountered in another. It will also differ with the amount of variation in the coal fiber of the different parts of the same mine. From this column it will be seen that the lowest power as shown by a chain machine was four and two-tenths horse power. This machine was at the Snake Hollow mine, where the coal is said to be the best for pick mining of any in the Hocking Valley. The machine had the full power of a 150 horse power generator, which gave it a uniform potential. The next machine in order required five and seven-tenths horse power. This is followed by four requiring from six and one-tenth to six and nine-tenths, and one which was consuming eight and five-tenths horse power.

The rotary bar machine requiring the lowest power was located at Murray City, in Hocking county; which was eight and nine-tenths horse power. This is followed in order by one requiring nine and two-tenths horse power; one, nine and five-tenths horse power; one, ten and eight-tenths horse power; and one twelve and two-tenths horse power, which is the highest in the list. Had these results been obtained in the same piece of coal they would at once establish the pre-eminent superiority of the chain machine. By a further comparison it will be seen that at Murray City, where both types were together in the same coal, there is a difference of two and six-tenths horse power in favor of the chain machine. At New Pittsburg and at Rock Run both types under the same conditions exhibit the advantage in favor of the chain machine, of three and one-half horse power in the first instance and two and three-tenths horse power in the second. At the Congo mine in Perry county, there appears the best opportunity to form a fair comparison as to the relative efficiency of the several makes of types of machine under consideration. In making these tests each machine had the full potential of the plant, and each was started with sharp knives. Care was taken that each machine be given an equal opportunity. The coal in this mine is harder than that of any machine mine in the State, and the machines that have so far been installed here have been built with increased strength to withstand the severe stress. The amount of resistance offered by the coal here will be more fully appreciated when it is known that the operators manufacture their own knives, which are said to exceed in number those made by the Jeffrey Manufacturing Company, and the cost of which has been estimated to amount to two and one-half cents per ton of lump coal produced. It will be observed that the two chain machines, which differ in the former comparison of averages, require six and seven-tenths horse power each, while the rotary bar machine required twelve and two-tenths horse power or forty-five per cent. more power than either of the chain machines to undercut one square foot of coal in one minute. By deducting from these averages the frictional load of each machine, the result obtained will be the amount of power required to displace the coal alone at the rate of one square foot in one minute. This calculation shows that at the Walhonding mine it would require three and thirteen one-hundredths horse power; at New Pittsburg the chain machine would require one and forty-three one-hundredths horse power and the bar machine two and four one-hundredths; at Orbiston the bar machine requires two and fourteen one-hundredths horse power; at Murray City the chain required two and fifty-nine one-hundredths horse power; and the bar three and thirty-nine one-hundredths horse power; at Snake Hollow the chain required but one and four-one-hundredths horse power, the lowest ever known; at Congo the two chain machines consumed two and thirty-six one-hundredths and two and forty-three one-hundredths horse power, respectively, while the rotary bar machine in the same coal and with like advantages, required four and fifty-one one-hundredths horse power, the highest in the list; at Rock Run the chain machine used two and twenty one-hundredths horse-power, and the rotary bar four and four one-hundredths horse power. In the mines were both types of machine are employed a comparison will show that at New Pittsburg the chain machine saves sixty-one one hundredths horse-power; at Murray City, eighty one-hundredths horse power; at Congo, two and eight one-hundredths and two and fifteen one-hundredths, or forty-eight per cent. and forty-six per cent., respectively; at Rock Run one and eighty-four one-hundredths horse power, or but fifty-four per cent. of the power required by the bar machine. These results seem to vindicate the theory of the writer expressed in a former article, in which it was asserted that the chain was the most approved instrument by which to cut coal. This belief was based upon the laws which govern the woodsman who cuts with the grain of the wood. The coal which is composed of decayed vegetation has retained its stratification, the difference between the two propositions being that in the tree the grain is vertical, while in the coal it lies horizontally. That is, that the chain machine, like the miner with his pick, attacks the coal with the grain and not across it. That is, it splits out a portion of the fiber and leaves the cleavage both above and below smooth and undisturbed. The misapplication

TABLE OF EXPERIMENTS.

MADE WITH ELECTRICAL MACHINES IN SEVEN OF THE MINES OF OHIO, COMPLETED JULY, 1895. THE RESULTS ARE THE AVERAGE PRODUCT OF 1,400 READINGS TAKEN WHILE 12 OF THE VARIOUS TYPES OF STANDARD MACHINES WERE OCCUPIED IN MAKING 75 CUTS. MADE BY R. M. HASELTINE, CHIEF INSPECTOR OF MINES.

A Morgan-Gardner projectile machine at the Walhonding mine was tested during a three-minute cut and found to require 3.75 horse power at a voltage of 225 v.

At the Orbiston mine a small motor driving an emery wheel was tested and found when running light to require 1.94 horse power, and when grinding bits, 1.33 horse power. At the same mine an electric pump of the triplex pattern was tested. This pump was made by Gould & Co., of Seneca Falls, N. Y., for exhibition at the World's Fair. Has a ten horse power motor and four-inch suction and five-inch discharge, forcing water 2,000 feet, and a height of seventy-eight feet. When running light it consumed an average of 3.4 horse power and when pumping, 4.6 horse power.

At the Murray City mine a motor driving a seven-foot Ray & McConnel fan, which was producing 43,000 feet of air per minute, was tested and found to require an average of 10.4 horse power.

W. E. HASELTINE, *Del.*

of power as exhibited in the rotary bar machine may appear clearer, if the reader will imagine a revolving shaft set with knives so arranged as to cut parallel to its axis, and attacking the end of a piece of timber. To be compared to this would be a saw running horizontally and being applied to the side of timber.

The economic results that accrue from machine mining form the vital factor of the subject under consideration. In the pursuit of information on this subject it was found difficult to obtain a wide range of record as to the amount of coal that machines of the reciprocating pattern are capable of producing. Great difficulty was experienced, also, in securing data by means of which to compare the results obtained by this type of machine, with those of the rotary bar or chain machine. This, in the main, was owing to the fact that the veins in which the reciprocating machines are most exclusively installed, differ greatly from those in which the other types of machine can be profitably used. For instance, in the mine where the former type is used exclusively the veins are much thinner than those in which the latter machines are employed. Again, in the latter class of mines a portion of the product is often secured by pick mining, of which the amount of small coal is not kept separate, therefore the results here considered lack the breadth of observation that the writer had desired. Futhermore, where all types are employed in the same mine, the projectile machine is mostly used to work around faults and in places where the coal is defective, hence its capacity is not considered important and no record is kept of the work performed even when it is cutting under favorable circumstances. However, the following interesting figures were obtained with reference to a reciprocating machine using air as a motive power, and by comparing it with electrical machines of the same pattern, and of apparently equal efficiency, we may arrive at a fairly accurate conclusion with regard to the general merit of the machine when using electricity as a motive power. The facts that were obtainable show that in a four and one-half-foot vein which is free from impurities, the reciprocating machines average twenty-eight tons of lump coal daily, which equals forty-two and one-half tons run of mine. In this vein this represents an average undercutting of about 170 square feet. The cost of mining is based on a ton of 2,000 pounds of lump coal. This is considered equivalent in this mine to 3,030 pounds run of mine loaded in the mine car at the room face. The practice is to subdivide this, giving to the machine man and his helper, conjointly, one-fifth, and to the loaders one-half of the price paid to the pick miner for the same amount of coal. Thus, on a basis of sixty cents for pick mining, the undercutting would cost twelve cents and the loading thirty cents per ton. At this mine the power is estimated to cost five cents per ton additionally, which, if added to the above, will make the total cost of a ton of lump coal in the mine car at the working face, forty-seven cents. The true amount of coal here represented, is lump, 2,000 pounds, nut, 424 pounds, slack and pea, 606 pounds, a total of 3,030 pounds. In another vein, which has an average thickness of three and one-half feet, the average space undercut daily during 1894 is given as 168 square feet, and the average daily production of each machine is twenty-one and three-fourths tons of lump coal. This is after it has passed over a one and one-quarter-inch screen of sixty feet area. The coal in this vein is strong in fiber and has well defined joints, hence it mines in large blocks. This will be more clearly seen by a glance at the production which consists of seventy and eight-tenths per cent. of lump, seven and seven-tenths per cent. of nut, and twenty-one and one-half per cent. of slack; or in a ton of coal, 2,000 pounds would be lump, 217 pounds nut, and 607 pounds slack, which is equivalent to 2,825 pounds run of mine.

At this mine during the two years previous when the coal was produced exclusively by pick mining, the proportion of lump was seventy-two and four-tenths per cent., of nut, eight and eight-tenths per cent., and of slack, eighteen and eight-tenths per cent. Thus it will be seen that the output of the mine, when produced by machines, contains two per cent. less lump, one per cent. less nut, and three per cent. more slack than when displaced by the pick of the miner. It is regretted that the horse-power required to operate compressed air machines of this type could not be obtained for this article, but it will be seen by referring to the foot notes of the table, that a Morgan-Gardner electric machine of this type, and of apparently equal efficiency, was tested in the Walhonding mine in Guernsey county. It was found that to operate it to its capacity required three and three-fourths horse-power.

In the consideration of the rotary bar and chain machines it will be observed that the wage scale, while based upon the price paid in pick mining, suffers a much greater subdivision. For instance, when pick mining is sixty cents, eleven cents per ton is paid for cutting entries, room necks and all narrow work, while for undercutting in rooms and for all wide work the price is eight cents per ton. For loading coal in the entries and room necks and for all narrow work, thirty-six cents is paid; for loading out of breakthroughs between rooms, thirty-seven and one-seventh cents, and in rooms and for all wide work the price is thirty cents per ton. Drilling preparatory to blasting the coal down, when done by the machine man, pays two cents per ton, while, if the loader does it, he receives three cents per ton. On this schedule it is found that the cutting and drilling costs ten and four-tenths cents per ton, and the loading, thirty and seven-tenths per ton. Thus it will be seen the cost of the coal on the mine car is forty-one and three-tenths cents per ton, exclusive of the power. It has been found that the cost of power per ton of coal produced has not been determined at any electrical mine within the range of this inquiry. Therefore, to compare results, the cost of power in the first case must be deducted. It will then be found that a ton of coal produced by the projectile machine is worth, exclusive of power, forty-two cents, while by either of the others the cost is forty-one and three-tenths cents. It will thus be seen that with either type of machine the cost of the coal, exclusive of the cost of power, is substantially the same.

As the cost of mining is based on a ton of 2,000 pounds of lump coal it is evident that the amount of fine coal produced is an important factor to the operator; and the relative amount produced by any type of machine enters largely into the question of its adoption. With the projectile machine the undercut is about four and one-half feet in depth, and in order to get the necessary height in which to make the full cut, it is customary to block down the coal along the edge to a height of eighteen inches, gradually decreasing to a height of about four inches at the back of the cut. When coal is mined in this way it contains a large amount of nut, pea and slack. Investigations on this point show that in a vein four and one-half feet in thickness, the lump coal equals sixty-six per cent., the nut forteen per cent. and the pea and slack twenty per cent. of the output. The records show that by pick mining in the same vein the lump formed sixty-five per cent., the nut fifteen per cent. and the slack and pea twenty per cent. of the entire output. These proportions were the result of passing the coal over a screen of sixty square feet area with spaces of one and one-half inches beween the bars, while the nut passed over three-quarter inch spaces. In another instance where the coal is three and one-half feet in thickness, the average proportion for the last two years has been lump, seventy and eight-tenths per cent., nut, seven and seven-tenths per cent., and slack, twenty-one and one-half per cent. During the two years preceding, when the coal was all produced by pick mining, the proportion of lump was seventy-two and four-tenths per cent., nut, eight and eight-tenths per cent., and slack, eighteen and eight-tenths per cent. The coal at this mine passed over a screen of sixty square feet area with one and one-fourth inches between the bars, while the nut passed over a three-fourths inch screen. A comparison of the above results shows that the results do not differ greatly in the production of small coal. It therefore follows that in a mine, situated conveniently to a market, the reciprocating machine is a desirable type to install. Again, where the coal is mined under a lease in which the royalty is based upon the lump coal, this type of machine will compare favorably with the pick miner whom it imitates. The rotary bar machine is found to carve a space about five inches in width, the chippings from which, on account of their fineness, are known as "Buck dust." All of this is thrown away and is therefore a total loss. As a rule this comes from the best portion of the vein. In the case of the chain machine it has been found that the space excavated is practically the same as that of the rotary bar machine. It is claimed that twenty-five per cent. of the cuttings are of a size that can be sold as pea coal, but in order to secure this it is necessary to take out the entire mass and screen it. It is therefore questionable if, after the dust has been hauled away and dumped, there is any profit in removing it from the mine. To get a comparison of the amount of fine coal produced by this type of machine with that produced by pick mining, has been found quite difficult; as, to select different mines would be unfair and where both methods are employed in the same mine, the fine coals are not weighed separately. Therefore the range of comparison is of necessity much narrower than was expected when this inquiry began. The comparison here made is based on the production of a mine located on the divide between the Sunday Creek and Hocking Valleys, where pick mining has recently been supplanted by machines, and the product of which is about equally divided between the rotary bar and the chain machines. By referring to the first comparison it will be seen that when the coal was produced by pick mining, the lump coal represented sixty-six per cent., the nut fourteen per cent., the pea six per cent. and the slack fourteen per cent. of the output. Since the introduction of mining machines the lump coal represents seventy-two per cent., the nut twelve and one-half per cent., the pea one and one-half per cent. and the slack fourteen per cent. of the production. It will thus be seen that in this instance the machine increases the amount of lump six per cent. and that it decreases the nut one and one-half per cent. and the pea four and one-half per cent., while the percentage of slack remains the same; so that when the coal was produced by pick mining, a ton of lump represented 3,030 pounds, but since the installation of machinery a ton of lump represents but 2,777 pounds run of mine. It will be readily observed that the projectile machine in the first instance in producing 2,000 pounds of lump coal produced 424 pounds of nut and 606 pounds of slack, while the pick miner in the same mine in producing 2,000 pounds of lump coal added 462 pounds of nut and 615 pounds of slack, a total of 3,077 pounds. At the mine where the second comparison was made the reciprocating machine in reclaiming 2,000 pounds of coal added 218 pounds of nut and 607 pounds of slack, a total of 2,825 pounds. Here the pick miner in mining 2,000 pounds of lump coal also mines 243 pounds of nut and 519 pounds of slack, a total of 2,762 pounds. Where the comparison was made with the rotary bar and chain machine it is found that while they produce 2,000 pounds of lump, there is an added tonnage of 347 pounds of nut, forty-two pounds of pea and 389 pounds of slack, a total of 2,778 pounds. In this mine the pick miner with every 2,000 pounds of lump coal, delivers additionally 424 pounds of nut, 182 pounds of pea and 424 pounds of slack, a total of 3,030 pounds. It will be deduced from the above comparisons that owing to the variation in the amount of fine coal produced by the several methods treated, to make the comparison on the relative cost of lump coal would be misleading. Therefore, to make the matter clearer the comparative cost of a ton of run of mine coal on the sixty-cent scale will be taken as the basis of the following calculation. In the case of the projectile machine first considered a ton of run of mine coal, exclusive of power, costs twenty-seven and seven-tenths cents, while a ton produced by pick mining costs thirty-nine cents. In the second comparisons made with the same type of machine covering a period of two years, the cost of a ton of run of mine coal is found to be twenty-nine and seven-tenths cents, while coal produced by pick mining during a like period cost forty three and one-half cents per ton run of mine. By comparing the rotary bar and chain machine, it is found that a ton of run of mine coal, exclusive of the power, costs twenty-nine and seven-tenths cents, while in the same mine when produced by pick mining it costs thirty-nine and six-tenths cents. This comparison indicates an apparent advantage in the use of the projectile machine, which will be largely equalized when the number of tons that each type of machine produces daily is taken into consideration.

A pertinent phase of the mining machine question, and one that has attracted the notice of the writer in his official capacity, is that of casualty in machine mining. Whenever coal has been mined by machinery and the records are available, a marked decrease is shown in the accident list. As an illustration, in Hocking county during 1894, seventy-three per cent. of the coal was mined by machinery, which amounted to 1,453,391 tons and but one fatal accident occurred in producing this enormous amount of coal. In the counties of Athens, Jackson and Perry each of which produced substantially an equal amount of coal, there occurred fifteen fatalities. A very small percentage of this coal was produced by mining machines. The State of Ohio during 1894 produced an output of 11,910,219 tons. In mining this there occurred forty-five fatal, 116 serious and ninety-six accidents of a minor character, or a total of 257 accidents, yet of all this number not one could be attributed directly to the mining machine. One of the principal reasons to be assigned for this is the fact that the number of men exposed to danger in machine mines is reduced nearly one-half. Again, the men selected to operate the machines and prepare the coal for their successful operation are usually of the highest order of intelligence to be found among the craft. Then there may be an element of selfishness which prompts the operator to use additional precaution in order to protect his $1,500 machine, and thereby furnish greater security to the mine employes.

Written for THE COLLIERY ENGINEER AND METAL MINER.

AN AUTOMATIC SWITCH.

For Rapid and Economical Handling of Coal at Shaft and Slope Heads.

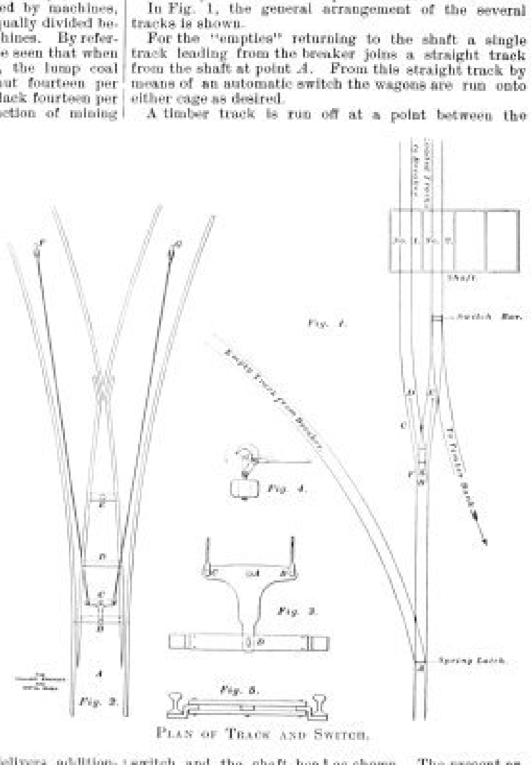
(By Baird Halberstadt, E. M.)

At the Packer No. 5 Colliery near Girardville, Pa., the shaft has four compartments for hoisting, two of which only are in use at the present time.

In Fig. 1, the general arrangement of the several tracks is shown.

For the "empties" returning to the shaft a single track leading from the breaker joins a straight track from the shaft at point *A*. From this straight track by means of an automatic switch the wagons are run onto either cage as desired.

A timber track is run off at a point between the switch and the shaft hea l as shown. The present arrangement of the timber track is but temporary and



PLAN OF TRACK AND SWITCH.

will, when the contemplated improvements are completed, connect with the straight track at a point between *A* and *B*. It will be observed that by the present arrangement, timber is lowered only through compartment No. 2.

As has been said the hoisting is done in two compartments. An empty car or wagon returning from the breaker runs by gravity to point *A*, Fig. 1. At this point a spring latch is placed. The grade of the shaft track is toward the shaft. A car passing point *A* continues on its course on an ascending grade until its momentum is overcome, when it is spragged and held until a loaded wagon has been brought up on the cage. The car is then released and runs onto the cage pushing the loaded car ahead of it and starting it toward the breaker.

For example, suppose the cage in compartment No. 1 has arrived at the head of the shaft with a loaded wagon, the switch is then set for the car to run on the track leading to this compartment.

At points *D* and *E* (Fig. 1) are placed hooks (Fig. 4); the passage of the car axle over one of these drives it forward to the second position as shown by dotted lines in Fig 4. Attached to these hooks and passing backwardly to the lever bar to which they are attached at points *B* and *C* (Fig. 3) are two round iron bars (½ inch) which impart the motion given the hooks, to the lever bar which in turn imparts it to the switch rails drawing them right and left to the main track as desired. If the hook at point *D* is in the position shown by the dotted line, that at *E* is in position shown by the full line, (Fig. 4).

As the cages in the shaft are lowered alternately the passage of a car over the hook on one track sets the switch to run the next car over the other.

In Fig. 2 the switch proper is shown on an enlarged scale. At point *E* is a pivot about which the switch moves. Between the points *A* and *B*, the switch rails are tapered as shown. At point *C* the lever bar works on a pivot. At *D* the switch rails are secured by a ½ inch iron plate 3 inches wide. At point *B* are the double bars and rail seats. An enlarged drawing of this is shown in Fig. 5.

Under the frog an iron plate (½ inch) is laid which permits of the free motion of the switch rails at this point. In Fig. 2 the switch is shown not fixed for either track. In Fig. 3 is shown, on an enlarged scale, the lever bar and the double plate bars, a section of these last is shown in Fig. 5. The apparatus has been in use for a number of years at the colliery and it has given and continues to give excellent satisfaction.

The switch was planned by Col. D. P. Brown, Division Superintendent of the Lehigh Valley Coal Company, and it was made by the colliery blacksmith under Col. Brown's direction.

A NEW CONVEYOR.

Important Improvements in Conveying Machinery for Coal, Ore, or Other Heavy Materials.

Through the courtesy of the Link-Belt Engineering Co. of Nicetown, Phila., we are able to illustrate and describe in this issue an important improvement in conveying machinery.

Monobar is the name given by the inventor to a new chain for long distance conveying and elevating, which combines strength, lightness, simplicity and durable qualities, and is destined to take a leading place among new and useful appliances for work of this class. Monobar may be briefly described as a series of bolts, flexibly connected, with attachments for conveyor flights or elevator buckets. Fig. 1 shows its appearance as employed in a conveyor, and will suggest to those familiar with chain conveying a superior advantage in that no material can lodge on the chain, or be carried under the wheels. Its construction is shown in Fig. 2, in which the malleable iron joint is in light tint and the abutting ends of the bolts in full shading. Having no welds, which are the chief points of weakness in wrought chains, and the malleable joints being so proportioned as to be in all cases stronger than the wrought iron

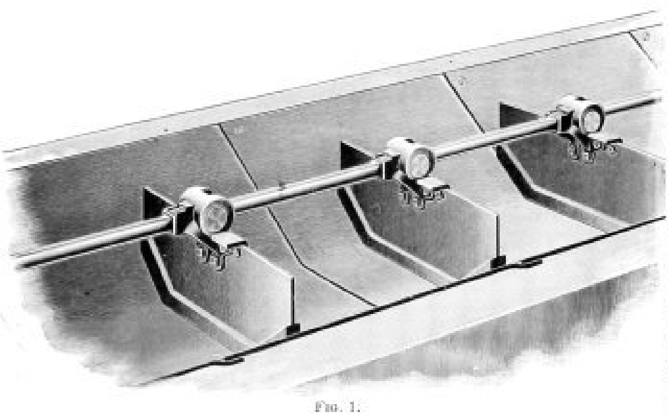


FIG. 1.

bolts, the strength of the chain is that of a high-grade wrought iron bolt of the diameter employed. This, for a one-inch bolt is about 29,000 lbs. No distortion occurring up to the actual breaking point of the bolts, Monobar is stronger for its weight than any other chain in use. Its design permitting and indicating the use of long bolts, the joints are relatively few, and both weight and wear are consequently reduced. It is detachable at every joint and readily and quickly assembled or taken apart. Accurate adjustment to pitch is secured by turning the nut on the end of each bolt, and, as the nuts are locked while in working position, this adjustment is permanent. The wearing surfaces are larger than in any known chain, and are designed for free lubrication while in motion. There is absolutely no wear on the bolts, so that restoration of the chain to its original con-

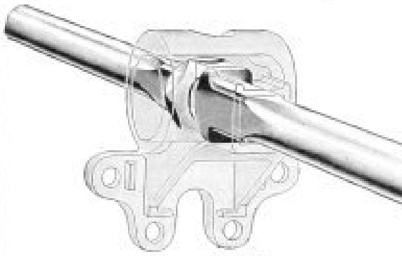

FIG. 2.

dition requires only a renewal of the joints, when, after long service, they have become worn out.

The first cost of manufacture being materially less than that of any standard chain for long distance conveying, the invention presents the double advantage of low first cost and cheap maintenance. The claims made for Monobar are substantiated by the record it has made in actual service. Conveyors in which it is employed as a chain, varying in length from 260 ft. to 600 ft. from end to end, have been in operation for some time past. One of them, 450 feet long, has been operated for the past six months by the Kidder Coal Co. at Wilkes-Barre, Pa., in conveying culm from the bank to the washery. The conveyor has been in steady use ten hours per day, exposed to the weather, and has been run without lubrication or attention. Under date of October 17, the superintendent of the Kidder Coal Co. writes:

"We have used four other styles of chain, and find the Monobar conveyor superior to any of them. It is easy to disconnect, and costs practically nothing for repairs. The equalizing gears largely overcome the lashing or uneven motion caused by the long pitch."

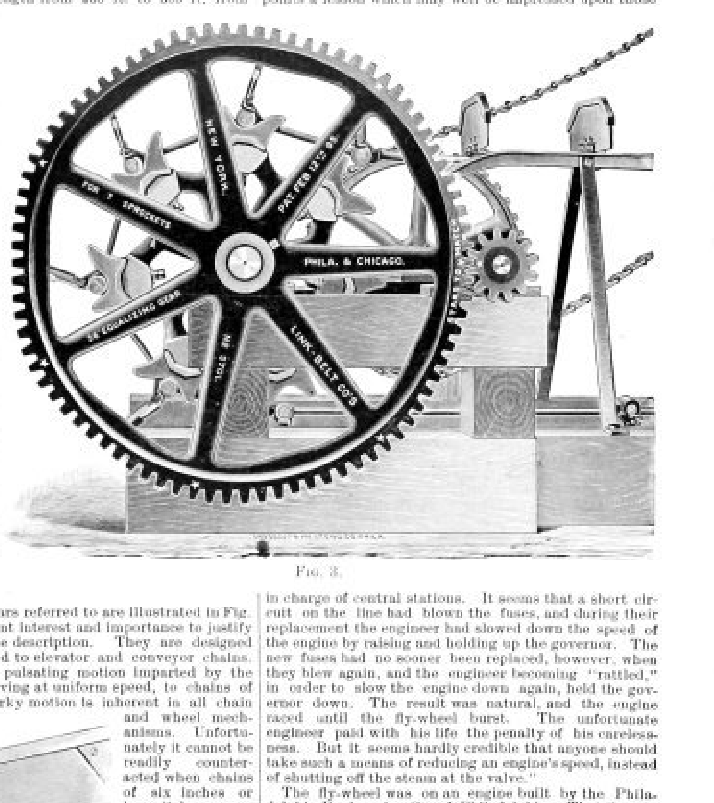

FIG. 3.

The equalizing gears referred to are illustrated in Fig. 3, and are of sufficient interest and importance to justify a somewhat complete description. They are designed to give uniform speed to elevator and conveyor chains. They counteract the pulsating motion imparted by the driving wheels revolving at uniform speed, to chains of long pitch. This jerky motion is inherent in all chain and wheel mechanisms. Unfortunately it cannot be readily counteracted when chains of six inches or less pitch are employed, though equally destructive, if less noticeable, than in case of longer links.

In the illustration a seven-tooth sprocket wheel is shown driving a chain of 18" links. As each link engages the driving sprocket, it is controlled by a radius 20¾" long, measured from the center of the sprocket wheel to the center of the hinge joint of the chain. When the wheel has made one-fourteenth of a revolution (or one-half the movement necessary to bring the next link of the chain into engagement with its sprocket) the controlling radius is reduced to 18⅝" (measured from center of wheel to middle of chain link.) This action is like that of a connecting rod, the horizontal movement varying in speed, though the wheel to which it is attached revolves uniformly. If the sprocket wheel makes ten revolutions per minute, these alternations of the chain speed occur 140 times per minute, and are necessarily fatiguing and destructive to the chain, producing a violent increase of the normal strain at frequent intervals without any useful result.

The equalizing gears are designed to impart pulsating motion to the driving sprocket wheel exactly counteracting the variations in chain speeds above explained, and this is accomplished by making the pitch diameter of the spur wheel conform to a wave line, the number of elevations and depressions in this line corresponding with the number of sprockets of the chain wheel, and driving the spur wheel with an eccentric pinion as shown in the cut, the sprocket wheel and spur wheel being keyed on the head shaft in proper relative positions.

A series of exhaustive tests has developed the facts stated and proved the value of this gearing. By its use less power is required and the destructive strain due to driving with circular gears is eliminated, thus permitting installations of greater lengths or the use of lighter chains.

The above described inventions mark a distinct advance in the application of modern methods to the handling of materials.

Why a Fly-Wheel Burst.

The following editorial in *The Electrical Engineer* of the 9th ult., explains the cause of the bursting of a fly-wheel in a clear and rational manner:

"The bursting of a fly-wheel and partial wreck of the Hudson Electric Light Co.'s station at Hoboken, N. J., points a lesson which may well be impressed upon those in charge of central stations. It seems that a short circuit on the line had blown the fuses, and during their replacement the engineer had slowed down the speed of the engine by raising and holding up the governor. The new fuses had no sooner been replaced, however, when they blew again, and the engineer becoming "rattled," in order to slow the engine down again, held the governor down. The result was natural, and the engine raced until the fly-wheel burst. The unfortunate engineer paid with his life the penalty of his carelessness. But it seems hardly credible that anyone should take such a means of reducing an engine's speed, instead of shutting off the steam at the valve."

The fly-wheel was on an engine built by the Philadelphia Engineering Co. of Philadelphia. That the accident was not due to any fault in the construction of the wheel is evident from the above editorial and the fact that the Hudson Electric Light Co. ordered the Philadelphia Engineering Co. to replace the broken wheel with one exactly like it.

Interesting Books.

"Cableway Sketches" and "Contractors' Methods employed on the Great Chicago Drainage Canal" are the titles of two very interesting illustrated pamphlets issued by the Lidgerwood M'f'g. Co. While primarily published to advertise Lidgerwood engines and cableways, they are of broader scope than mere trade catalogues. The illustrations are attractive and the text is full of valuable pointers to engineers, mine owners and mine officials. They are sent free on request to the Lidgerwood M'f'g. Co., 96 Liberty St., New York.

Large Boiler Sales.

Messrs. H. E. Collins & Co., Pittsburg, Pa., Sole Sales Agents for the Cahall Vertical Water Tube Boiler, manufactured by the Aultman & Taylor Machinery Co., Mansfield, Ohio, advise us of the following sales of Cahall boilers within the past ten days:

Mahoning Valley Iron Co., Youngstown, Ohio, second order 300 H. P.; Sharon Iron Co., Sharon, Ohio, second order 500 H. P.; Phoenix Glass Co., Pittsburg, 75 H. P.; Citizens' Gas Co., Bridgeport, Ct., 330 H. P.; Isaac Harter Milling Co., Fostoria, Ohio; Hainsworth Steel Co., Pittsburg, 500 H. P.

INGENIOUS MINING CONTRIVANCES.

This department is intended for short and plain descriptions of unpatented ingenious contrivances or methods used at mines and found of value. When necessary, articles will be illustrated with cuts, if the writer will send a clear pencil sketch from which our artists can make the necessary drawing.

If the ideas are clearly expressed we will make all needed corrections in composition.

All accepted articles will be paid for at the rate of $5.00 per column, payable in any books in our catalogue, or that of any other publishers.

An Automatic Switch.

By J. J. Ormsbee, E. M.

At the Westmoreland shaft of the Westmoreland Coal Co., near Irwin, Westmoreland county, Penna. some years ago, an accident occurred from a car of slate running into the shaft. The surface arrangements were about as indicated in the diagram, Fig. 1. The loads were run from the shaft to the tip by gravity. The empties and slate cars were carried up grade from *A* to *B* by means of an endless chain, the incline hoist being driven from the head-frame sheave. From the knuckle

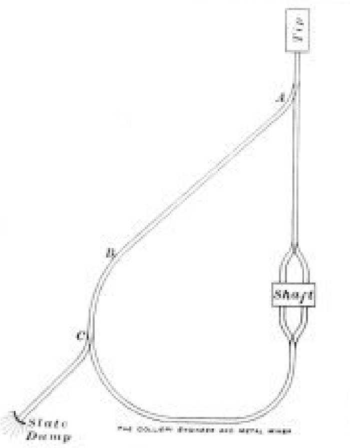

Fig. 1.

at *B* the cars ran by gravity to the shaft, or to the slate-dump *via* the switch at *C*, as the case might be. The accident was due to a wrong setting of this switch; and to guard against any repetition of it, Mr. Robt. Ramsay, then Supt, devised an automatic switch that gave full satisfaction. It has not, to the writer's knowledge, been described in print heretofore, although its simplicity and ingenuity would warrant it.

The sketch, Fig. 2, shows its main features. To the the two bridles near the ends of the switch-rails were fastened small rollers, as shown. The bridles were prolonged and connected to a rocker shaft, to which a counter-weight was attached. The rails leading to the slate-dump were depressed below the level of those leading to the shaft, and the stringers underneath the switch-rails were made with a bevel so as to bring these rails to the right level for the slate track when the switch was thrown for it. Plates of iron were inserted in the paths of the rollers. The counter-weight was so adjusted that

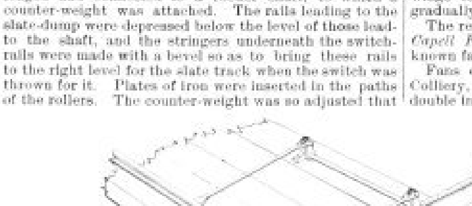

Fig. 2.

when an empty car came along, the switch remained in its normal position as shown in the sketch, allowing the car to go to the shaft. But the weight of a loaded car caused the switch to move down the inclined plane, raising the counter-weight. Immediately after the passage of the car this weight, acting though the rocker shaft, brought the switch to its normal position. So well was it balanced and so nicely did it work that a heavy man in an empty car would throw the switch to the slate-dump.

Compressed Air Locomotives.

We are informed by Messrs. H. K. Porter & Co., of Pittsburgh, Pa., that their compressed air mine locomotives are meeting with such favor that they are now building four for different parts of the country.

Written for The Colliery Engineer and Metal Miner.

THE CAPELL FAN.

An Interesting Account of the Invention and Subsequent Improvement of this Wonderfully Efficient Mine Ventilator.

Great inventions, like great discoveries, are sometimes made in seeking for some other thing. The ventilation of coal mines, was not in the mind of the Rev. G. M. Capell, rector of Passenham, Stoney Stratford, England, when he made a fan after his own fancy. To dry hay, was the work for which he designed it. In his case, necessity was truly the mother of invention. Season after season, the glebe hay crop had been spoiled by the peevish persistence of St. Swithen, the patron Saint of wet weather, a mouthful of sweet hay had become a very scarce article in the rectory hay mow; when Mr. Capell conceived the idea of putting his *green* hay under cover, and drying it by blowing fresh air through, thus removing the risk incidental to exposure in the open fields, in the climate of England.

With the village blacksmith, as executive, and the parson, with his physics and mathematics, as designer, was produced, the germ from which the present fan grew.

In 1893–1894 Mr. Capell succeeded in making great improvements in the power of his fans. He placed the the inner wings at an angle, causing the air to be driven screw-propeller fashion into the fans body; he then formed the ends of these wings in the inlet into a scoop of special form, the portion nearest the center (or at point of slower motion) presenting a larger collecting surface than that near the junction of inner and outer wings to which the inner wings set on an incline and gradually lead up the air.

The result has been to increase the power of the *New Capell Fan* an average of 30% compared with well known fans of the earlier patent.

Fans on this system are now at work at Garswood Colliery, Wigan, England, 17 ft. 6 in. diameter, double inlet, capacity 450,000 cubic feet per minute and 6 in. water gauge. Two at Allerton Main, Yorkshire, 12½ ft. double inlet. One at Hutton Henry Colliery, Wingate, Durham, England, and at about 20 other places in Great Britain, Germany, Belgium and France.

One fan 13½ ft. diameter and 5 ft. wide, at Sanquhar Colliery, Scotland, gave 100,000 cubic feet of air per minute and 1 in. water gauge at 80 revolutions.

The table below shows the performance of two fans each, of new and old construction.

The American fans built under this patent have hitherto beaten the best British and German practice, as was shown in our last issue, when we give the record made by a Capell fan at the Youghiogheny Coal Co.'s No. 1 Mine, at Scott Haven, Pa. This is a single, eight foot fan, it runs at 208 revolutions per minute and exhausts from a mine having about two miles of entries and workings through which the air traverses. It

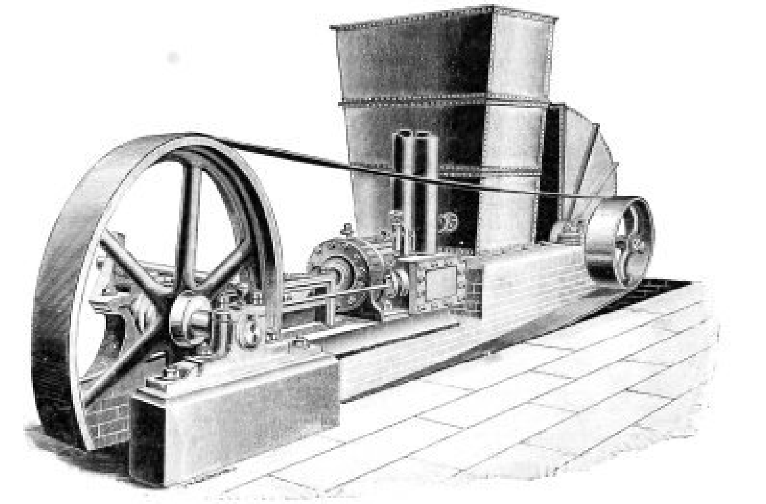
develops a water gauge of 1 inch and passes 85,000 cubic feet of air per minute. It was guaranteed to pass 65,000 cubic feet of air at 325 revolutions, so that it is doing about 30% more work at less than ⅔ speed. So that the guarantee of Mr. Wm. Clifford, the sole licensee and manufacturer was certainly a conservative one.

Mr. James Blick, Inspector of Mines for the Seventh Bituminous District of Pennsylvania, sends us the following results of a test of a Capell fan, at Moon Run Mine in the Pittsburg district:

The fan is 8 feet in diameter and 7 feet wide with two inlets. In drawing air from the mine it was run at a speed of 208 revolutions per minute, developed a water gauge of 1.1 inch and produced a current of 108,000 cubic feet of air per minute. After carefully checking this test, the mine was sealed off, and no air passed to the fan. It was then run at the same speed, (208 revolutions per minute) and developed a water gauge of 2 inches. It will be noticed that when the mine was sealed off and the fan was passing no air the water gauge was doubled. In noting these figures, Mr. Blick says:

"I have tested other types of fans under similar conditions to the above and found the W. G. to be practically the same, when passing air from the mines and

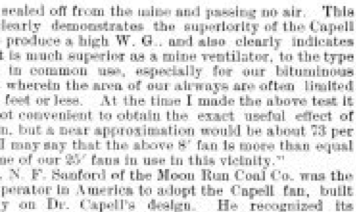


Capell Fan, Driven by Belt from Engine.

when sealed off from the mine and passing no air. This fact clearly demonstrates the superiority of the Capell fan to produce a high W. G., and also clearly indicates that it is much superior as a mine ventilator, to the type of fan in common use, especially for our bituminous mines wherein the area of our airways are often limited to 40 feet or less. At the time I made the above test it was not convenient to obtain the exact useful effect of the fan, but a near approximation would be about 73 per cent. I may say that the above 8' fan is more than equal to some of our 25' fans in use in this vicinity."

Col. N. F. Sanford of the Moon Run Coal Co. was the first operator in America to adopt the Capell fan, built strictly on Dr. Capell's design. He recognized its strong features as soon as he saw the shape of the inside of the fan.

It is claimed that in this fan, the energy of centrifugal force is practically undiminished by impact against non-energizing surfaces, and that its lines allow of the free



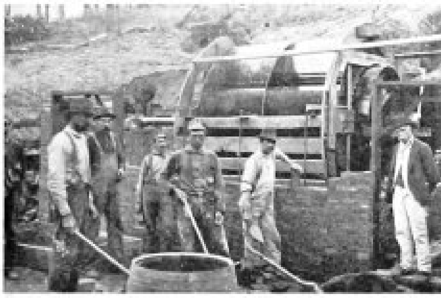
Capell Fan, Showing Latest Improvements.

flow of fluids in accordance with those well-known laws which govern them.

The Capell fan has been the subject of severer criticism than usually falls to the lot of inventions so intimately affecting coal mining. The asperity of British criticism arose in the main from professional prejudice against the manner in which the fan was first described in mining papers, its force being principally directed against such statements put forth in Wm. Capell's name, as that the fan gave 129 per cent. of mechanical efficiency, as the result of numerous and repeated experiments by eminent mechanical engineers.

This controversy was noticed in The Colliery Engineer and Metal Miner at the time, and to many of our readers is ancient history. But it was not until 1888, that the seeming paradox was lucidly and scientifically explained, by Monsieur H. Bochet, Chief Inspector of mines, Paris.

More recently, experiments were made by a Belgian Commission on fans; with the Rateau, Capell and other fans, in which the Capell was given a poor place. In nearly every foreign exchange which reached us, the facts that the commission was a commission of one person, and that he was the engineer to the owners of the Rateau patent was not stated. So that we welcome the advent of the Capell fan in America, where our own experts can see it and test it for themselves.



Capell Fan in Course of Erection at Moon Run, Pa.

This fan is driven by belt or other rope like most other important ventilation installations abroad built during the last 10 years. But we think with the so many durable and quick running engines to choose from here, and the freedom from prejudice on part of our engineers and operators, direct driving will in many cases be adopted.

A Mine Foreman Killed.

Mr. Thos. West, mine foreman at No. 3 Mine, Sherodsville, Ohio, was instantly killed on the first ult., by the explosion of a dynamite blast in the bottom of an air-shaft. He was at work in a hole being driven from the mine to meet the shaft. Through a mistake in instructions the men sinking the shaft fired a shot which broke through and caused the sad accident. Mr. West was born at Cammerton, Somersetshire, England on May 3, 1866. As a boy he attended the public schools. Though compelled to earn his livelihood in the mines at an early age, he was ambitious to secure a technical education. At the age of 19 he took a special course in mining under Mr. Wm. Tate, then editor of *Science and Art of Mining* at Wigan, England, and now assistant editor of The Colliery Engineer and Metal Miner. After completing this course, he successfully passed his examination and received a certificate of competency as a mine manager from one of the British examining boards. Mr. West came to America in the fall of 1892, and soon became foreman of a mine at Dell Roy, Ohio. In February of this year, he resigned that position to accept the foremanship of the mine in which he lost his life. He was a man of most excellent habits, and a close and constant student. Had he not been cut off in his early manhood, his industry and study would eventually have resulted in his attaining a high place in the mining industry. Mr. West is survived by a widow and two small children.

A Large Air-Compressor Plant.

The Ingersoll-Sergeant Drill Co. has just received a large order for a complete plant of air-compressing machinery for running drills, engines, pumps, etc. on the Jerome Park Reservoir work, New York.

The contract for the construction of the reservoir was awarded to Mr. J. B. McDonald at $5,473,060. It involves the removal of upwards of 3,000,000 cubic yards of rock. The contractor has since the letting of the work made a thorough investigation looking to a determination of the question whether or not machinery for excavation can best be run by steam, or from a central compressed air plant. The central plant system has been adopted as the best and cheapest, the saving in expense being largely in labor and fuel.

The plant made by The Ingersoll-Sergeant Drill Co. and adopted by the contractor involves the use of compound condensing Corliss air-compressors run by high class boilers transmitting and distributing compressed air at 80 pounds pressure throughout the work.

It is contemplated to use a battery of several air-compressors placed side by side, the unit adopted being a duplex compressor with steam cylinders 24″ & 44″ in diameter, stroke 48″, driving two piston inlet air cylinders each 24¼″ in diameter by 48″ stroke, the capacity in free air of this machine being between 3,000 and 4,000 cubic feet per minute. This is a duplicate of the compressors at work at the Anaconda Mines in Montana where very economical results have been obtained.

Cahall Boilers.

Messrs. H. E. Collins & Co., Pittsburgh, Penna., sole sales agents for the Cahall vertical water tube boiler, manufactured by the Aultman & Taylor Machinery Co., of Mansfield, Ohio, have opened a branch office in the Havemeyer building, New York City, for the sale of Cahall boilers for that district in charge of Messrs. Wm. R. Sattler & Co. Mr. Wm. R. Sattler is an engineer of national reputation, having been for some time at the Brooklyn Navy Yard and Mr. Geo. C. Tewksbury the other member of the firm, is well and favorably known throughout the New England and Eastern territory as a very successful salesman in the line of engines, boilers and general mill machinery, and Messrs. Collins & Co. are fortunate in having secured their services.

Collins & Co. also advise us that they are now shipping the second lot of boilers on the order for 10,000 H. P. from the Apollo Iron & Steel Co. for their new mill at Vandergrift

WATER-POWER IN MINING SERVICE.

A Solution of the Problem of Regulation.

A problem which confronts every prospective user of water-power—and not a few actual users of it—is the regulation of it to secure constant speed of the machinery driven, under the inevitable changing conditions of load and water pressure.

This problem assumes serious proportions when electrical generators, in turn driving other machinery, are to be operated. For in such cases not only the efficiency of the plant, and the quality of product are to be considered, but sudden changes of speed materially effect the life of the machinery.

Knowledge of these facts and lack of knowledge of means for overcoming the troubles named, in fact, until within a very recent period, lack of such means, has prevented attempts being made to utilize what in many instances, are highly valuable water-powers. But with the recent accomplishments in the transmission of electrical energy over long distances, and in the use of compressed air, the utilization of water-powers at points far removed from the necessary location of the power plant proper, is receiving serious thought in many places, and, here and there, practical application.

It is probable that in no part of the world will better examples of engineering progress in this direction be seen than in the mining districts of the Rocky Mountains in the United States. Here the conditions are in the highest degree favorable to the development and utilization of water-powers, once the solution of the problems of transmission and regulation is demonstrated. High cost of fuel, and often scant supply of water for steam purposes at the exact location where power is needed, on the one hand, and an abundant supply of water under high head for power purposes, one to fifteen miles distant, on the other hand, are conditions which frequently prevail in this region, and which any live mine manager cannot look upon, at least should not look upon, with indifference.

It is perhaps not too much to say to submit that there are to-day mining and milling properties in the Rocky Mountains, barely paying expenses if not doing worse, which by a thorough revamping of power plant along the lines of modern approved engineering practice would become dividend-paying propositions.

The matter of transmission of power, either electrically or by compressed air has now reach a very satisfactory stage. The loss or "drop" can be calculated almost to a nicety and the plant designed accordingly. The advance within the last few years has been rapid but no less certain and successful, until to-day, profitable examples of power transmission up to fifteen miles are not unknown. Some installations of much greater magnitude have been made, with more or less success, and been attended with a great amount of hurrah, but these for the most part do not greatly concern the mining engineer. The cases will be few and far between where if water power can be utilized at all at a profit it cannot be reached within fifteen miles, and it is not unlikely that a ten mile radius will be found to encompass the large majority of plants of this type. Put another way, it may be safely said that if all the mining properties which have water power within ten miles profitably available were now utilizing it, there would to-day be an unprecedented demand for hydraulic, electric, and compressed air equipment.

Within the past two years as great advances in the matter of governing water power have been made as in the transmission of power thus generated, though the success of such efforts has not been so widely heralded. A water power regulator which has met a very favorable reception and which probably has been installed in more plants than any other, is shown in the accompanying illustrations. It is known, from its inventor, as the Replogle governor, and is made by the Replogle Governor Works, Akron, Ohio.

The Replogle water-wheel governor consists essentially of a regulator. (Fig. 1), a high speed engine governor (Fig. 2), and a gravity battery with its circuit (Fig. 3). The electric circuit indicated in Fig. 3 is that used in what is known as the "Compound" governor for service under severe and sudden changes of load, such as electric railway or power equipment.

The speed governor (Fig. 2) is belted to the shaft to be governed, and a rise or fall in the speed causes a corresponding rise or fall in the lever *B*. The lever *B* is a part of the battery circuit and in rising makes or completes the circuit at *C*, energizing magnet 4 (Fig. 1) which causes an engagement of its pawl, and through such pawl turns a shaft (the large shaft shown in the front in Fig. 4) directly connected with the water-wheel gates, and causes such gates to open. An opposite variation in the speed causes the other pawl likewise to act, and closes the gates.

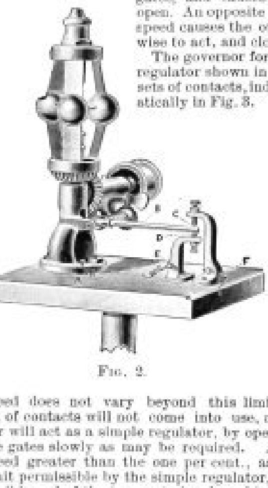


Fig. 2.

The governor for the compound regulator shown in Fig. 4 has two sets of contacts, indicated diagrammatically in Fig. 3. The small lever has a flexible tongue attached to its free end and the extreme end of this tongue has a second set of contacts. The contact points being adjusted so that the outer ones make their circuit at one per cent. variation in speed, if the speed does not vary beyond this limit the second set of contacts will not come into use, and the governor will act as a simple regulator, by opening or closing the gates slowly as may be required. A variation in speed greater than the one per cent., assumed as the limit permissible by the simple regulator, will cause the flexible end of the tongue to bend, making a second contact, and throwing into action a second set of magnets, thus doubling the gate motion. This second set of magnets may be brought into action at any desired variation greater than the first, and may be used as a safety against great changes of load.

The builders of this governor make one hint to users of water power which will apply equally well to any regulator. The gate rigging should be in good order, but it should *not* be exactly balanced; it should have a constant tendency to close at all points of gate opening. The point in this is to prevent back lash of intermediate gearing. If the pressure is always one way there can be no lost motion. Another matter of importance is to have the proper speed for the head of water. It is impossible to govern a wheel that is running too slow, and besides it is wasteful of water. A wheel that runs too fast will waste some water, but it will govern all the better for its excess of speed. This however is a matter for water wheel manufacturers to give information about, and each such will determine the proper speed for any given wheel to attain best results.

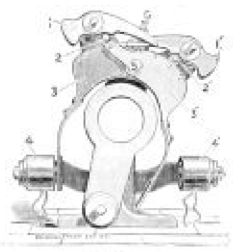

Fig. 1.

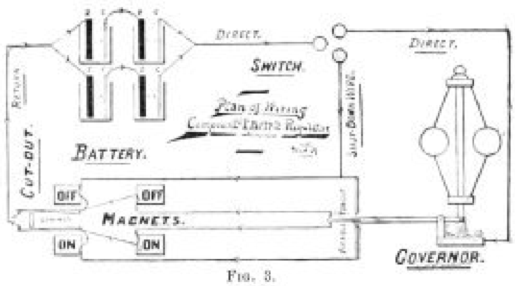

Fig. 3.

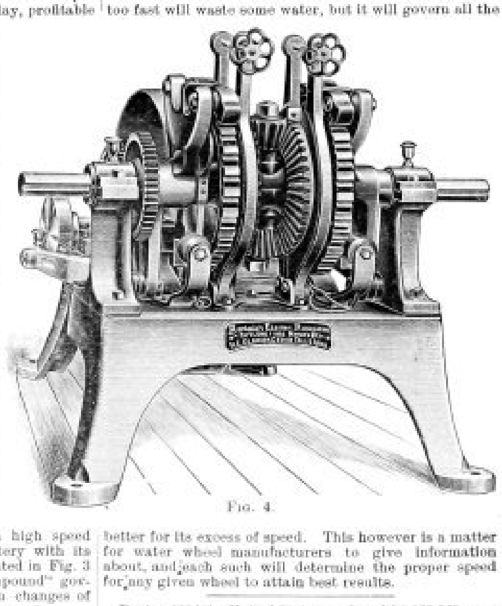

Fig. 4.

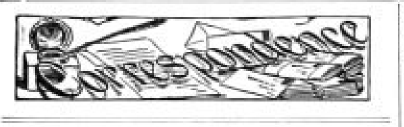
During 1894 the United States produced $6,829,260 more gold than silver, taking silver at its commercial valuation.



This department is intended for the use of those who wish to express their views, or ask, or answer, questions on any subject relating to mining. Correspondents need not hesitate to write for supposed want of ability. If the ideas are expressed, we will cheerfully make any correction in composition that may be required. Communications should not be too lengthy, and personal reflections should be carefully avoided.

All communications should be accompanied with the proper name and address of the writer—not necessarily for publication, but as a guarantee of good faith.

The Editor is not responsible for views expressed in this Department.

☞ *Correspondence should be in as simple language, and as free of technical terms and formulæ as possible, consistent with clear solution.*

Questions on subjects not directly connected with mining will not be published.

Hoisting.

Editor Colliery Engineer and Metal Miner:

SIR:—Please insert the following questions in your valuable paper for some of the readers to answer.

1. There is an engine located at the Merrian Colliery which has double conical drums which are 12 feet on the big end and 10½ feet on the small. The two first motion engines have a five feet stroke and 24 inch cylinders. The slope is 315 feet deep and pitches at 65°, and has a two inch rope. Why is it that the tar does not stay on the drum 18 inches from the big end and it stays on the rest of the drum? It flys off about a foot wide on the floor and does not come off the rest of the drum.

2. I am running an engine which has a drum 12 feet in diameter and has a 2 inch rope. The rope has two gunboats on and one dumps 5 feet higher than the other. How will I take the slack up.

Yours etc.,

Mt. Carmel, Pa. P. S.

Pumping.

Editor Colliery Engineer and Metal Miner:

SIR:—Will some correspondent please give a simple rule for determining the size of steam pump necessary to pump 30,000 gallons of water per day from a mine where the vertical lift is 160 yards. The steam pressure at the boilers on the surface averages 90 lbs. per sq. in. and the pipe which is covered with asbestos covering runs on the surface for 56 yds. then down the shaft 160 yds., and then 8 yds. to the pump? What size steam pipe and what size column pipe should be used? Also will a separator placed in the steam pipe near the pump permit of the use of a cheaper plant than if there is no separator.

Yours etc.,

ASS'T. SUPT.

Oct. 11, 1895. Nelsonville, Ohio.

How to Mine.

Editor Colliery Engineer and Metal Miner:

SIR:—Will you please publish the following question in the next number of the COLLIERY ENGINEER AND METAL MINER for answer: I am mining a 6 foot seam of splint coal which is located 38 feet under another seam 8 feet in thickness, the parting being 2 feet of coal and slate as roof of lower seam, and 36 feet of hard sandstone (Lower Freeport). How will the upper seam be affected if the lower one is mined out on the stall and pillar system and the room pillars drawn?

Yours etc.,

INQUISITIVE,

Oct. 6, 1895. Mammoth, Kanawha Co., W. Va.

Surveying.

Editor Colliery Engineer and Metal Miner:

SIR:—I am working a seam of coal that outcrops on a piece of land which I cannot enter. The horizontal distance of the land line from the high side of the gangway is 110 ft. I have driven a hole up on a pitch of 34° for 53 ft. from the high side of the gangway and at this point the pitch changed to 57°. I have driven on this last pitch a distance of 56 ft. How much farther can I go on the same pitch before I reach the land line.

Yours etc.,

TOM,

Oct. 22, 1895. Minersville, Pa.

Ventilation.

Editor Colliery Engineer and Metal Miner:

SIR:—Will some of your contributors please answer the following question: What is the best method of removing the smoke from a tunnel 7 ft. wide 6 ft. high and 630 ft. long, running into a mountain? The truck or car used in taking out the rock requires a space 4½ ft. wide and 4 ft. high.

Yours etc.,

JOHNSON,

Oct. 12, 1895. Durango, Col.

Ventilation.

Editor Colliery Engineer and Metal Miner:

SIR:—I notice in your July issue that Joseph Virgin, of Holsopple, Pa. gives the following rule to find the total quantity of air in a ventilation question which was asked at a recent Nova Scotia examination.

$$\sqrt[3]{\frac{a^3}{s}} : \sqrt[3]{\frac{a^3}{s}} :: 50{,}000 : x$$

$$\text{or } \sqrt[3]{\frac{30^3}{220{,}000}} : \sqrt[3]{\frac{91^3}{242{,}000}} :: 50{,}000 : 147{,}474$$

cubic feet.

Now the question asked was: Suppose that by a given power 50,000 cubic feet of air per minute pass through an airway, 6 × 5 feet in section, and 10,000 feet long, and that a change is made by dividing the current into three splits of the following dimensions:

First 6 × 6 feet, 4,000 feet long.
Second 5 × 6 feet, 3,000 feet long.
Third 5 × 5 feet, 4,000 feet long.

What quantity of air will pass through each of the splits that are now substituted for the original airway the power remaining the same?

ANS. Now, to clearly analyze the question and prove the answer correct we will first find the actual units of work done, which will be found from the following formulas. The coefficient used is the one recommended by THE COLLIERY ENGINEER AND METAL MINER some time ago.

$$P = \frac{k\,s\,v^2}{a} = \frac{.00000001 \times 10{,}000 \times 22 \times \left(\frac{50{,}000}{30}\right)^2}{30}$$

= 203.70374 lbs. pressure.

$W = P\,Q$ ∴ 50,000 × 203·70374 = 10,185,187 units of work.

For a constant quantity of air with equal lengths of airway, with any change that is made in sectional area and surface, then the pressure per square foot would be in ratio to surface, and to the square of the velocity, and in inverse ratio to sectional area. Now the pressure per square foot $= \frac{s\,v^2}{a}$ and from the following relative figures we get the following relative pressure and power because power increases at the same rate as pressure with constant quantity.

$$\left(\frac{3 \times 30}{91}\right)^2 + \left(\frac{1 \times 91}{30}\right)^2 = 9.30334568.$$

The lengths are as 10 and 11, and they must act in an inverse ratio ∴ $\frac{9.30334568 \times 10}{11} = 8.457587$ and for the three airways the relative pressure and power is as follows:

8.457587 × 3 = 25.372761, and relative quantity = $50{,}000 \times \sqrt[3]{25.372761} = 146924$ cubic feet.

From $P = \frac{k\,s\,v^2}{a}$ we find pressure to be as follows:

$$\frac{.00000001 \times 242{,}000 \times \left(\frac{146{,}924}{91}\right)^2}{91} = 69.32289 \text{ lbs.}$$

pressure.

Units of work = 146924 × 69.32289 = 10,185,196.

Now from the terms of the question, the pressure in the three airways must be the same instead of the power, but the total power must be constant, and having got one relative pressure we must find the other from the following rule $\sqrt{\frac{a}{s}} \times a$.

Then,

$$\sqrt{\frac{36 \times 3}{24 \times 4}} \times 36 = 38.18376 \text{ for first airway.}$$

$$\sqrt{\frac{30}{22}} \times 30 = 35.03245 \text{ '' second ''}$$

$$\sqrt{\frac{25 \times 3}{20 \times 4}} \times 25 = \frac{24.20614}{97.42235} \text{ '' third ''}$$

The pressure being constant for the three airways, it is only neccessary to get the quantity and pressure in one airway, and we will use the second one:

∴ 97.42235 : 35.03245 :: 146924 : 52833 nearly.

$$P = \frac{k\,s\,v^2}{a} = \frac{.00000001 \times 66000 \times \left(\frac{52833}{30}\right)^2}{30} = 68.2324.$$

Having obtained the two relative pressures we get the total quantity as follows:

$$\sqrt{\frac{69.32289}{68.2324}} \times 146.924 = 147702.6 \text{ cubic feet.}$$

And from $\sqrt{\frac{a}{s}} \times a$, we get the quantity in each airway.

97.42235 : 38.18376 :: 147702.6 : 57890.63
97.42235 : 35.03245 :: 147702.6 : 53113.00
97.42235 : 24.20614 :: 147702.6 : 36698.97

147,702.60 cubic feet.

Taking second airway for pressure we have,

$$P = \frac{k\,s\,v^2}{a} = \frac{.00000001 \times 66{,}000 \times \left(\frac{53{,}113}{30}\right)^2}{30} = 68.9575.$$

Units of work = 147702.6 × 68.9575 = 10,185,202.

Joseph Virgin will see from this that his answer is entirely wrong.

Yours etc.,

THOMAS SHAW.

Jenny Lind, Ark., Oct., 1895.

Ventilation.

Editor Colliery Engineer and Metal Miner:

SIR:—I shall be greatly obliged if some of your correspondents will inform me why most fans are run by belts instead of direct connected engines?

Yours etc.,

JOHN K.

Oct. 3, 1895. Edwardsville, Pa.

PRIZE CONTEST.

PRIZES GIVEN FOR THE BEST ANSWERS TO QUESTIONS RELATING TO MINING.

For the best answer to each of the following questions, the value of $1.00 in any of the books in our book catalogue, or six months' subscription to THE COLLIERY ENGINEER AND METAL MINER.

For the second best answer to each question, the value of 50 cents in any of the books in our book catalogue, or three months' subscription to THE COLLIERY ENGINEER AND METAL MINER.

Both prizes for answers to the same question will not be awarded to any one person.

Conditions.

First—Competitors must be subscribers to THE COLLIERY ENGINEER AND METAL MINER.

Second—The name and address in full of the contestant must be signed to each answer, and each answer must be on a separate paper.

Third—Answers must be written in ink on one side of the paper only.

Fourth—"Competition Contest" must be written on the envelope in which the answers are sent to us.

Fifth—One person may compete in all the questions.

Sixth—Our decision as to the merits of the answers shall be final.

Seventh—Answers must be mailed us not later than one month after publication.

Eighth—The publication of the answers and names of persons to whom the prizes are awarded shall be considered sufficient notification. Successful competitors are requested to notify us as soon as possible as to what disposal they wish to make of their prizes.

Competition Questions for November.

QUES. 187. I am still busy with the invention of our proposed new safety lamp, and I still crave for a little of your assistance, which I have no doubt you will cheerfully give by answering the following three questions:

1st. What should be the diameter and length of the gauze cylinder if I use one; or if I use two, as is done in the case of the Marsaut, what would be the best dimensions for each of them, and give reasons why you prefer the sizes you name?

2d. What should be the sizes of the wires and meshes of the gauze, and how many lines should there be to the linear inch?

3d. What is the use of the bonnet or close shield, and should we adopt one in our new lamp?

QUES. 188. We are going to try some experiments by exploding fire-damp in a close, strong vessel, made of steel, and strong enough to resist the greatest pressures to which it may be subjected. The fire-damp is a diffusion in which 10 volumes of air are saturated with one volume of marsh-gas. To the steel vessel we are going to attach a pressure gauge, and I will feel obliged if you will tell me what the pressure will be at the moment of the explosion and after the steel shell and its contents or remaining gases have cooled down to the present or actual temperature of the outside air?

QUES. 189. We have on hand a ventilating fan that can discharge 120,000 cubic feet of air per minute, with a useful effect of 30 H. P. We are going to sink two rectangular shafts, whose lengths have to be twice their breadths and their areas have to be equal. One of them will be an upcast and the other a downcast for the ventilation, and to prevent a needless waste of energy we wish the shafts to be of such an area that only one-third of the ventilating power, or 10 H. P., shall be necessary to overcome the friction of the shafts. Will you, then, calculate for us the area and the length and breadth required for each shaft?

QUES. 190. We have two airways which we will call A and B, and they are both 2,000 yards in length, and the air is blown through each of them with a difference of potential equal to 2 inches of water gauge. A, however, is 10 feet wide and 6 feet high, and B is 15 feet wide and 10 feet high, and as we do not require more air to pass through B than through A, will you find what quantity is passing along A, and what should be the area of a regulator in B to pass the same quantity as that of A; the *vena contracta* being taken at .65, and k at .00000001.

QUES. 191. An important vein of iron-stone is outcropping on a hillside, and I will be obliged if you will calculate for me its height above a point we will call A. To reach the outcrop, the nearest course is to descend from A to B and then ascend to C, and from C ascend the hillside to D. Now D at the point A makes an angle of elevation of 29° 3′. The distance from A to B is 91 feet, and B makes an angle of depression at A of 26° 26′. The distance of C from B is 125 feet, and C at the point B, makes an angle of elevation of 18° 26′. The distance of D from C measured up the side of the hill, is 240 feet. What then is the vertical height of D above the level of A, when the points A, B, C, and D all lie in the the same vertical plane?

QUES. 192. What would occur if the force pumps for feeding a boiler were set at an elevation of 5 feet above the level of the feed water in the heater when the temperature of this water was 212° F.

Answers to Questions which Appeared in September and Previous Issues, and for which Prizes Have Been Awarded.

QUES. 175. There is at present a ready market and a good price for fire-bricks; flooring tiles for fire-proof buildings; common bricks for filling and backing; glazed and unglazed facing bricks; sewer pipes and drain traps.

Our Coal Mining Company wish to share in this manufacture and trade, and have desired me to make sample bricks out of the underlays of five different coal seams we are working. I have done so with the following results. Clay of seam A makes a hard strong red brick coarse in the grain; clay of seam *B* contains iron balls, but the dressed clay makes a soft white brick that is very porous; clay of seam *C* makes a soft white brick that is very porous and speckled with blackish brown spots; clay of seam *D* makes a hard coarse grained brick, and of a black and bluish color; clay of seam *E* makes a white brick that is very strong and fine in the grain. Now I desire to know two things to enable me to make a satisfactory report to the company.

First. What classes of goods are each of the clays best adapted for making?

Second. What are the constituents in the clays that give to the bricks their different characteristics?

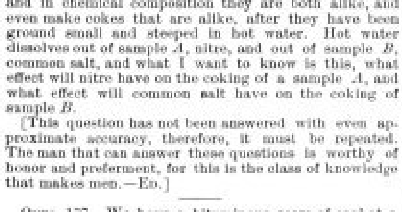
[We are sorry to say this question has not been satisfactorily answered and let us give a hint to those of our w'se competitors, that are thriving for advancement in their profession or intended profession of mining. That such knowledge as is required to answer this question is of the right character to promote its possessor. Numerical questions and answers are of great value but without a substantial knowledge of chemistry, mineralogy, geology and practical mining, mere figure knowledge is of no account.—ED.]

QUES. 176. Here are two samples of bituminous coals, and in chemical composition they are both alike, and even make cokes that are alike, after they have been ground small and steeped in hot water. Hot water dissolves out of sample *A*, nitre, and out of sample *B*, common salt, and what I want to know is this, what effect will nitre have on the coking of a sample *A*, and what effect will common salt have on the coking of sample *B*.

[This question has not been answered with even approximate accuracy, therefore, it must be repeated. The man that can answer these questions is worthy of honor and preferment, for this is the class of knowledge that makes men.—ED.]

QUES. 177. We have a bituminous seam of coal at a depth of 400 feet and lying nearly level, and we are going to work it by the system of longwall retreating. The floor is a soft shale and the roof is a slate. We will be obliged if you will give us a map of the best plan of working, together with all the necessary explanation.

ANS. I would work the coal on the principle of the accompanying plan and make the heading pillars from



150 to 200 feet and would advance the face with brattice cloth partitions to direct the intake and return air currents.

After the east and west headings have reached the boundary line and are connected with a face road I would arrange the ventilation to properly air the haulage roads and the working face.

JOSEPH VIRGIN,

Second Prize, WILLIAM HODGE, Holsopple, Pa.
Forbush, Appanoose Co., Iowa.

QUES. 178. We find the roof of a coal seam we are working is an argillaceous lime stone, and what our neighbors call the same seam in the surrounding collieries has in some cases a slate roof, in others a sandstone roof and in others an arenaceous limestone roof. Do you think it is the same seam of coal in all the cases, and if it is, under which kind of roof will the coal be thickest?

ANS. It is more than likely that the same seam has the different covers mentioned in the question, for such differences of the roof strata occur in this state, that is, Pennsylvania, and by observation I have found the thicknesses of the seams under the different covers to vary as follows:

Thickest under calcareous shale.
Thick under argillaceous shale.
Much reduced under calcareous sandstone.
Thin under sandstone roofs.

JOSEPH VIRGIN,

Second Prize, JOHN VERNER, Holsopple, Pa.
Lucas, Iowa.

QUES. 179. I am now a fire-boss, but I am promised promotion if I can learn to level, will you therefore, show me with a sketch and an explanation how to level upgrade for 25 yards? Make the surface very uneven, and after setting up the instrument read the staff every five yards.

ANS.—

Sta.	B. S.	F. S.	H. of Inst.	Elevation.	Remarks.
B. M.	6.449		1416.500	1410.051	Nail in pine stump.
1		11.300		1405.200	
2		2.400		1414.100	
T. P.		1.976		1414.524	Top of stake 2.
	10.523		1425.047		
3		3.747		1421.300	Summit.
4		9.147		1415.900	Basin.
T. P.		0.776		1424.271	
	11.241		1435.512		
5		9.300		1426.212	
6		0.009		1435.503	

In taking levels the elevations may be "independent," that is, on any assumed height as 100, 1000, etc.; or they may be referred to some fixed point, the elevation of which, above tide water has been previously determined.

In the present case we will suppose that a fixed point or "Bench Mark" is located between the two first stations of our line and its elevation is 1410.051 ft. above tide level. The line is divided into stations of 5 yards each which for convenience are called 1, 2, 3, 4, 5 and 6. The staff or rod used is a 12-ft. sliding rod reading to the thousandth part of a foot.

First, place the instrument in any convenient location being careful not to have it more than 12 ft. above the surface at station 1. It need not be necessarily on the line. Then with the rod on the B. M., take the reading 6.449 and write it in the column marked "Back Sight." This reading added to the elevation of the B. M. gives the first "Height of Instrument." Move the rod to station 1 and read 11.300 which is the first "Front Sight."

Subtracting front sight readings from height of instrument gives the elevations of the points corresponding to to the readings. With the rod at station 2, the reading on surface is 2.400, a front sight.

It is plain to be seen that the instrument must be placed higher in order to see station 3, but before moving it, take a reading on some solid, well-defined point, as for instance, the top of a stake, and call it a "Turning Point." Now move the instrument up the hill, taking care to be less than 12 ft. above the turning point, and set it near the small summit noted at station 3.

Then sighting to a rod on the T. P. read 10.523, a back sight, and take the readings at stations 3 and 4 which are lower than the instrument. Establishing a new T. P. on a stone near station 5 move the instrument once more and set it in a position to take the T. P. and Sta. 6.

To check the calculations find the difference between the sum of the back sight readings and the sum of the front sight turning point readings. The difference thus obtained represents the elevation lost or gained in the operation.

Second Prize, E. H. BAILEY, E. M. PORTER,
Rock, W. Va. Eckley, Pa.

QUES. 180. The action of one of our mine pumps is very peculiar, and it will startle you when I tell you, that any increase above a certain speed of the piston reduces the lifting power of the pump, and at another increase of speed the pump loses the water altogether. Now as I would like you to explain the tricks of this peculiar pump, I will give some particulars. When the pump piston is at the bottom of its stroke, it is 12 feet above the level of the supply water, and as the force to lift the keep valve and overcome the friction of the water moving through the tail of the pump is equal to a two-feet column of water, we may reason the mean lift to be 14 feet. Will you then tell me two things?

First. What is the highest speed at which this pump can be run to obtain a maximum effect?

Second. At what piston speed does the pump lose the water altogether.

[This question has not been correctly answered and must, therefore, remain open.]—ED.

QUES. 170. A wealthy land owner has just granted me a lease to mine a lignite bed 10 feet thick and making an angle 70° with the plane of the horizon. The lease confers on me the right of way and the power to utilize any of the surface or underlying strata. The surface is on a bed of sand 20 feet thick and at first sight that would appear to be an unfavorable condition, but the lignite coal is good, and can secure an open market at a high price; we have however certain difficulties that must be overcome in the mode of working; for example, this coal is exceedingly subject to spontaneous ignition, and any small in the gob, or pillars left in, takes fire as soon as subjected to increased pressure. Therefore we must extract the *whole* of the coal, and I wish you to instruct me how to do it with the use of very little timber, at a small cost per ton, and with safety to the miners. To secure a good plan, think over all the modes of *vein* and *bed* mining in general use.

ANS. This lignite bed will require special treatment and I would work it on the filling system, using the surface sand for the filling material, and this could be sent into the mine by a pipe line, a six-inch pipe would run sufficient filling with a good supply of water, if the bottom gangway along the strike, is situated above the drainage level. The sand could be supplied to the pipe line with a steam shovel and conveyor, and the gob would be filled as the coal was removed, and as none of the coal face would be long exposed, the spontaneous ignition of the lignite would thus be prevented.

JOSEPH JAMES, 1014 North Street, Tacoma, Wash.

Immense New Turbine Plant.

Four new turbines for Niagara: The Niagara Falls Hydraulic Power and Mfg. Co., have recently contracted with James Leffel & Co., of Springfield, Ohio, for four of their improved double discharge horizontal shaft water wheels, to be of eight thousand (8,000) horse-power capacity, under a maximum head pressure of 218 feet, which is far the highest head, under which turbines of large capacity, have ever been applied in this country or elsewhere. These wheels will drive eight electrical generators, which will be connected direct to the horizontal turbine shafts without gears or belting; the wheels and generators all running in vertical planes. This is the second large order for turbines built by James Leffel & Co. for Niagara Falls; there being already several of this make of wheel, each of 1,200 horse-power, in daily operation in the Cliff Paper Co. Mills, located at the cliffs, near the tunnel. This water-wheel company is also building four of their Cascade wheels for one company, to be operated under seven hundred and thirty feet head, part of the power to be electrically transmitted, by connecting the wheel shaft directly to the generators. The Cascade wheel is, however, essentially and entirely different in construction and operation from the turbine, being in principle an impulse and reaction wheel. This Cascade wheel plant will have an aggregate capacity of six hundred (600) horse-power.

LEGAL DECISIONS ON MINING QUESTIONS.

Reported for THE COLLIERY ENGINEER AND METAL MINER.

An Agreement Creating Landlord and Tenant.—An agreement whereby a party had the exclusive right to mine coal under certain land for 20 years, unless the coal sooner gave out, and to use in connection with the mine five acres of the surface land to erect buildings upon, and to build and operate railroads and flow water over such land, for a certain royalty per ton of coal mined, not to fall below a fixed amount per year, payable as rent for all the privileges granted. Such agreements confer present rights; they are assignable; they are for a fixed period; they provide for an annual rental independent of the mining of coal; the right to mine the coal is exclusive in the lessees for the period fixed in the lease; the rent or royalty is by express terms payable for all use of the surface of the land, as well as for other privileges specified, and for coal mined. In principle, the rights granted are not different from those where one leases a stone quarry or sand bed or the like. The fact that in the one case the article taken is on or near the surface and in the other it is beneath the surface is no reason why in the one case privileges granted to take and carry away stone or sand should be held to be leases, and in the other the right to mine and carry away the coal and the valuable surface rights granted should be held to constitute a sale of the coal merely. In either case the sum stipulated to be paid, whether it be called "rent" or "royalty," is a profit issuing out of the use granted, even more so than it would be to use the land for agricultural purposes. In the latter case no perceptible quantity of the soil is taken, though the product is produced at the expense of utilizing the strength of the soil. In the former case a portion of the granted property is itself taken. This is in accord with the character of the grant, the use of the thing granted. The sum agreed to be paid is for the use of the land, upon and under the surface; and such use involves the taking away of the coal. This construction of such contracts is in harmony with their provisions, and in accord with usage touching such property; nor is it in contravention of the provision of the statute, but creates the relation of landlord and tenant within the statute, giving a landlord's lien for "rent."

Lacey v. Newcomb (Supreme Court of Iowa.) 63 N. W. Rep. 704.

Placer Patents.—The fact that a placer claim for which a patent has been issued included at the time of its location part of a lode claim, which had not then been forfeited, is a matter which cannot be considered in a collateral attack upon the placer patent; by one who has made a subsequent vein location upon part of the same land after the issuance of the placer patent.

The presumptions are all in favor of a placer patent as against a lode claim located subsequent to its issuance upon part of the same ground; and where the patentee files an adverse claim against the application for patent to the lode, and brings an action in support of such claim, the burden is upon the lode claimants to overcome these presumptions and to show by clear and convincing proofs that the vein on which the lode claim was located was a known vein at the time of the application for the placer patent.

In order that a vein or lode, included within the limits of a placer patent shall be excluded from the operation of the placer patent, under the U. S. Statutes, so as to be subject to subsequent location, such vein must have been known, at the date of the application for the placer patent to exist and to contain minerals in such quantity, and of such value and quality, as to justify, under the circumstances then existing, expenditures for the purpose of extracting them.

Montana Cent. Ry. Co. v. Mogeon (U. S. Cir. Ct.) 68 Fed. Rep. 811.

Notice of Location of Mining Claim.—Under the statute, requiring one who discovers a mining claim to file a declaratory statement of such discovery or location, on oath, describing said claim in the manner provided by the laws of the United States, the statement must be of the discovery or location, as well as of the description of the claim, and an affidavit which merely states that "the description of said lode" is true is fatally defective. The statement, in a verification of a location notice, that the locators have "fully complied with the requirements" of law, and local customs regulating mining locations, is merely a conclusion of law and does not verify any fact.

McCowan v. McLay (Supreme Court of Montana.) 40 Pac. Rep. 602.

Mining Claim.—The Supreme Court of California says: Independent of the acts of Congress providing a mode for the acquisition of title to the mineral lands of the United States, the term "mining claim" has always been applied to a portion of such lands to which the right of exclusive possession and enjoyment, by a private person or persons, has been asserted by actual occupation, or by compliance with local mining laws, or rules, or customs. The words "mining claim" as used in the law have no reference to the different stages in the acquisition of the government title. In our opinion it includes all mines, whether the title is inchoate, as in the case of a mining claim in its strict sense or perfect as in the case of a fee simple title.

Morse v. DeArdo, 40 Pacific Reporter, 1018.

Competency of Servants.—The employment as trapper in a coal mine of a boy 14½ years old, shown to be competent and careful, and who has had several years experience in various kinds of work in coal mines, is not negligence, so as to render his employer liable to a fellow servant for his carelessness.

Kansas & T. Coal Co. v. Brownlee (Supreme Court of Arkansas.) 31 S. W. Rep. 453.

The Colliery Engineer

AND

METAL MINER.

ESTABLISHED 1881, INCORPORATED 1890.

PUBLISHED MONTHLY AT SCRANTON, PA.

WITH WHICH IS COMBINED THE MINING HERALD.

Entered at the Post-Office at Scranton, Pa., as second-class matter.

THOS. J. FOSTER,
RUFUS J. FOSTER, MINING ENGINEERS, } EDITORS.

THE COLLIERY ENGINEER COMPANY, PUBLISHERS.

TERMS.

Subscription, (*Postage in the U.S., Canada, or Mexico, prepaid.*) **$2.00 a Year**

TO FOREIGN COUNTRIES IN THE UNIVERSAL POSTAL UNION $2.50.

Remit by P. O. Order, Express Money Order, Bank Check or Draft or Registered Letter.

P. O. Orders.—You can buy a Money Order at your Post-Office, payable at the Scranton Post-Office.

Express Money Orders can be obtained at any office of the American Express Company, the United States Express Company, and the Wells, Fargo & Co.'s Express Company.

Registered Letters.—If a Money-Order Post-Office or an Express Office is not within your reach, your Postmaster will register the letter you wish to send us on payment of eight cents.

We Cannot Be Responsible for money sent in letters in any other way than by one of the four ways mentioned above.

EXPIRATION OF SUBSCRIPTION.

The date after your name on the wrapper of THE COLLIERY ENGINEER AND METAL MINER shows to what time your subscription has been paid.

RENEWALS, ETC.

If you do not want THE COLLIERY ENGINEER AND METAL MINER continued for another year after your subscription has run out, you should notify us by postal card to discontinue it. The courts have decided that subscribers to newspapers who do not order their paper discontinued at the expiration of the time for which it has been paid, are held liable for the payment of their subscriptions up to the date when they order the paper discontinued.

NOTICE OF DISCONTINUANCE.

THE COLLIERY ENGINEER AND METAL MINER is sent to subscribers until an explicit order for its discontinuance is received by us, and all payment of arrearages is made, as required by law. *Papers returned are no notice of discontinuance, as we cannot tell where they are from.*

CHANGE OF ADDRESS.

A Subscriber wishing to have his address changed should be careful to give his *former* as well as his present address; otherwise we cannot find his name on our mailing list.

All communications should be addressed,

WHAT ARE OTHER MINE OFFICIALS DOING?

"WHAT are other mine officials doing?" is a question that should frequently arise in the minds of mine managers and their subordinate officials. It should be of such force as to lead them to visit other mines and find out. No one mine official in the world will be an unqualified success if he depends on his own knowledge and ingenuity only. Literature descriptive of general methods is all right in its way and is of great value in leading a mine official into lines of thought that will result in greater economies at his mine and safer plans of working, but such literature is, as a rule, too general. What makes a great improvement a success is the degree of perfection with which its details are worked out. These details can best be studied and comprehended by a personal inspection of the method of work in question. The writer during the past month visited a large colliery where, in the course of a few years, a broad minded manager increased the production nearly fifty per cent., and reduced the cost of mining and preparing coal in about the same proportion. When asked how he did it, he replied "by taking advantage of every economical device and method I had ever seen and in some instances improving on them." This manager was a man who had in his long experience visited many different collieries and gauged the methods employed at each with a practical eye. He is a reader of first-class technical literature, and this, with a faculty of discernment coupled with his practical knowledge, has made him a valuable official, and the great corporation for which he works recognizes his value in a substantial manner. No one official or set of officials can expect to produce the best results if they depend solely on their own intelligence. An occasional visit to neighboring districts or even neighboring mines will result in every instance, in gain, if the visitor is broad minded and enterprising enough to recognize the fact that other officials sometimes know points that he is unfamiliar with.

The experience of a prominent mining company in Western Pennsylvania has proved that a policy of sending an intelligent official on a two weeks' tour of inspection of the mines of other operators has proven of great value. A casual visitor to the mines of this company will instantly notice the many economical devices and methods in use. These are not the development of ideas of the officials of the company. As a rule they are adoptions of methods and devices in use at many different mines.

The writer once met the general superintendent of the company in question at a mine over a hundred miles from his own locality. The object of his visit was to look at a system of haulage in a use. After an inspection he stated that the only idea that he would use was the design of the detaching hook. His own system of haulage was equally as good, and in some respects better than that at the mine he visited, but the detaching hook, designed at the mine was just what he needed to increase the efficiency of his own plants. The time and money spent in this visit was repaid to his company many times over in the next few months. This simple incident is merely given as an illustration. Every intelligent mine official sent on an occasional similar tour will gather several such "illustrations" which when adopted will frequently embellish the balance sheet of his employer with good sized figures on the profit side.

EDUCATION A NECESSARY QUALIFICATION IN A MINE OFFICIAL.

IN a recent address, a very prominent English mining authority, whose name is familiar in every part of the world where mining is a prominent industry said: "Education conjoined with natural ability will now and hereafter be the guiding star of mining enterprise. As a proof that technical education is the key that unlocks the mineral treasures of the earth we have have only to notice the skill required in the designing and application of mechanisms that make the manual labor easier and produce better results. The application of natural forces in hydraulic mining, and the combinations of natural and mechanical forces for dressing the ores and for the separation of the metals from the baser elements all show the results of technical education coupled with practical experience. Again, ores that seem utterly worthless to the unlearned become of great value in the hands of the educated miner. The latest developments in the preparation and coking of coal, as well as the most improved methods of mining and bringing the coal to the surface, are not the outcome of practical experience only. They are the outcome of the application of technical knowledge applied by practical men.

"There is is no reason why a thoroughly practical knowledge of mining should not be accompanied by considerable scientific attainments, and the mining engineer will find it advantageous to have some acquaintance with nearly all the exact and physical sciences.

"It is true that no amount of purely scientific or theoretical knowledge will fit a man to manage even a small mine in the absence of practical experience, but the capability of the practical man is greatly increased by scientific knowledge, and the developments in mining which may occur in the the future, are likely to be in a direction where such knowledge will be more necessary than ever.

"Technical education consists of not only a knowledge of the natural and mechanical forces, but it consists of a knowledge of how to apply them. This knowledge becomes a broad knowledge only when the student keeps posted on the manner or methods employed in applying these forces by other successful men. If he depends on his own apitude only he will work in a comparatively narrow groove.

"I would therefore urge all young men studying mining to endeavor to obtain scientific knowledge as well as practical training. Apart from the material advantage to be derived from scientific knowledge, it trains the intellect, and often develops a taste for some special branch, the study of which, instead of being a task, becomes a source of absorbing interest and unalloyed pleasure."

ACCIDENTS FROM FALLS OF ROOF AND SIDES.

MR. W. N. ATKINSON, in his presidential address to the members of the North of England Institute of Mining Engineers, showed that in Great Britain, as well as in this country, the most frequent cause of accidents in mines was "falls of roof and sides." While it is true that many accidents of this character arise from neglect, and a total disregard of the promptings of the instinct of self preservation, yet it must be admitted that many of our best and most industrious miners are liable to injury or death from this cause. Their anxiety to secure a "good day" inclines them to run risks that place them in jeopardy.

The following table, covering a period of forty-two years in British mines, is of great value in supplying a contrast for gauging the progress being made in reducing the number of accidents due to this cause.

Class of Accidents.	Total No. of Accidents 1851 to 1894.	No. of Deaths from this Cause 1851 to 1894.	Percentage Proportion of Deaths.
Explosions of fire-damp and coal dust,........	2,126	9,706	21
Fall of roof and sides, .	18,226	18,814	40⅛
Shafts,....................	5,565	6,263	13⅛
Miscellaneous, underground,...............	7,199	8,160	17⅛
Surface,....................	3,302	3,484	7½
Totals,...............	36,418	46,427	100

Mr. Atkinson say's, "Falls of roof and sides in mines have always been, and probably always will be, accountable for more accidents and deaths than any other cause. It is a danger common to all mines, and one to which every person engaged underground is to some extent continually exposed."

Any proposal, therefore, that embodies a good scheme for reducing the percentage of this class of accidents cannot but be hailed with unqualified pleasure, and as the president of the Institute noticed a probable plan of accomplishing this very desirable end, we give it here:

"On the other hand, there appears to be a growing feeling that by the adoption of what is called systematic timbering, greater safety would be secured, and my own experience leads me to conclude, that, conjointly with efficient supervision, this is the most likely direction in which to look for further improvement."

BORE-HOLE EXPERIENCES.

IT may almost be said, that we know more about the surface of the sun than we know of the interior of the earth, but with increased knowledge of the physical and exact sciences, and especially with the aid of the new revelations, that the core system of boring is continuously bringing to our notice, we will soon be able to sound the depths of the nether regions. These remarks are prompted by the facts given in *Kuhlow's German Trade Review*, concerning a boring in Germany. It appears a deep boring is in the course of being made at Sondra in Germany with a 7 inch bore tube, and after reaching a depth of 354 feet, by some strong, and unusually active interference, the tubes were disjointed and jammed, and therefore operations had to be for some time suspended until they were recovered. It is further shown that the tubes alone cost $2500 so that the cost of 354 feet of hole, and the cost of the tubes, were jointly an investment that was worthy of recovery, and therefore great efforts were made with strong grapples, to disengage the upper lengths, and so reach the bore end containing the core, and in this they were successful in the face of unparalled difficulties, even greater than those experienced in oil-holes. This brings us to the point that is of interest in this article. At a depth of 354 feet the bore cut into a cleft or open gash in the strata, that was so small, indeed, that it made a gash in the six-inch core, but did not cut it in two, and out of this small cleft a mighty blower of carbonic acid gas rushed into the bore-hole, with a pressure of from 39 to 42 atmospheres, or 588 pounds pressure on the square inch, and the terribly intense cold due to the expansion of this gas and the deluge of water thrown with it, along with a shower of small stones like pebbles, all conspired as allies to defeat the task of the drillers, who were doing their best to extract the broken tubes. This task required heroism to combat with the intensely cold "mineral" water, (or perhaps, as the depth of cold would suggest, the *salt water*), the cannonade of pebbles and the suffocating gas. It appears that the vertical column of water, gas and stones reached an elevation of 46 feet. The query confronting us, however, is this: What was the source of this gas? and as we have no particulars given in the account before us of the topography of the region, we must remain in speculative uncertainty, but let us notice that in all occurences of this character we should know the cause or causes, or be careful to furnish such details or descriptions as might lead us by inference to forecast such a large outburst of gas in future cases, and in knowing the cause to work out a remedy.

ELECTRIC MINE LOCOMOTIVES.

THE General Electric Co. recently supplied the Enterprise Coal Co. with one of their excellent electric mine locomotives for use in the Enterprise colliery near Shamokin, Pa. While this locomotive is the first of its kind in the neighborhood of Shamokin, it is not the first electric mine locomotive used for underground haulage in an anthracite mine with the coal seams on considerable inclination, as is stated in the daily newspapers.

The first electric mine locomotive in practical use in America was put to work in the Lykens colliery of the Lykens Valley Coal Co., near Lykens, Pa., in the summer of 1887. This locomotive was, and is still in use in a water level opening, and the seam of coal cut by this opening has as heavy, if not a heavier pitch than that at Enterprise. This locomotive was illustrated in THE COLLIERY ENGINEER AND METAL MINER for September, 1887. It was designed and built from plans by Mr. Schlesinger, of the Union Electric Co. of Philadelphia, a company that has been out of existence for several years. Besides this original locomotive, a second one built on the lines of the first, and constructed at the colliery has been in operation for several years past, and in a gangway driven in an inclined seam. The credit of being the first mine manager in America to adopt electric mine haulage belongs to Mr. T. M. Williams of Lykens.

There is no reason why the introduction of an electric locomotive in a mine working inclined seams should be remarkable, as such mines, as a rule present even simpler haulage propositions than mines working flat seams. The question of electric haulage in flat seams has long ago been settled in a manner highly favorable to the electric locomotive.

AN IMPORTANT OPINION.

AN opinion that is of great importance to the coal mining industry, is that recently formulated by Deputy Attorney General Elkin of Pennsylvania for State Mine Inspector William Stein of Shenandoah, Pa. This opinion is to the effect that the word miner as used in the phrase "practical experience as a miner," in the anthracite mine act of 1881, includes laborers, loaders roadmen, repairmen and others who work in the mines, but who do not actually mine coal. This opinion will doubtless increase the number of applicants for examination for mine and assistant mine foremen.

EXPLOSION OF GAS.

An Explosion of Gas at Dorrance Colliery, Wilkes-Barre, Pa., Results in the Death of Seven Men, Including an Entire Corps of Surveyors.

An explosion of gas at the Lehigh Valley Coal Company's Dorrance colliery at Wilkes-Barre, Pa., on the 7th ult., resulted in the instant death of three young mining engineers and a fire-boss, and injuries to two others of the engineer corps and a miner, which subsequently caused death.

The mining engineer corps, under the direction of William Jones and consisting of William Cahill, Llewellyn Owen, Robert Blanchard and Robert Miller, entered the mine early in the day to make the regular periodical survey. They were accompanied by Daniel J. Davis, one of the fire-bosses of the colliery, whose duty it was to enter the various openings ahead of the corps and examine them for gas, so as to avoid unnecessary danger.

The corps had about completed its work for the day, and the young men comprising it, with fire-boss Davis, were on their way to the foot of the shaft. Mr. Jones, on examining his blue print of the workings, which he had along for reference, discovered that he had forgotten a little work. Leaving Miller and Blanchard where they were to take care of the instruments, Jones took Cahill, Owens and fire-boss Davis with him to finish the work. About ten minutes after leaving Blanchard and Miller, the party went into some old working, encountered a large body of gas, which was ignited, with the fatal results already noted.

How the accumulation of gas occurred is not definitely known. The mine has always been known as a gaseous one, and every effort was made to keep it free from dangerous accumulations of gas. The opinion of General Superintendent Moister, as expressed at the coroner's inquest, was that the gas accumulated in the old chamber while the fan was stopped for about three hours, the previous day, to enable some repairs to be made on it.

District Superintendent Jones, in his testimony, did not hold to this view, but thought the accumulation of gas might have been due to a local fall of roof blowing out some air stoppings and thus causing the ventilating current to take a short route past the workings in which the gas accumulated. Foreman Thos. Samuels testified as to the method of circulating the air through the mine. He had no theory to express as to what caused the accumulation of gas. He did not know of any stoppings having been blown out by a fall, and was unable to state whether the stoppage of the fan the day previous caused it or not.

Fire-boss John Bloomberg testified to having examined the chamber in which the explosion occurred, the morning previous, before the fan was stopped, and said he found no gas.

The testimony of several miners working in that district of the mine was to the effect that the ventilation was all right, and the usual quantity of air was passing the several points at which they were working.

The evidence also deduced the fact that Inside Foreman Samuel had directed Fire-boss Davis to go ahead of of the engineers and see that every place was safe before they entered.

When Davis's body was found his safety lamp was hanging at his belt, and an ordinary miners' lamp was on his hat. This was presumptive evidence that he fired the gas by using a naked lamp, and the Corner's jury brought in a verdict that the accident was caused by his carelessness. This accident is, therefore, another instance of carelessness causing the death of not only the man responsible for it, but the loss of six other valuable lives.

Morris, the miner among the killed, was 40 years of age. Davis, the fire-boss was 35 years of age, and was well-known in Welsh musical circles, as he was possessed of a fine baritone voice. He was a man of most excellent character and reputation as an official. He undoubtedly thought the workings free of gas, and he paid the penalty for the assumption with his life.

The men comprising the engineer corps were all promising young men of superior intelligence, and excellent character. Jones, the head of the corps, was the only son of aged parents, of whom he was the only support. Owen was the son of W. D. Owen, Division Superintendent of the Lehigh Valley Coal Co's, Pittston and Smithville collieries. Cahill was the son of William J. Cahill, chief mason for the Lehigh Valley Co. Blanchard and Miller whose injuries resulted in death some days after the accident were both promising young men.

MINE INSPECTION IN ILLINOIS.

The Recently Appointed Inspectors, Their Districts and Governor Altgeld's Instruction to Them.

Through the courtesy of Hon. Geo. A. Schilling, Secretary of the Bureau of Labor Statistics of the State of Illinois, we are enabled to publish the following information regarding the future State mine inspection in Illinois.

On the 21st inst. Governor Altgeld re-appointed James Keating, of Peoria; John Keay, of Springfield and Thos. S. Cummings of Gardner, as mine inspectors. He also appointed Charles Duncan, of Streator; Robert Picket, of Spring Valley; Henry Malloy, of Decatur, and James Bennett, of Hallidaysburgh, as new inspectors. Previous to this time the State was divided into five inspection districts. The last legislature increased the number of districts to seven, the two new districts being formed from portions of old ones.

The new districts, with the inspector assigned to each are as follows:

First District.—James Keating, Inspector; consisting of the following counties: Boone, McHenry, Lake, De Kalb, Kane, DuPage, Cook, LaSalle, Kendall, Grundy, Will, Livingston and Kankakee.

Second District.—Charles Duncan, Inspector; Jo-Daviess, Stephenson, Winnebago, Carroll, Whiteside, Ogle, Lee, Rock Island, Henry, Bureau, Mercer, Stark, Putnam, Marshall, Peoria and Woodford.

Third District.—Robert Pickett, Inspector; Henderson, Warren, Knox, Hancock, McDonough, Schuyler, Fulton, Adams and Brown.

Fourth District.—Henry Malloy, Inspector; Tazewell, McLean, Ford, Iroquois, Vermillion, Champaign, Piatt, DeWitt, Macon, Logan, Menard, Mason, and Cass.

Fifth District.—John Keay, Inspector; Pike, Scott, Morgan, Sangamon, Christian, Shelby, Moultrie, Douglass, Coles, Cumberland, Clark, Edgar, Montgomery, Macoupin, Greene, Jersey, and Calhoun.

Sixth District.—Thomas S. Cummings, Inspector; Monroe, St. Clair, Madison, Bond, Clinton, Fayette, Marion, Effingham, Clay, Jasper, Richland, Crawford, and Lawrence.

Seventh District.—James Bennett, Inspector; Washington, Jefferson, Wayne, Edwards, Wabash, White, Hamilton, Franklin, Perry, Randolph, Jackson, Williamson, Saline, Gallatin, Hardin, Pope, Johnson, Massac, Union, Alexander and Pulaski.

The old Inspectors failing of re-appointment were Hugh J. Hughes, of Litchfield; and Edward Fellows, of Galva. The inspectors are appointed for two years at a salary of $1,800 per annum.

On Wednesday, October 23, 1895, the seven inspectors appeared at the Executive Chamber by appointment, and Governor Altgeld took occasion to give them a general talk respecting their duties, and the policy of his administration regarding the mine inspection service.

The governor said:

"The mining laws of this State were enacted for the protection of the weak and poor. The operator, who is strong, can take care of himself. These coal miners are sometimes ignorant of their rights; always poor and dependent, and cannot manifest their dissatisfaction with objectionable conditions prevailing around the mines without risking their jobs. You are therefore appointed by the State to do for them what they cannot do for themselves. I therefore insist that in inspecting mines, you do so without permitting the operators or their representatives to accompany you.

"Make your inspection thorough and independent, without their aid. After you have done so, find out from the men if there is any ground for complaint among them. The relation of the inspectors and coal miners of the State should be of the most confidential and cordial character. No miner should hesitate to speak to you about the condition of the mine, for fear that he might be reported. While I insist upon a rigid and thorough enforcement of the law, for the health and safety of the miners, I expect at the same that you will be respectful and courteous to the operators.

"I further wish to say that there have been entirely too many accidents; not that there have been more within the last few years than formerly, but I mean to say that there were some accidents that should have been avoided. I know that accidents will occur, in spite of all that you can do, but I desire that, in the prosecution of your work the coming year, you will be so vigilant in the discharge of your duty, that no accident will occur which can by proper attention be avoided. Should there be any such accident the inspector in whose district it occurs will be in peril of losing his job."

The governor here entered into a lengthy explanation of the causes of the accident at Petersburg where several men were crippled, and said that while the inspector may have had no knowledge that the company was dropping their cage with greater speed than the law allows, still had he sounded the men during the inspection, he might have secured from them the information that the company was transgressing the law. Furthermore, when an accident occurs, he forbade them from going to the injured man's home with the company's representative insisting that the miners would not, and could not speak in their presence with the same freedom, respecting the cause of the accident, that they would with the inspector alone.

He also cautioned them from becoming agents of mining tool companies, because it would lead to more or less dependent relations with the coal companies, and would destroy to that extent their efficiency in the service of the State.

The conversation then turned upon the practicability of enforcing the enactment of the Thirty-ninth general assembly, making the mine inspectors ex-officio inspectors, of weights and measures, that is to test scales at coal mines. It is believed by the inspectors, and the belief is shared by Secretary Schilling, that the enforcement of the law is problematical, because of the expense it will entail it carrying the weights from place to place. The inspectors thought that no less than 1,000 pound weights would be adequate. The law insists upon one inspection every six months. The express companies would charge $4 for shipping 1,000 pound weights fifty miles or less. Additional cost for hauling from station to mine, including helper, and again from mine to station, would cost an additional $4. This would make for the 850 shipping mines throughout the State something like $27,000 for the two years, for which the Thirty-ninth general assembly did not provide one cent.

The inspectors and governor, however, will consider ways and means by which the law may be enforced at a nominal expense, meanwhile the subject is *in statu quo*. In taking his departure, the governor again reminded the inspectors that he wanted them to discharge their duties with more vigilance and energy than had ever been done before, and that he would be satisfied with nothing less.

Mine Equipment Makers.

With this issue of THE COLLIERY ENGINEER AND METAL MINER, the Mineral Ridge Mfg. Co. of Mineral Ridge, O., begin a series of advertisements calling attention to the line of mine equipment they are now prepared to build. Mine cars are a specialty, but they are prepared to undertake anything from a car wheel to a steel tipple. Screens and coke larries also occupy a prominent place in their catalogue.

A miners' pick is as important in its way as a hoisting engine, and with this issue the Fulton Tool Works of Canal Fulton, O., begin an advertisement of the mining tools and supplies made by them. They are prepared to furnish anything in mining tools needed either in the anthracite or bituminous mines.

Users of wire rope will hereafter find among our advertisers of such, the card of the Williamsport Wire Rope Co., Williamsport, Pa., and will, we trust, not overlook the new patrons of THE COLLIERY ENGINEER AND METAL MINER, when in need of rope for hoisting or haulage use.

A Handsome Publication.

The Repauno Chemical Co. of Wilmington, Del., the largest manufacturers of high explosives in America, have just issued a beautiful pamphlet of eighty pages profusely illustrated by half-tone engravings and all printed on heavy plate paper. The book is an exceedingly interesting one, and will be appreciated by every mine manager who receives a copy of it. It will pay to send for a copy, which will be sent free on request to the Repauno Chemical Co., Wilmington, Del.

PERSONALS

Mr. Chas. S. Herzig, E. M., whose interesting descriptions of the Tamarack and Osceola copper mines were published in this journal a few months ago, has accepted a position with the Anaconda Mining Co. at Anaconda, Mont.

THE PROGRESS IN MINING.

ABSTRACTS FROM THE PROCEEDINGS OF THE MINING SOCIETIES

And Journals of Europe and America, Illustrating the More Modern Developments in all Branches of the Mining Industry.

Steel Girders for Mines.—In September, this year Mr. E. Thompson read a paper on the "Use of steel girders in mines," before a meeting of the Federated Institute of Mining Engineers, and here is the important portion of the paper:

"An instance of the advantageous substitution of steel for timber is found in the present extensive use of steel girders in engineering structure where timber beams were formerly employed. Although the conditions of the use of girders in mines differ very considerably from their use in building construction, yet the various properties of steel, its strength and durability, enable a girder to show equally satisfactory comparative results when used there for supporting the roof, as when used for any other purpose. As an instance of the difference in the working conditions to be met with in a mine, it may be mentioned that the weight to be supported in some places is not only unknown, but practically irresistible, and the strain is further complicated by pressures both from the top and the sides. Instead of being regular and uniform, the load is varied, and in cases increases with sudden and tremendous force. In addition to these strains, earth movements occur, which tend to displace the supports of the beam, and tend to allow the framework to collapse. Heavy falls of roof also occur on the breaking of the beam, involving heavy costs in clearing away, and by the inconvenience of the delay caused by the obstruction. In such cases the strength, durability and ductility of a steel girder, as compared with a timber, are seen to great advantage. They carry heavier loads, the safe dead load of an iron girder being one-fourth of its breaking load, to one-fifth of the breaking load in the case of timber. Steel girders seldom break under sudden weights, and by bending give indications of pressure and an opportunity of relieving it. As a proof of their ductility a Bessemer steel girder, 5 in. in depth by 4 in. in breadth of flange, weighing 22 lb. per foot, with the weight applied at the center, took a permanent set of 1½ in., under a load of 14 tons, and showed a deflection of 7 in. under a load of 17 tons without breaking, and instances of greater deflections have occurred in practice. It may be mentioned that in the mine where girders were placed here and there amongst timber bars, the latter have been broken while the girders remained u-injured. If not too much bent, girders can be reset, crown upwards, or can be straightened for resetting, at a moderate cost, and are but slightly impaired by the process. These severe conditions do not exist everywhere; there are many roads in mines where the weight may be taken as fairly uniform, an approximate estimate formed as to the strength of the beam required, and a suitable girder can be selected, so as to obtain the best results. The sections of girders in general use in main roads are as follows:

Depth of girder.	Width of flange.	Thickness of web.	Weight per foot.	Estimated safe dead distributed load for an 8ft. span
In.	In.	In.	Lb.	Tons.
5	4	[illegible]	16½	7
5	4	[illegible]	22	9
6	4½	[illegible]	24	12

"The safe loads are calculated at one-third of the breaking weight of the girders. On account of the varying conditions of mines it is impossible to give a table of fixed minimum and maximum length at which the various sections may be safely used. In some instances a 9 ft. girder (for an 8 ft. span), of the highest section, is used in the place of larch timber 9 in. in diameter. In others (taking the same span) a section weighing 22 lb. per foot is required in the place of larch 10 in. in diameter. The heaviest section in other cases has to be used as a substitute for heavier timber. Under comparatively equal loads the various sections of girders may be used as follows:—

Weight per foot.	Length of bars.
Lb.	Ft. Ft.
16½	6 to 8
22	8 to 10
24	10 to 14

"Where weights come on suddenly and with great force it is safer to use the heaviest section, and in exceptionally heavy parts of a road the girders may be spaced more closely together. In wider spaces, where a central support can be used, the strength of a girder is doubled by adopting their use. The relative costs are easily ascertained at any time, being dependent upon the fluctuations of the steel and timber markets. At the present time, estimating the girders at £5 per ton, these sections cost respectively 9d., 1s., and 1s. 1d. per foot. Comparing these prices with best larch timber, the cost of girders is very little in excess of timber, and if the cost of cutting and trimming the timber be included, with an allowance for waste, steel girders will probably be found to cost less per foot, and in addition prove much stronger. Steel girders are also more easily handled, and cost less to set in position. A larch bar 9 in. in diameter and 9 ft. long contains 5 cubic feet, and weighs when dry, 19 lbs. per foot. A larch bar 10 in. in diameter and 9 ft. long, contains 6¼ cubic feet, and weighs 24½ lbs. per foot. At 1s. 3d. per cubic foot these bars cost respectively 6s. 3d. and 7s. 9½d. each, while a 9 ft. steel girder of light section costs 6s. 9d., and of medium section costs 9s. A larch bar, 10 in. square and 8 ft. span, is calculated to break under a load, placed at its centre, of 17 tons. Girders compare favorably with timber, as they give an additional 4 or 5 in. in the height of the road; they possess greater durability where exposed to moist air, which, in some mines, destroys the timber in a few weeks; and they are equally suited for pit bottoms, main roads and return airways. Girders intended for use in very wet places may be tarred at a slight cost. They can be drawn and reset many times, where perhaps timber would not be worth the cost of recovery. In the event of fire, timber is not only destroyed, but helps to spread its effects, while girders remain intact, and the road in good order. The blocking of the roads caused by floating timber is also avoided should the mine be flooded with water. The methods adopted in the setting of steel girders are similar to those employed in setting timber bars. The most general modes are to insert the ends of the girder into holes cut in the sides of road, or to support them on walls or wood props. When side pressure has to be met, girders resting on wood props must be wedged at the joint, to prevent the props from being displaced. Another method is to form a shoulder on the girder to form a support for the head of the prop. It is very important to keep the girders upright; where allowed to cant over their utility is considerably lessened. A ready method for maintaining them upright is to place light timber horizontally from girder to girder, the ends of the timber being held between the flanges of the girders. When canting over they tend to split the wood props upon which they rest, owing to the edge of the flange of the girder being forced into the timber. To meet these cases a shoe, made of iron or steel, may be placed upon the under flange of the girder. Its under side forms a cap, and fits on the top of the wood prop. This shoe answers the triple purpose of preventing the canting of girders, the splitting of the wood props, and their being displaced by lateral pressure, or by collision with tubs. Girders are also used as props to supports the girder bars, the light section being equal in strength to the timber generally used for that purpose. To secur the girder props, and so form steel settings, various appliances have been introduced, so that in constructing the settings there is no need for cutting or punching of the girders, which would tend to weaken them. The first of these appliances is an iron or steel clip, made in two pieces, one-half of which fits on either side of the bar and prop when set in the required position, and a bolt passed through the clip securely holds the framework against distortion by any pressure. The ends of the girder being firmly held, it is able to carry nearly double the weight carried by a girder whose ends are loose. Another appliance is a wrought iron holdfast or band, made in one piece, and placed obliquely over both the girder and prop when set. An iron bolt is passed through the holdfast at the point where the girder rests on the prop, and forms a shoulder to prevent its displacement. As the holdfast passes over the top of the girder it has a greater leverage and extra proportionate power in preventing the canting of the girder. A third appliance is an iron or steel chair, in which the end of the girder and the top of the prop are placed, and are held securely against any movement. Steel settings are also constructed, in the formof arches, circles, rectangles, or squares, and are capable of resisting enormous pressure, and prove an efficient substitute for brick-arching."

Recovery of the Karwin Colliery.—The following important particulars of the recovery of the Karwin colliery in Germany, that was lost by a fire resulting from an explosion on June 14, 1894, are taken from the Colliery Guardian. "The commission appointed to organize the works necessary for the recovery of this colliery after the explosion of June 14, 1894, had several more or less conflicting circumstances to consider in deciding on the means to be adopted. In the first place it was desirable, both from the owners' and the miners' point of view, to reopen the pits as soon as possible. On the other hand lay the risk of the fire not having been extinguished, and the consequent danger of its extension on the readmission of air—a danger militating against the adoption of the most rapid method—viz., direct ventilation. Against the proposal to put out the fire by flooding the mine was the serious objection that with the natural supplies of water available this would take about twenty months to accomplish, seeing that some 870,000 cubic metres of water would be needed to fill the pit, not to mention that the pumping out again of this amount of water, coupled with that of the average daily influx, would occupy a further space of 320 days with the pumps at hand kept constantly at work. Besides, the region of the fire would naturally be the last portion of the mine to be reached by the water, and the first uncovered by its removal, so that inundation would not constitute any positive guarantee against renewed outbreak. After reviewing all these points it was decided to proceed by first ventilating the Tiefbau (pumping) shaft as being farthest away from and least affected by the explosion.

"All the shafts had been closed after the accident, and frequent samples of the air in the mine taken for analysis. It being found that up to the end of June the percentage of CO was barely noticeable, it was assumed that the fire at any rate was making no headway, and that careful ventilation of the Tiefbau shaft might safely be attempted. Accordingly, on July 2, the pumps having been set going a week earlier in order to clear the flooded V. horizontal, this shaft was opened and the fan set to work. Shortly before mid-day a party descended and visited the II., III., IV. and V. horizontals as far as the sixteenth seam. The erection of stoppings to shut off this portion of the pit from the seat of the fire was commenced, but the explorers had to retire at about 3 p. m. on account of the increase of CO in the atmosphere. On the following day the erection of stoppings was continued, but a rise in the percentage of CO (up to 0.5) again forced the workers (seventy-five men) to withdraw at about 10 p. m. Owing to a breakage in the pumps the work in this shaft could not be resumed until the 11th of July, but in the interim the cover of the Franziska shaft was removed to allow the escape of the high-pressure fire-damp, although nothing further in the way of ventilation was practicable for fear of feeding the fire. The difference of density between the fire-damp in this shaft and the outside air caused a current to set in towards the fire, and it was with difficulty that this could be arrested by stoppings, since the interruption of the southward draught caused an influx of fire-damp from the east, filling up the seventeenth seam. However, the erection of these stoppings isolated the Tiefbau shaft, and rendered its thorough ventilation possible, and the next proceeding was the isolation of the Wilhelm seam at the IV. horizontal, a necessary preliminary to the recovery of the Franziska shaft. The air being free from CO, the men where able without danger to fix a brattice against the crossway in the nineteenth, seam, and cut this off from the Franziska.

"By September 25 the ventilating apparatus in the Franziska shaft was completed. The shaft was then explored down to the water level, and the stoppings examined and made good. As behind the sluices a depression of about 30 mm. prevailed, it was found necessary to erect partitions a few yards from the troughs, shuttered in order that the varying amount of depression could be counteracted in the intermediate space. Similar means were adopted in the eastern section of the pit to overcome the compression of the afterdamp from the seat of the fire.

"A good deal of water from the direction of the Tiefbau shaft was dammed up by the *debris*, and the simultaneous removal of both was attended with difficulty. To prevent air entering through the watercourses, sliding shutters were fixed at the base of the dam doors, by which means the channels could be completely closed.

"The men worked in three-hour shifts in the respirators, and for a further three hours as watchers at the partitions, attending to the respirator tubing, &c.

"A quantity of water found dammed up at the IV. horizontal was run off on October 1, its removal being followed by a remarkable change in the composition of the air in the Tiefbau shaft, where the amount of CO_2 rose suddenly from 3.6 to 8.5, the oxygen decreasing from 12.2 to 0.6, with an alteration of pressure from — 22 to + 10. This gave rise to considerable uneasiness, as being possibly caused by a sudden extension of the fire, but it was afterwards ascertained to be due to the sinking of the heavy afterdamp into the workings previously filled by the water in the Wilhelm seam.

"The results obtained from the observation of the variations in the composition of the gas in the mine may be summarized in the statement that diminution of atmospheric pressure induces an increase of CO_2, and a decrease in the amount of oxygen, the internal depressions tending to disappear and the compressions to rise; in other words, the proportion of oxygen increases with depression and that of CO_2 with compression.

During the months of September and October work was continued by the erection of stone stoppings in III. and IV. horizontals and the removal of *debris*. The building of an explosion-proof stopping of cemented masonry, 43 in. thick, and with a rounded face on the danger side completed the isolation of the III. horizontal. The compression test having revealed a connection with the fire region *via* the II. horizontal, stoppings were begun at that level, the recovered part being ventilated by means of horizontal troughs, 30 cm. in diameter, branching from the vertical main.

"After erecting an explosion-proof dam in the II. horizontal, rather thicker than the one on the next level, the exhauster and troughs were removed from the Franziska shaft, the large cage replaced, stoppings made good, and the clearing up of the recovered workings proceeded with. Coal-getting was resumed in both shafts about Christmas, and the sphere of action in recovery work transferred to the Carl shaft, where the same procedure was adopted as in the western section. As soon as the stoppings were erected the compression of gas from the burning portion of the pit rose to such an extent that it was deemed advisable to bore through the safety dams and convey the gas through iron pipes up to the bank.

"The percentage of methane in the horizontal workings amounted to between 40 and 60 per cent., and was, therefore, beyond the limits of explosibility. Nevertheless, for the first few yards beyond the partitions, owing to the admission of air every time these were opened for the men to pass through, the proportions of air and gas were such as might readily explode should a spark be produced or one of the electric lamps be broken; in fact, in the Carl shaft such an explosion did result from the breaking of a lamp by a stroke of the pick, and eleven men were injured. The lamps were therefore strengthened by extra glass, and a covering of wire gauze. As regards efficiency the English Bristol lamps were much more satisfactory than those obtained from Vienna, burning six hours, whilst the latter only lasted for two or three hours without recharging.

"So far the burning field has been isolated from both sides, and subsequent operations will be directed towards still further encroachments on its area, but this difficult and dangerous work will be of necessity slow, and the damage wrought in a moment by the explosion of 14th June will take years to repair."

The Rock-Phosphate Deposits of Florida.—Two papers treating on the phosphate deposits of Florida, were read by Messrs. G. M. Wells, of Ocala Florida and E. T. Cox, of Albion Florida at the March meeting, 1895, of the American Institute of Mining Engineers. The time is near at hand when nations and people will jealously safe-guard their phosphate deposits as treasures that cannot be exchanged for gold. The elements carbon, hydrogen, oxygen, nitrogen and lime are indispensable in the building up of organic compounds, but the selective principle of life that gives activity to the organs of an organism in the discharge of their functions is phosphorus.

This element is possessed of great vitalizing power, and when used to recuperate the soil, it replaces sterility with fertility, and as human poverty and despair and wealth and satisfaction, are coeval with, in the first case an exhausted soil, and in the second with a productive soil, we can see that the phosphates are of inestimable value to man.

The most abundant supplies of phosphate of lime or phosphoric acid are derived from animal remains, in one of two forms, first, as recent surface deposits that are found along the coasts of continents, or are found to cover the surfaces of lonely islands in the sea. As the coast of Peru on the shores of the Pacific ocean, and the coast of some of the main lands in the Antarctic seas, where live and die in countless millions those singular birds the wingless penguin. The other source of the phosphate is a mineralized deposit of the petrified dung of fish lizzards, that swarmed in the seas of the Tertiary period and this mineralized form is recognized by different names, such as coprolites, and hard rock phosphate as Mr. Wells calls it and boulder and gravel phosphate as Mr. Cox calls it.

Now we arrive at the consideration of that phase of the subject treated on by the papers under notice. First then the Peninsula State of Florida has a surface area on the Pliocene rocks, of great extent. The outcropping rocks at the southern end of the State, between the 25th and 28th parallels of latitude, and stretching from the eastern to the western shores of the State, are all of the Pliocene period, and the surface rocks near to, and along the north-western shores of the State are all of the Miocene period, and it is in the latter, that the phosphates are found and mined, and this is made very clear by a well drawn map of the State that is introduced for illustrating Mr. Wells' paper.

The phosphates are found in pockety clusters, within a belt of rocks of nearly uniform width and the string of pockets from the Apalachicola river on the western side and northern end of the State to the Caloosahatchee river on the western side and the southern end of the State. The belt of pockets is therefore about 250 miles long and 15 miles broad and runs nearly parallel to the major axis of the State.

A good idea of the course of this zone of phosphate can be obtained from Mr. Wells' paper in which he says: "Each of the groups is made up of a series of small deposits, many of which have a surface area of only one-eighth of an acre, while some have an area of three quarters and others an area of four acres.

"A few of the patches are larger than those noticed, but when this is the case, the productive rock does not reach so great a depth as in the case of the smaller pockets; and further, in these deposits of large surface area the stone is of a lower grade and so interstratified with the limestone strata that easy and profitable mining cannot be pursued." At the southern end of the State, overlying the Pliocene rocks, drift deposits of pebbles broken from the phosphate rocks are found.

Mr. Cox says: "In this district, Albion, the phosphate is designated as 'hard rock' or 'boulder phosphate,' or gravel phosphate. The boulders range from lumps as large as a man's head, up to 50 tons in weight.

"When cleaned it yields on analysis from 75 to 85 per cent. of tricalcium phosphate of lime, and from 2.5 to 3 per cent. of phosphate of iron."

The phosphate miners of Florida have furnished another proof of the fact, that mining to be scientifically and commercially successful, requires courage, and the true genius of mechanical resource. For the risk of capital can only be reduced to a minimum by the adroitness of the mining engineer that can originate new appliances to make the transaction pay by the adoption of processes adapted to the conditions under which the mineral is found.

Mining by water as a solvent has been very successful in obtaining salt and sulphate of copper, but mining by dredging is certainly something new. It appears that a great inflow of water takes place below depths of from 10 to 20 feet in the phosphate, and pumping was at first tried to drain the mines but the volume of inflow was so great, that the cost of drainage cast the balance on the wrong side of the accounts, and then dredging or scooping was tried with the result, tt at we will let Mr. Cox narrate:

"Mr. W. N. Camp of the Camp Phosphate Company, concluded that he would try mining with a steam dredge. Accordingly, he had a dredge boat made and launched into the pool of water. Contrary to all predictions of failure, it proved to be a grand success, and solved the problem of hydraulic mining with a dredge. The importance of mining with a steam scoop-dredge can be understood when it is shown, that two-thirds of the mineral lies below the water level, and that the scoops can do the mining cheaper than the hand-pick and shovel, for mining by hand costs from \$2.50 to \$3.00 a ton, whereas, mining with Mr. Camp's steam scoop dredge rarely costs more than \$1.00 a ton. Surely this is a grand reward for the new departure in which the water that submerges the mineral, is made to assist the steam scoops in mining it."

West Virginia Mine Inspectors Reports.—The Reports of the Mine Inspectors of West Virginia are to hand for the year 1893 and ending in June 1894. The reports for the first district shows that the output of coal for the year was 2,714,818 tons of 2240 pounds to the ton, and the output of coke was 208,146 tons of 2000 pounds to the ton. These figures show a falling off in the production, as the result of a strike. The total number of employes engaged in the coal and coke production was 4,716. The total number of non-fatal accidents was 33 and the majority of these were due to falls of coal and slate. There were 13 fatal accidents from different causes, but chiefly from the same prevailing cause as in the non-fatal accidents. There are 44 mines in the first district, 22 have natural ventilation, 1 steam jet ventilation, 6 furnace ventilation, and 15 are ventilated with fans, so that the fan maker has a nearly virgin district for his productions. The tables of the analyses of coal and coke show that the West Virginia fossil fuels, or "black diamonds" are of grand merchantable quality, for the average of the coal ash is 5 per cent, and that of the coke is 9.5 per cent.

The report of the second district shows that the output of coal for the year under notice, was 10,928,820 tons, at 2240 pounds to the ton, or a slight decrease from that of the previous year. The output of coke was 1,090,809 tons at 2000 pounds to the ton, or a large decrease on that of the previous year.

The number of employes engaged in coal and coke production is not given. The number of non-fatal accidents is given as 6, and the two causes, were falls of coal and slate, and falling between the cars. There were seven fatal accidents, and all but one, were caused by "falls of slate." There are 32 collieries in this division, and only 6 of them are ventilated with fans, 7 have natural ventilation, and 19 are ventilated with the furnace. By the tables of analysis the percentage of ash in the coke, is 9.7, and the average ash in the coal is under 3 per cent.; now this cannot be right, for supposing the coke produced be 65 per cent. of the coal poured into the ovens, then the percentage of ash should be 6.3.

Report of the mine inspector for the third district shows that the output of coal for the year under notice was 5,476,857 tons at 2,240 pounds to the ton, a slight decrease on the previous year, and the production of coke was 858,556 tons of 2,000 pounds each, a slight increase on the previous year. Total number of employes engaged in the production of coal and coke 11,730. There are 98 collieries in this district and 9 of them are ventilated by natural means, 36 are ventilated with fans, and 49 are ventilated with the furnace, one is ventilated with the fire-basket or fire-cage. There were 39 fatal accidents and the prevailing cause was falls of coal and slate. There were 90 non-fatal accidents and the chief cause was falls of coal and slate. Altogether the West Virginia reports are capable of much improvement.

Modern Coal-Tipplers.—In the Transactions of the Federated Institution of Mining Engineers, England, 1895, is a paper on the above subject by Mr. J. J. Prest, and he introduces the subject as follows. "The many different designs of coal-tipplers are evidence of the great advances made during the past ten years in the efficiency and improvement of colliery-plant, and particularly in the appliances adopted for screening and cleaning coal. Formerly a long array of fixed bar screens, each fitted with its own tippler, was seen at all coal-drawing shafts, but now the entire output of a large colliery is concentrated at one point, and passed through a single power-driven tippler at considerably less cost, and with greater efficiency then was the case under the old order of things." He next notices the principles of construction and mode of action of 9 varieties of the power-driven tipplers.

These decanting or emptying devices are a *necessary* adjunct to the "jigger screens" and "sorting belts" used for sizing and dressing the bituminous coals at the mines in England, for here the jigging or oscillating screens are worked by steam power, and therefore rapidly carry forward the coals onto the "cleaning belts," and to keep the screens and belts going, it is neccessary that a copious supply of coals should be constantly pouring onto the jigging screens, and for this to be done with sufficient despatch the tippler must be so constructed as to quickly overturn and empty the cars of coal as they arrive, and for doing this, power must be used, and this is supplied by the engine that oscillates the jigging screens and turns the belts. There are three distinct types of the power-driven tipplers, first the rotary tipplers, or those in which the plane in which the tippler turns is parallel to the plane of the car wheels, and generally considered, the mode of action is as follows, the the cars gravitate from the mouth of the hoisting shaft down a gentle pitch into a frame, that revolves the moment a clutch is made to seize by being actuated with a hand lever, the frame now turns once round, and empties the car and then discharges it, when it moves over a horned belt, one of the horns of which catch the hinder axle, and carry the car up an ascent, where it is disengaged and continues its journey by gravitation down to the mouth of the shaft again. Of this class of tippler Mr. Prest gives Wood and Burnett two varieties, Silvester, Shelton, and the Heenan and Fronde.

The second type is the end tipplers as the Heath and Woodworth, and the third type or side tipplers, are the Blackett, the Pelsall, and the Tate.

The Cornwall Ore Hills.—Mr. J Birkinbine in the Iron Age says: "The Cornwall ore hills in Lebanon county, Pennsylvania, have a history stretching back over one hundred and fifty years. The earliest mining of the ore was restricted within the limits of the small local demand of neighboring iron works, to which the ore was carried by wagon haulage. The ore was owned by several individuals, each of which had contracted for the entire supply of certain of the small smelters and therefore, the names of the old mines or excavations are really the specific names of the furnaces then in use in the district. The early mining, or open digging in these hills was confined to such outcrops as furnished loose ore ready for loading into wagons, and in this way advantage was taken of large accumulations of "nigger heads," for this class of ore was of superior grade, because it had been for a vast period exposed to the leaching influence of the weather. Among other varieties in iron ore found exposed in these hills, are fine examples of loadstone or magnetic ore. These early miners and smelters fully understood the purifying influence of the weather, for they used to leave extensive faces of the ore in their open excavations exposed for long periods of time.

The march of progress in iron manufacture, as in other branches of art, has made what was once a doubtful variety of ore, one now of first-rate quality.

The ore contains very little phosphorus, but some copper and a rather high percentage of sulphur, the result was in the early days the copper rendered the iron red short, and it was therefore unsuited for foundry castings. Now, however, the same ore is of great value in the manufacture of Bessemer steel on account of the small percentage of phosphorus it contains, and the oxidation of the copper and its consequent elimination as the result of the high temperature at which this class of steel is made. During the last ten years the output of ore from the Cornwall hills has been 6,192,852 tons and of course this large quantity of ore could not have been mined but for the aid of railway transport. The deposit is so vast that it will be long, very long, before the period of exhaustion arrives.

Sampling.—A paper by T. Clarkson, C. E., on sampling, was read before the members of the Federated Institution of Mining Engineers, England, early this year, and as its contents are of some importance, let us here notice the points in it of special importance. First then he shows that the promiscuous or partial sampling of a heap of ore, a heap of coal, or lot of cement cannot do other than mislead the experimenter or tester, and here are some of his claims.

"One of the details which concerns mining engineers, and which has not hitherto received the attention it merits, is the important operation of sampling. This work is frequently done in a most perfunctory and slipshod manner, although so much that is of value depends upon the result. Surely sampling is co-equal in importance with chemical analysis, being in fact, the first practical step in that analytical operation."

Mr. Clarkson after showing why sampling should be accurately done stongly advocates the mixing and sampling of the mass by machinery, and here are the views he thus sustains. "Generally the only way to correctly sample a large bulk of material is to deal with the whole heap, and not as at present with only a small percentage of it." To deal with the bulk is not practicable by hand labor, therefore it is necessary to employ machinery.

"The employment of machinery for sampling has the great advantage of the work being done impartially, the results are obtained more quickly, and, most important of all, the utmost possible accuracy is secured." Referring to an English machine he says:

"Several kinds of sampling machines are in use in America, but the one shown in the model exhibited is, the writer believes, the only one in use in England."

An Outburst of Gas.—The following paper appears in the Transactions, 1895, of the Federated Institution of Mining Engineers, England, and is by Mr. W. Washington on an outburst of gas at the Mitchell Main Colliery of which he has charge. It appears the mode of working is longwall, and the line of the face or working line, is given as half "end on" and "half board," or nearly *short-horn*. The "pack-walls" or gate road-packs are 9 feet wide on each side of each gateway, and the gateways are 66 feet, or 22 yards apart, and at the time of the outburst of the gas from 18,000 to 20,000 cubic feet of air per minute were passing through the district so that the gas could not be a gradual collection and must therefore have been suddenly disengaged.

It appears the gas burst out from the floor of the seam, and this indicates either a workable seam of coal heavily charged with gas under the present workings or else the existence of "coal-pipes," or thin layers of of gaseous coal in the underlying shales. The gas must also have been pent up at a very high pressure, for says Mr. Washington: "The greater portion of the gas appeared to come from the floor, and for a distance of 150 or 200 feet along the face, the floor was considerably lifted, the roof also subsided and the height of it reduced from 5 feet 6 inches to 3 feet. The deputy overman said that the concussion appeared to shake the 'separation doors' at a distance of 840 feet from the point of the outburst."

Iron Ore in California.—Mr. J. J. Crawford in the report of the State Mineralogist, of California, describes the extensive deposits of iron ore which are found in many of the counties of California and if a supply of suitable fuel was at hand, they would no doubt be utilized. Some years ago an extensive plant was errected in Placer County for smelting the ore with charcoal, but the buildings and plant were distroyed by fire and were not restored, the result is iron manufacture has almost ceased in the region. A few hundred tons of iron ore, however, from Shasta county were used by local rolling mills and foundries in 1893, but this was the limit of the production. For a number of years California has been the only seat of the production of chrome iron ore in the United States, and its occurrence has been observed in several counties, but the chief centers of its yield are now the counties Alameda, Glam, San Luis Obispo, Shasta and Tehama. The ore industry in so far as mining is concerned is not very extensive, owing to the facility with which the ore can be imported from Asia Minor. The California output represents only about one-fourth of the total consumption at Baltimore and Philadelphia and cost of transit to these cities is the main reason that the excludes the Californian product.

Iron Ore Mining.—Mr. J. Main in the Iron Trade Review says: Hematite iron ore occurs in the carboniferous limestone in the Whitehaven district in England. The deposit is peculiar in its occurence as it is sometimes found in vertical gashes in the limestone, at other times in pockets, and frequently it is found in what appear to be horizontal beds.

The veinlike masses occur in the partings of faults, and shafts are therefore often sunk on the upthrow sides of the faults and levels are driven 120 to 180 feet apart to intersect the ore. Workings are then commenced right and left, and raises are put up on the foot wall, leaving pillars 60 to 70 feet long. Levels are driven horizontally every 15 to 30 feet from the raises, and when the ground has thus been opened up the pillars are robbed, those farthest from the shaft being worked first.

Debris is used for packing, as far as possible, assisted by timbering. The bed-like deposits occur most frequently in what are known as the first, second, third and seventh limestones and they are worked by the pillar and stall method with the winding shaft sunk to the point of the greatest depression in the lowest bed. The pillars range from 430 to 1620 square feet in area, the size varying according to the local character of the deposit.

When the ground has been opened up, the pillars are taken out, and when the bed is thick the ore is taken out in two layers or benches.

Nickel Ore Deposits.—The following facts are collected from a paper read by Mr. J. F. Kemp before the American Institute of Mining Engineers. Nickel ore is interesting because it has not hitherto been found in great abundance in the United States, and yet it is extensively used in the coinage of the Republic. The principal deposits of this ore found anywhere in the whole of the States, are in the region of Gap Mine, Lancaster County, Pennsylvania, and at Anthony's Nose on the Hudson. The Gap Mine ore is found in a lenticular mass, the greatest length of it being 1,500 feet from east to west, and the width from north to south, 500 feet; it is true there are other regions in the States where the ore of nickel yields a relatively small percentage of the metal but this ore cannot be made to pay in consequence of the reduced price. The metal sold in 1874, for $2.60 per pound, and the selling price now is 75c. The metal is of great value in the manufacture of German silver when it is alloyed with zinc and copper. It is now extensively used for electro plating other metal, and it is therefore interesting to know that 400,000 pounds were used in the United States alone, in 1884, and in 1883, no less than 703,426 troy ounces were used in the coinage of the Republic. The ore called copper-nickel, derives its name from the copper color of the ore, and it contains from 39 to 48 per cent. of nickel and from 46 to 54 per cent. of arsenic. Some of the poorer varieties of nickel ore however, yield as little as one-1 per cent. of the metal.

Iron Ore Mining on the Mesabi Range.—Mr. H. V. Winchell in The Iron Trade Review gives the output of iron ore from the Mesabi Range as 684,194 tons in 1893 and 1,781,574 tons in 1894, when probably not more than 40 per cent. was strictly Bessemer ore although the iron contents probably exceeded 62 per cent. Three quarters of the deposit was obtained by stripping and the mining cost was undoubtedy less than the maximum figure of 42c. given in 1892. After stripping, the ore is either loaded by steam shovels direct into the railway cars, or it is sent down winzes into trams, that are run to the shaft and hoisted to the surface. The cost of working by stripping and filling with the steam shovel is given for the present time at 15c. per ton.

Great variations are found in the character and quality of the ore and some of the mines producing true Bessemer are restricting their output. The non-Bessemer is generally found in the upper bench of the bed of the Mesabi and Iron Mountains, but the entire body of the ore is subject to continual change of character. There are at least two hundred million tons of this ore in the Mesabi district but probably not more than 40 per cent. of this ore is Bessemer and the disposal of the remainder may be a matter of future difficulty.

One of the largest steam shovel mines shipped in about six months 505,000 tons of the ore with a normal force of 85 men on an average of 40 tons of ore per man. The tendency, however, of this large output per man is to produce lower grade ore owing to the mixing of all sorts. Several systems of mining have been tried, but it will probably be found best to work the ore in benches to secure a better selection.

Spathite in Tennessee.—Mr. C. Wilson in the proceedings of the Alabama Industrial and Scientific Society, describes a six-foot bed of spathite, or spathic iron-ore which is found at Iron City, Tennessee, between beds of limestone. It looks like hematite or red ore, and the iron is present in it as ferric oxide, but the percentage of metallic iron in the ore is only about from 21 to 22, and taking this along with its specific gravity which is 2.78 and its percentage of phosphorus .5 and sulphur a mere trace, it is singular that the thickness of the seam, the specific gravity of the ore, and its percentage of metallic iron are strongly characteristic features of spathite in other regions, and in other lands. For example, the spathic ore of Cleveland, England, yields from 21 to 32 per cent. of metallic iron, has a specific gravity of 2.8 to 3.1 and the bed found interstratified in Middle Lias has an average thickness of 6 feet, and to produce a first class variety of Bessemer steel it is mixed with red hematite from Bilboa, Spain. Now the spathite of Tennessee, when mixed with two parts of brown hematite, makes an iron that commands the highest price.

Iron Ore in New Jersey.—From the report of the State Geologist, Trenton, New Jersey, we learn that the deposits of iron ore in the region, are of sedimentary origin, and it appears that the ferruginous mud, or suspended particles were carried by water into basin-like depressions and deposited, and after the cavity was filled it was in time covered with other sedimentary matter, and thus the whole series of these rocks are of sedimentary origin, although metamorphosed and of Algonkian age. It appears that "pitch and foliation replace each other," and this fact sustains the conclusions that different sections of the region were subject to greater and lesser lateral pressures, hence the greater rock waves that produce great pitching, and the lesser ripples of foliation.

We need not wonder then that pitch and foliation replace each other, or that where the one occurs, the other does not. The metamorphism and crystallization of these rocks as we now find them, to some extent obscures their real sedimentary origin.

Durability of Chalk Marks.

About five years ago an article appeared in one of the city papers stating that when the old city bell was taken down to be replaced by the new one chalk writing was found, plainly written 13 years before by a young engineer. In the year 1822 the bridge over the Big Gunpowder falls, at Ridgely's iron works, about 14 miles from Baltimore, was constructed by Robert Burr, considered at that time a famous architect and engineer of New Jersey. When the bridge was erected, several persons wrote their names thereon with chalk, and they can easily be read at this day, and the date, July 4, 1822. —*Philadelphia North American.*

Hon. W. L. Connell, mayor of Scranton and president of the Enterprise Coal Co., whose operations are near Shamokin, Pa., was on the 16th ult. presented with a handsome gold headed cane by the employes of the company. Mayor Connell, as president of the company, personally looks after the general management of the colliery, and the occasion chosen for the presentation was the date of the first operation of the new breaker, which replaced the one destroyed by fire on May 16th last. The employes testified their appreciation of the genial, fair minded and handsome mayor in a manner that shows his efforts in running the colliery harmoniously and profitably has made them among his strongest friends.

THE COPPER DEPOSITS OF MICHIGAN.

By M. E. Wadsworth, Ph. D., Director of the Michigan Mining School.

(Read at the Annual Convention of the Michigan Bankers' Association, September 12, 1895.)

In looking at the map of the Great Lake region, you have all noticed the backward bending thumb of Michigan projecting into the icy waters of Lake Superior; yet but few of you, perhaps, have realized that extending along that thumb there runs a band or ring of native copper.

It does not, like most gold or silver bands, extend around the finger, but along it—from the base of the hand to the end of the thumb—this central band lies imbedded in the flesh binding all together.

Shall we now dissect it, laying bare its flesh, muscle and bone, and try to explain its marvelous organization?

To do this it will be necessary to drop much of our simile and to make as clear as possible the geological structure of the district in question. Roughly, its central portion extending from the south-west to the north-east, may be said to be made up of an elevated plateau, bearing upon its wrinkled surface protuberances or hills, locally called mountains, like warts upon a finger.

Flanking both sides of this higher land lie lower lands extending down the to the level of the lake.

This lower level is formed of hardened beach muds, sand and shingle laid down on the shores of a tide-washed sea.

We find in it the ripple marks made by the waves, the mud cracks formed when exposed to the drying sun, and the prints of the soft rain drops that fell, at ebb, upon the gently sloping beach.

This formation is known to you all through its affording the beautiful Portage Entry or red sandstone, so much used now in building.

It is, however, with the central higher or Plateau region that we have the most to do with at present.

You are all familiar with the descriptions or with the sight of the lava beds of Vesuvius, or of Etna, or on Iceland or on the Sandwich Islands. You know how the lava flows onward towards the sea, now rolling with a rough, ropy, clinkery surface; and now gliding with a comparatively smooth one. This Lake Superior Plateau is composed of a series of lava flows like those from Kilauea, generally smooth but sometimes clinkery. Let us imagine a large sheet of ice extending over a lake, when from some cause a long fissure rends it open on one side, and the water wells up through the sheet and overflows the icy expanse. This overflow congeals; the ice is again rent in twain; a new overflow takes place, and so on until the ice continually sinking, is piled up in successive thicknesses, hundreds or thousands of feet.

Let us now more exactly explain what has taken place in Northern Michigan. The present promontory of Keweenaw Point once formed the gently sloping tide-washed shores of a sea. Over this shore poured the vast floods of lava, the same kind as now flows out from Etna, Kilauea, and the majority of active volcanoes of the present day. These flows, like those of Kilauea, were apparently quiet, and not explosive like those of Vesuvius and Etna.

At the time of the outpouring of those vast floods of lava, the shore was gradually sinking, so that the congealed rock was exposed to the action of the sea waves.

You all know of the effect of the storm-dashed waves upon a rock-ribbed coast, how the rock is torn down and worn away and then piled up along the shores as a resulting mud, sand, gravel and shingle.

In like manner our lava flows, along the shores of that great northern sea, where now Superior rolls were subject to the alternate tide and storm-waves, and to the action of sun, rain, wind and frost. The result of this all must have been, that the exposed portions of these flows were buried under their own debris, mingled with that of associated rocks. Besides the lava flows before mentioned, we find other flows and masses, similar in chemical composition to our granites, which being much harder and more enduring than the basaltic lavas, make up by far the larger portion of the debris now visible.

This region, then is composed of a series of interbedded basaltic lava flows, with their associated shingle, sand and mud now forming conglomerates, sandstones and shales.

In order to show more clearly what has happened since, let us take a new metaphor and look upon all these layers as forming a sort of marbled cake. Now let this cake be cut lengthwise along one side of the thumb-like mass, the cut extending north-east and south-west, nearer to the south-eastern side. Consider that the north-western part has been lifted up at a varying angle from 30° to 60°, and also cut across by fissures running north-west to south-east; and you have a fair idea of what has happened.

It is well known that in all regions where volcanic forces have been active, when these forces die out, hot water action is one of the last results, the waters gradually growing cooler until they are at the normal temperature, so that in time there is no evidence of the former hot state except that shown by its results on the rocks.

In the Lake Superior district the water action, mostly hot, sometimes cold, was strongly marked during the fissuring and movement, or as it is technically termed, "faulting of the rocks," as well as for a long time subsequently. During the time of this water action all the rocks, without exception, were penetrated by these percolating waters, much of their materials dissolved out, or chemically re-arranged, or removed and replaced by other elements.

It was then that the native copper now found in the rocks was stored up on its present banks of deposits, from which it is now being rifled by means of the drill, sledge, and dynamite. Three different systems of local deposit have been employed by Dame Nature on Keweenaw Point. The profound and repeated fissuring previously spoken of caused huge vaults to be made where the percolating waters left, securely locked up, their treasures of copper; and here the largest single deposits were made and the drafts have been fully honored. The vaults extend mainly in a north-west and south-east direction, cutting across the country. These deposits are technically known as fissure veins; and as examples there may be cited the Central, Cliff, Phœnix and other mines, mainly on the northern end of Keweenaw Point.

As one would naturally suppose, the various lava flows would differ in thickness, owing to the varying amounts of volcanic material erupted, as well as to the inequalities of surface. Like variation would also exist in the extent and amount of deposited conglomerate, shale and sandstone, on account of similar inequalities of the surface, the time it was in forming, and the area exposed to the tidal or wave action.

Returning to the lava flows, it has been found that the thinner ones are more glassy and hence more easily acted upon by the percolating waters; thus large amounts of the original rock materials have been dissolved out, removed and their places, as well as those of all other cavities, have been filled with deposits of copper and other mineral matter.

These deposits are mined and form the melapyr (locally called amygdaloid) mines, such as the Quincy, Osceola, Franklin, Atlantic, and Huron. These mines are worked on old lava flows that have been impregnated with copper, the same as a flow from Mount Etna might be worked, if it were likewise filled with valuable mineral.

Altogether it is popular to speak of these mines as worked upon veins, that is an error, as they have neither the structure of a vein nor any sign of a vein on or about them. They are simply flow deposits.

At the same time our fissure or vein and overflow deposits were formed, similar deposits were made in the interbedded detrital or sea-beach materials, or conglomerates. Here the percolating waters removed much of the cementing mud and the more easily soluble pebbles, filling in the places thus left with copper and other mineral matter. This form of deposit gives rise to our conglomerate mines, such as the Calumet and Hecla, Tamarack, Peninsula, and Allouez.

As before, these mines are not worked upon veins but upon old sea-beach shingle, the same as if any one of your beaches here, after having been covered up, should be worked for any mineral matter. They are not veins and they have no sign of a vein upon them; but they are simply bed deposits.

You may ask, whence came the copper now deposited in these three different kinds of safety vaults—vaults that were found by prehistoric man to be thoroughly fire-proof, but which are not burglar-proof, when attacked by the modern earth robber with power drill and dynamite.

No one can tell whence came this copper; he can only infer.

The largest amounts of copper are generally well within the series of lava flows, and associated with or underlying the thicker and heavier beds. Further, it has been seen that the general course of the copper was downwards, as it extends frequently like icicles, from the overhanging bed into the one that is worked, while sheets of it are wrapped around the angles of the broken blocks, like paper around a grocer's package. These and numerous other facts show that the copper was deposited from water subsequently to the fracturing and faulting of the rocks; and that it was probably originally disseminated through the lava flows and has since been concentrated in the various banks of deposit by the percolating waters, which penetrate all rocks.

Did time permit, the evidence in behalf of all the statements made here, could be laid before you—these evidences are picked up one by one by the earth's detectives, the geologists, who, like the Sherlock Holmes's, study the ashes, the mud, and every relic left by that thief, Time, in the depositories of old Mother Earth.

As you read the story of each coin and bill, each check and draft, so we read the story of each pebble and rock; and learn to ferret out the secret deposits of Dame Nature.

Electrical Mining Machinery.

The Link-Belt Machinery Co., Chicago are unusually busy in all departments of their Works at the present time, and especially so in the Electrical Mining Machinery Dep't. Contracts for this line of machinery have recently been closed with the following companies, Bessemer Land & I'mp't. Co., Bessemer, Ala., Electric Mine Haulage, consisting of 2 15x16'' McEwen Engines, 2 100 KW "Independent" Mine Type Generators, 2 80 H. P. "Independent" 4 wheel Locomotives, marble switchboard, circuits, etc.

Pittsburg Block Coal Co., Pittsburg, Pa. 2 6 ft. "Independent" Chain Breast Machines, 1 35 H. P. 4 Wheel Locomotive, 1 100 KW Dynamo, switchboard, etc.

Brazil Block Coal Co., Brazil, Ind. 1 100 KW "Independent" Mine Type Dynamo, 5 6 ft. Chain Breast Machines.

Joseph E. Thropp, Everett, Pa. 1 15x16 McEwen Engine, 1 100 KW Dynamo, 3 6 ft. Chain Breast Machines, 1 35 H. P. 4 Wheel Locomotive and necessary switchboards, circuits, etc.

In placing his order with the L. B. M. Co. Mr. Thropp takes the occasion to say that "after a thorough investigation of the mining machinery manufactured by the different companies by my superintendent, I have decided to accept your proposition for the complete equipment of my Kearney mines with dynamo, locomotive and coal cutters. I am fully satisfied your machinery is equal to, if not superior, for mine use to any we have examined.

New facts in welding by pressure at temperature below the melting points of the metals have been reported by the Royal Society of Belgium. Pressed together by hand-screws, cylinders of gold, lead and tin were well united in a heat of 200 to 400 degrees for three to twelve hours, bismuth and antimony less perfectly so. The more crystalline the metal the less was the softening.

EASY LESSONS ON MINING.

This Department contains articles to assist ambitious Miners to educate themselves, and obtain Certificates of Competency as *Mine* Foremen, or to become *Mine Superintendents.*

The articles are written to be understood by the unlearned and the learned alike. Plain language is used, no obscure terms are employed, and each subject treated, is made as clear and easy to understand as possible.

Further: The Questions asked at the different Examinations for Mine Foremen and Mine Inspectors, are printed and answered.

☞ The Series of Articles "Geology of Coal," "Chemistry of Mining," "Mining Methods" and "Mining Machinery" was commenced in the issue of March 1894. Back numbers can be obtained at twenty-five cents per single copy, $1.00 for six copies, and $2.00 for twelve copies.

MINING MACHINERY.

The Central Orifice of a Fan.—The Three Orifices of a Fan.—The Correct Orifice for Measuring Quantities.—The Required Breadth of Fan Blades.—The Radial Length of Fan Blades.—The Loss by Wave Movements in Fans.—The Loss of Energy Due to Intermittent Action.—The Best Dimensions for Ventilating Fans.—The Laws of the Areas of the Fan Ports.—To Calculate the Diameter of a Fan.—Recapitulation of the Former Article.

76. The Central Orifice of a Fan.—Again we resume our investigation of the principles of action of the ventilating fan, and at the outset it is wise to refer to our last, by noticing that our conclusions were only arrived at by using an assumed value which we then called "the constant C," and gave it the numerical value of .6. We were careful, however to point out that .6 was used in lieu of .65 the constant for the *vena contracta* or the constriction or narrowing of a port or orifice through which a fluid is made to pass. The cause of the contraction is found in the inertia of the converging particles that choke the entrance of the port, and reduce its available area from 1 to .65.

Now, we did not take .65 but .6, and said that for reasons that we did not give then, the "constant was sometimes as low as .3." Therefore, before we can make further progress in our investigation it is important that we cast off the assumption and put in its place a correctly determined value. The constant .65 would require no qualification if the *correct* area of the port of entry into the fan was known, but this area is not easy to determine for two reasons, first, it will be seen by Fig. 117 that the area of this orifice is partly covered by

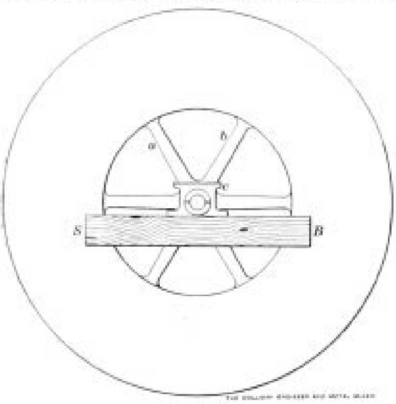

Fig. 117.

the spokes of the fan wheel, the carriage or bearing, and the shaft as at a, b and c and still further by the "main beam," $S\ B$; second, the spokes in their motion produce a whirl that still further reduces the area for the *free* entry of air, and the result is, with a port of entry that is relatively small, and largely obstructed, the constant, .65 is "sometimes reduced to .3," and this being so, we discover that the efficiency of a fan must be favorably or unfavorably affected by the lessor or greater obstruction that occurs at the port of entry, and as this is the case, it becomes all the more important that we should be able to estimate this available area, to enable us to calculate the ventilating power of the fan. If we defer the consideration of the estimate of the available area of the port of entry, until we have found what that area ought to be in a fan of good construction, then, we will be better able to make a correct determination.

77. The Three Orifices of a Fan.—There are three orifices in a fan that require attention and estimation, and these are the central orifice of entry, the entry at the throat of the fan, and the orifice of discharge at the circumference of the fan.

The central orifice of the fan ought to be as large as possible without being made to shorten the radial length of the fan blades; for if the blades are shortened the velocity of the fan must be increased, and then such an increase in the diameter of the central orifice becomes a defect, or one defect has been substituted for another, and it is therefore clear that there are to be found some proportions that jointly produce the best results. Let us then for the present assume a value that we will afterward prove to be the correct one, namely, that one square foot of area in the central orifice, should be provided for every 1300 cubic feet of air that are to pass through the fan per minute, or if Q is the quantity per minute, then $\frac{Q}{1300} = A =$ the area of the port of entry. Not many fans are found in which the ports are so large, but by constructing the fan to intake air at both sides, the required area can be provided without interfering with the length of the blades. The throat of the fan is the cylindrical orifice whose length is equal to the breadth of the blades, and whose

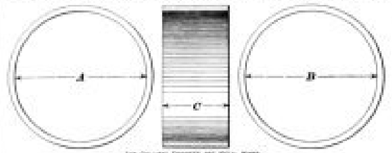

Fig. 118.

radius is equal to the radius of the central orifice of entry, see Fig. 118, and there C is a section of the throat cylinder, and A and B are supposed to be the dual cen-

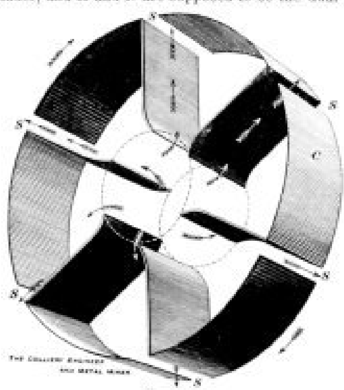

Fig. 119.

tral orifices of entry of a fan that takes in air at both sides. Now if the diameters of A, B and C are equal, then the area of entry at the throat of the fan, will be equal to the areas of A and B conjointly, and then the length of the throat area is equal to the radius of the central ports of entry, and when the air enters the fan at one side only, then the length of the throat area can be found by dividing the area of the central orifice by its perimeter, and the quotient is at once the length of the throat and the breadth of the blades.

The dotted lines in Fig. 119 are here introduced to illustrate what we mean by the term "throat area," and it will be seen to be the analogue of the surface of a cylinder which if too short, causes a constriction, and then the volume of air entering a fan can only be determined by this area, it being smaller than that of the central orifice, or orifices, or the orifice of discharge.

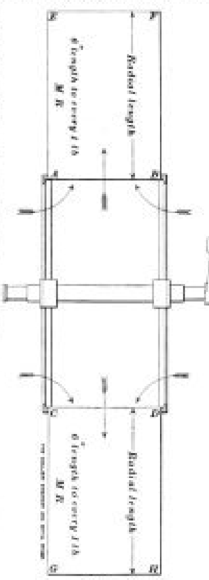

Fig. 120.

78. The Correct Orifice for Measuring Quantities.—While this fact is before us let us repeat in a decisive manner that in every case, the quantity of air flowing through a fan must be found with the smallest of the three orifices, that is, the central, the throat, or the discharge orifice; and to make no mistake about it let us call the smallest orifice d, and therefore, if the area of the central orifice is the least, then it is d, or if the throat area is least, then take it for d, or if the orifice of discharge is least, take it for d, as for example in the case of a Guibal fan where the area of discharge, or that uncovered by the shutter is generally smaller in area than the orifice of entry.

79. The Required Breadth of Fan Blades.—So far then we are in a position to calculate the breadth of the fan blades by taking for our unit of the intake areas the assumed number 1,300, and relying on it until it is proved to be correct, let us proceed to find the central and throat areas, as follows: When the required volume of the ventilation is 150,000 cubic feet of air per minute, then $\frac{150,000}{1,300} = 115 +$ square feet the areas required. If the air enters at one side only, then the diameter of the central orifice is $\sqrt{\frac{115}{.7854}} = 12.1$ feet, or if it has two central orifices their diameters will be $\sqrt{\frac{115}{.7854 \times 2}} =$ 8.56 feet.

Now in the first case for a single orifice the breadth of the blades should be as follows: $\frac{115}{12.1 \times 3.1416} = 3.025$ feet, and in the second case the breadth of the blades for two central orifices should be $\frac{115}{8.56 \times 3.1416} = 4.276$ feet.

No doubt can be entertained concerning these calculations, but our great aim just now is to forewarn and forearm our readers about the possibility of the area in the throat of a fan being the smallest, and, therefore, the gauge by which quantities passing through the fan are to be measured.

No advantage is gained by making the area of the throat greater than that of the central intake, but a great advantage is gained by producing a large central area of intake with a minimum radius, because this provision does not reduce the radial *length* of the blades as shown in Fig. 120 at $A\ E$ and $C\ G$. The breadth of the blades is seen to be equal to $A\ B$ and $C\ D$. The diameters of the orifices of entry are seen to be equal to $A\ C$ and $B\ D$.

80. The Radial Length of Fan Blades.—The thing, however, of the greatest importance in this figure is the radial length of the blades, and the scale that determines this proportion is derived from the mine resistance, and, therefore, to secure the best results with the

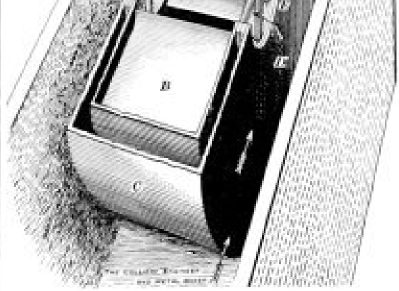

Fig. 121.

lowest peripheral velocity, we find that for every one pound on the square foot of mine resistance, at least six inches should be given to the radial length of the fan blades, and this fact, coupled with that of the area of the orifices of entry, establishes the negative and positive conclusions, that if the orifices of entry are too small to obtain a given volume of air, the fan must run faster to generate within itself a greater depression, and if the blades are too short, then the fan must run faster to make the required depression. Here, then, we can no longer doubt the propriety of large orifices of entry, and we further see that short blades in a fan give a short motive column, and positively, therefore, the larger we make the area of intake and the longer we make the blades, the lower will be the peripheral velocity at which the fan will do its work. Fig. 121 is an illustration, partly in plan and partly in perspective, of a ventilating fan constructed to intake air at both sides, as at P and E. Two of the blades are marked B and B. The fan is covered with a case C, built in the fan drift D and D. A glance at the figure shows at once the advantage of the double entry and the large blades, but here the word *large* suggests the possibility of something being overlarge, and as assumptions are of little value unless they can be afterward sustained, let us try to discover when the blades of a fan are over large, and when they are too small, and thus remove the ambiguity from the assumed number 1300, out of which we determined the area of the central and throat ports of entry, and the breadth of the blades. First then to make the blades too large, let us use two large fans to do the work of one, the mine resistance being the same for two as for one. This being the case, two fans would not, and could not in any way increase the volume or quantity of air circulating in the mine, because to increase the quantity, the velocity, the resistance, and the pressure must all be increased, and you cannot increase the one without increasing the other. Again as the blade surface is increased the velocity of the fans will be reduced, and the question arises, how much? Let us suppose that the velocity of one fan is 80 revolutions per minute, and that with that speed the total difference of potential between the ejected air, and the depression in the fan drift is 13 pounds per square foot, the mine resistance being 10 pounds per square foot. Now if we set two fans to do the same work as the single one, the mine resistance for the same quantity at the same velocity in the mine will still be 10 pounds per square foot, and all the two fans can do, is, to reduce the difference $T - M = 13 - 10 = 3$. Now the reduction by the two fans will be as $\frac{1^2 \times 3}{2^2} = \frac{1 \times 3}{4} = .75$, therefore, with the two fans T would *appear* to be 10.75, but with such a small difference of potential, other and serious resistances arise in the running of the two fans.

Now on the face of it there appears to be a real advantage gained by practically doubling the area of the blades and that of the ports of entry, because only half of the air is entering each of the two fans, that previously passed through the port of entry and along the blades of one fan; and further, if no new resistance interfered, the velocity of each of the two fans would be, if the single fan was 80 revolutions per minute, $\sqrt{\frac{10.75 \times 80}{13}} = 72.72$ revolutions per minute, and we now see that by still further increasing the number of fans, or the sizes of the ports and blades of one fan, the difference between T and M might be reduced almost to nothing. But another enemy of these subtle refinements steps in and calls halt!!, and that is the "state of instable equilibrium."

81. The Loss by Wave Movements in Fans.—With large ports of entry and discharge, the difference between T and M becomes very small because the air enters and leaves the fan or fans at a very low velocity, and let us suppose by way of illustration that we have six fans doing the work of one. Now the mine resistance would be the same for six as for one fan, therefore if one fan made 80 revolutions per minute, each of the six would have to make at least 70 revolutions per minute to sustain the required depression. It is true that only one sixth of the air would pass through one of the six fans, that would pass through the fan that did the whole of the work, and it might therefore be thought that the six fans would conjointly do no more work than the single fan; but this is not so, because the difference between T and M has become less than one pound on the square foot, instead of three pounds as before and the result is the smallest variation in the velocities of the engines produces wave motions that considerably increase the work to be done.

82. The Loss of Energy Due to Intermittent Action.—When resistance has to be overcome by intermittent efforts, the loss of effective energy is considerable, and to explain fully what we mean Fig. 122 is

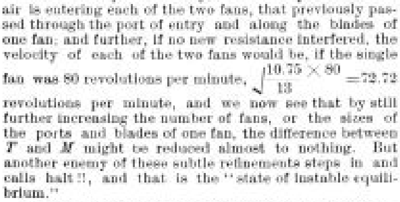

Fig. 122.

introduced. A and B are two rowers who apply their energy intermittently with their oars; now the resistence that a boat meets with in progressing through water varies as the *cubes* of the velocities and therefore the velocities vary as the cube roots of the powers, and it is now our business to show that a force continually applied, propels a boat at a greater mean velocity than the same force would do applied intermittently, for the following reasons that will be given in proportionate, instead of actual values. Suppose then a rower applies for the propulsion of his boat a power of 125 units of work every alternate second of time. We see that during one second 125 units are applied, while during the next second the momentum of the boat and its load is consumed in its own propulsion, it therefore follows that the mean velocity of the boat will be $\sqrt[3]{125} \div 2 = 2.5$. But if $\frac{125}{2} = 62.5$ units of work are applied continuously instead of 125 intermittently, the mean velocity will be $\sqrt[3]{62.5} = 4$ nearly. Or while a continuous power will propel the boat 4 miles, the same power applied intermittently will only propel it 2.5 miles. Now what is true of the boat is also true of the fan, for the power producing mine ventilation varies as the cubes of the velocities, and as a jerking pulse, or wave motion takes place in the air stream flowing through a fan in which the orifice of discharge is *too large*, and therefore the difference between T and M is *too small*, we have a cause of intermittent action as in the boat. All mine currents move pulsatively, and very markedly so, when the resistance is considerable, and when therefore the difference of potential already referred to is small, the jerky pulsations of the mine current enter the fan and react on the engine, and the result is, such a fan, as an open one with a *very large* area of discharge, gives out a small percentage of efficiency. The loss of energy in the fan often arises from another cause, as where the blades are too short, and therefore the fan has to be run at a high velocity to obtain the required difference of potential, and the result is the velocity of the fan is constantly varying as the engine passes through full crank, and the dead points.

It was to remedy this very pronounced wave motion in the Guibal fan, that the Walker shutter was introduced. The wave movements in a fan sometimes synchronise and the result is a loud note. The writer has heard the loud moaning, or roaring sound of a fan at the Letch Colliery near Moorsley, County Durham, England, a mile away.

83. The Best Dimensions for Ventilating Fans.—To secure good results in a fan then, the blades must be of sufficient length and breadth to prevent the loss due to wave motion; and to make the difference between T and M sufficiently large, the areas of the orifices of entry and discharge must be made such a size that they will on the one hand reduce resistance, and yet on the other hand not make that resistance so small that the difference of potential will not be sufficient to prevent the instability of equilibrium. The areas that secure the best results then are for the central port of entry $\frac{Q}{1300} = A$. Here Q is the required ventilation in cubic feet per minute, 1300 a constant, and A = the area in square feet. For the throat of the fan $\frac{Q}{1300} = A$, and for the port of discharge $\frac{Q}{2600} = a$.

To find the breadth of the blades of a fan, divide $\frac{Q}{1300}$ by the circumference or perimeter of the central port of entry and the quotient will be the required breadth of the blades correctly.

Fig. 123 is given to clearly establish in the mind of

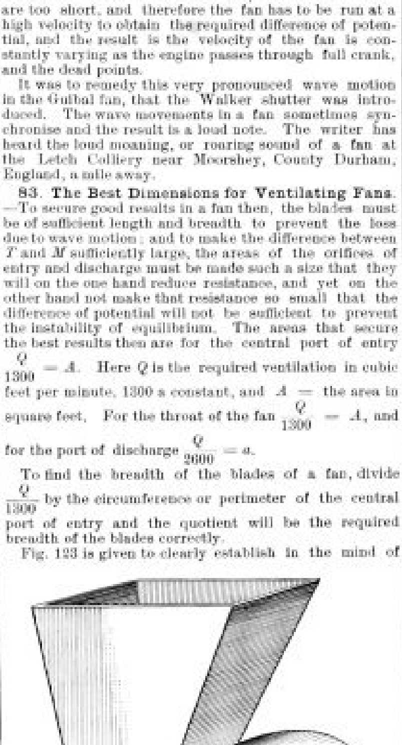

Fig. 123.

the reader the characteristic depressions and the pressure of discharge as exemplified in the action of the fan.

First. The depression in the fan drift measured by the gauge D D.

Second. The depression in the fan as shown by the gauge F D.

Third. The pressure of discharge as indicated by the gauge S P.

Now to understand the values of the three measurements, call the depression for injection i and the compressions for ejection e, then $M - i + e = T$, or $T - M = e - i$, assuming that $M - i$ is the zero of pressure. When the port of entry is equal in area to the port of discharge, then the depression below M is equal to the compression above the atmosphere, and then the air passing through the fan moves pulsatively, and when the area of discharge is greater than that of the intake as in the open running fan, then the air flowing through the fan dances tumultuously and wastes the energy that should do useful work. Further, when e is at a higher pressure above the atmosphere than i is at a pressure below M, then the fan does its work with economy.

84. The Laws of the Areas of the Fan Ports.—Fig. 124 furnishes to the eye at a glance the conviction that the air passing up the upcast shaft S will never be greater than that due to the pressure producing the ventilation of the mine, and therefore, if one, two or twenty fans, were made to exhaust out of the same drift, unless their velocity was such as to first balance the mine resistance, which might be say 10 pounds per square foot, the velocity of the mine current would reduce, and although i and e, would both be reduced, because the united areas of the ports of entry would conjointly make

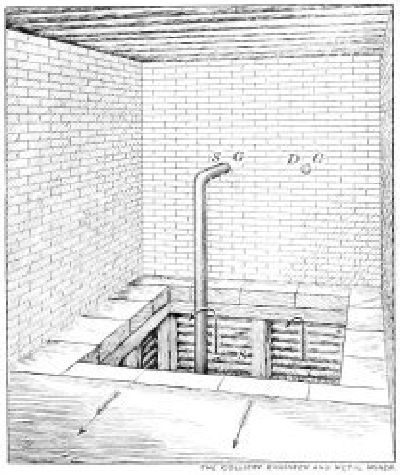

Fig. 124.

a large one, and the united areas of the ports of ejection would do the same, yet the loss of energy would be considerable, as the result of the united port of discharge being *over large*, and e being too small to check the intermittent flow through the fans. It does seem to be a paradox that two fans should make nearly the same number of revolutions as a single one, and yet exhaust no more air from the mine, and yet it is so, and we have made the reason plain by posing and transposing, until we have found x.

Before leaving this figure let us notice another interesting feature in it, namely, the water gauge connections as DG, that is made to measure directly the depression in the fan drift, and SG that measures the depression due to the mine only. A pipe from SG is carried 20 or 30 feet down the shaft, and always gives a *little* less reading than DG.

85. To Calculate the Diameter of a Fan.—The diameters of fans for exhausting certain volumes of air can be found as follows, but, let us first notice that the dimensions furnished by the rule are reliable deductions.

Let Q = the ventilation in cubic feet per minute, then $\sqrt{\frac{Q}{200}} = D$. D being the diameter. Suppose then we require a fan for a quantity of 200,000 cubic feet of air per minute, then $\sqrt{\frac{200,000}{200}} = 31.16$ feet the diameter of the fan required.

Or the rule is, divide the required quantity in cubic feet per minute by 200, and the square root of the quotient is the diameter of the fan required.

86. Recapitulation of Facts.—1. Obstructions in front of the orifice of entry reduce the constant .65.

2. There are three ports in a fan, namely, the central, the throat and the port of discharge, and the smallest of these must be taken for calculations.

3. To find the volume of air passing through a fan, multiply the smallest of the three ports in square feet, by the calculated velocity of the air in feet per minute, and the result will be the volume of the ventilation in cubic feet of air per minute. Note carefully, the orifice taken must be the least of the three.

4. To find the *minimum* radial length of the blades of a fan, allow 6 inches in the radial length, for every pound in the pressure per square foot of the mine resistance. If possible, 7 inches per pound of resistance is best, because it gives a lower peripheral velocity. Suppose the resistance to be 10 pounds per square foot, then $10 \times 6 = 60$ inches, or five feet, the required radial length of the blades.

5. The area in square feet of the central orifice or orifices of entry should be, when Q stands for the quantity of air in cubic feet per minute, $\frac{Q}{1,300} = A$ = area of port of entry.

6. The area in square feet of the cylindrical entry in the throat of the fan should be $\frac{Q}{1,300} = A$ = area of the throat.

7. The maximum area of the port or ports of discharge should be $\frac{Q}{2,600} = A$.

8. The diameter required for a fan should be $\sqrt{\frac{Q}{200}} = D$.

9. The loss that arises when a ventilating force is applied intermittently is the result of wave motion.

10. The small advantage obtained by setting two or more fans to do the work of one, is the result of M remaining the same for an unaltered velocity.

87. Recapitulation of the Former Article.—First, to obtain T, find the diameter of gyration by the following method: Add to the diameter of the central port of entry the radial length of the blades, and the sum is the required diameter of gyration. Suppose the diameter of the central port of entry is 10 feet and the radial length of the blades is 5 feet, then $10 + 5 = 15$.

To find the velocity of the center of gyration in feet per second, and also T, when the velocity, diameter, areas of the ports and lengths of the fan blades are given.

Let $W = .0766 \times B$, B being the length of the fan blades.

v = the velocity in feet per second.

g = the gravitation unit 32.16.

P = the total pressure in pounds per square foot of the tangential force produced by the fan. Then $\frac{W v^2}{3.1416\, g} = T$. As an example, let the diameter of the fan be 20 feet, the length of the blades 5 feet and the number of revolutions per minute 70. Now, to generate a constant that will ever after save time and trouble, let us make a full statement, and let the letter c be set before every *recurring* factor, and then we can proceed at once with the reduction, as

$$\frac{15 \times c\,3.1416 \times 70 \times 15 \times c\,3.1416 \times 70 \times 5 \times c\,.0766}{c\,60 \times c\,60 \times c\,3.1416 \times c\,32.16} = T.$$

Now the constants in the order of their places in the dividend and divisor are

$$\frac{3.1416 \times 3.1416 \times .0766}{60 \times 60 \times 3.1416 \times 32.16} = .00000208.$$

The true result is .0000020785528, therefore, .00000208 is a little too much, but in this form it is easy to remember. Now to find T, let

B = the length of the blades in feet,

R = the revolutions per minute;

D = the diameter of gyration in feet;

C = the .00000208.

Then $B R^2 D^2 C = T$, or $B R^2 D^2 \times .00000208 = T$, and in the case suggested $5 \times 15^2 \times 70^2 \times .00000208 = 11.466$ or we may say that T is equal to 11.466 pounds pressure per square foot above the depression in the fan drift.

Second. To find the velocity in feet per second of the air entering or leaving a fan, the number 1,800,000 was introduced to expedite the calculations, and it was shown that this number represents the square of the velocity in feet per second of air rushing into a vacuum; and it was further shown that the squares of all other velocities are in the same proportions to 1,800,000, as the pressures that generate them. For example, suppose the pressure setting air in motion is equal to 4 pounds per square foot, and if in this case there are no qualifying factors that interfere, like the depression in the fan drift, or the still greater depression in the fan itself, then the squares of the velocities will be directly in proportion, as 4, the pressure per square foot given, to 2120 the pressure in pounds per square foot of the atmosphere,

then $\frac{4}{2120} \times 1,800,000 = 3396.2264$. This means that a pressure of 4 pounds per square foot sets air in motion with a velocity, whose square is 3396.2264, or with a velocity that is equal to $\sqrt{3396.2264} = 52.277$ feet per second.

It would be noticed in our last lesson that the equivalent of the pressure of the atmosphere was given as 2130 instead of 2120. The reason of this is the 10 pounds are added to balance a slight variation with regard to the center of gyration, and thus prevent a very intricate calculation that would be required to correct a relatively small error.

Third, it was shown that the rush of air into the orifice of entry of an exhaust fan, could be calculated by the expression $\frac{(T - M) \times 1,800,000}{(2130 + M^2)} = v^2$, and that the expression for a blowing fan was $\frac{(T - M) \times 1,800,000}{(2130 + M)} = v^2$. Further it was shown, that the velocity in feet per second multiplied by 60 for feet per minute, and that product multiplied by the area of the orifice of entry in square feet, gave the cubic feet per minute passing through the fan.

Fourth, it was explained that the density of air varied inversely as the temperature, and directly as the pressure, and that the weight of air entering a fan was always equal to the weight of air discharged by it, but the velocity of the air entering a fan was always greater than the velocity of that discharged and in the case of an exhaust, the squares of the velocities were in the proportion of $\frac{T - M}{2130 + M^2}$ and for a blowing fan $\frac{T - M}{2130 + M}$.

CHEMISTRY OF MINING.

68. Electric Modes of Action.—Electric energy is characterized by four phases that are known as positive, negative, static, and dynamic electricity, and all the manifestations of this force are the resultants of the conjoined action of all the phases. For example, positive electricity is attracted by the negative phase, and therefore when the static positive particle is attracted by the negative static particle, their approach becomes a dynamic manifestation. Static electricity is the mode or phase of the force that takes the form of potential or static energy, and may become dynamic or kinetic, or active, or transposed force, according to the conditions that control it, for example Fig. 111 is an applied illustration of what is meant, and here the monkey or drop weight of the pile driver is raised by a chain subject to a *static* strain equal to the gravity of the monkeyweight. In the weight itself energy is in the course of being stored up potentially during the period of lifting, and when the weight reaches its highest elevation it is detached from the chain by being unfastened automatically, when it descends as a dynamic force or the medium of kinetic energy. If a weight falls it is capable of exerting great force through a small distance, but the foot pounds of energy developed never exceed what is due to the earth's attraction.

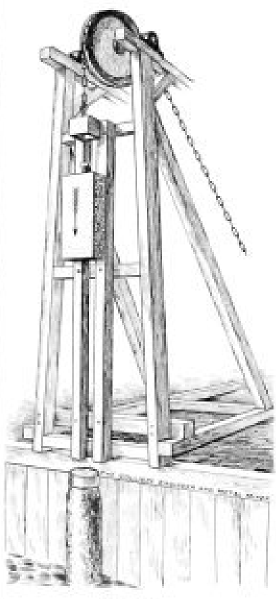

FIG. 111.

Energy in this case is inert, and for that reason *foot* pounds become *inch* pounds, if the force is consumed by its exertion through one inch of space. For example, if 100 pounds fall from an elevation of 100 feet then the energy stored up in the moving mass is equal to 10,000 foot pounds, that is to say this falling body can exert a mean force of 10,000 pounds through the space of one foot, or a force of $10000 \times 12 = 120,000$ pounds through the space of one inch, or a force of $120\,000 \times 8 = 960,000$ pounds through the space of an eighth of an inch, or a force of $120,000 \times 100 = 12,000,000$ pounds through the one hundredth of an inch. We see then that the force stored up in a moving mass could be infinitely multiplied, through an infinitely small space, but for the elasticity of matter within the range of molecular attraction.

Static electricity is only another mode of inert force, and in every respect is the result of the operation of the same mechanical laws, and its mode of action should therefore be known, if we wish to acquire a useful knowledge of electrical appliances; for example, in the transmission of electrical energy for the purpose of doing work in mines, we are doing very well, if 50 per cent. of the horse power of the steam engine driving the generating dynamo is utilized in useful work, and we may therefore inquire what has become of the other 50 per cent. that is lost, and the answer is, it has been dissipated as heat developed by the resistance produced by static induction, for you cannot send a current of dynamic and yet intermittent or pulsating electricity through a wire without starting and stopping the synchronic motions of the constituent molecules, the result is, the manifestation of an opposing inert force.

If you do not understand the laws of static charge, you will try to do what is impossible, that is to recover the lost 50 per cent. of work, and if you understand the resistance due to static charge you will seek to improve electric generators by reducing the intermissions in the inducing impulses, so as to minimize the loss due to molecular inertia. A flash or electric discharge of static electricity from a cloud will split a tree, and rend and shatter the noblest artificial structures, but it is after all, only an example of a relatively small inert force, exerted through a small distance such as the expansion of the sap in the vesicles of the wood of the tree, and the expansion of the metal binding, or the moisture in the mortar in the joints of the stones of a building, or even in the stones themselves. Fig. 112

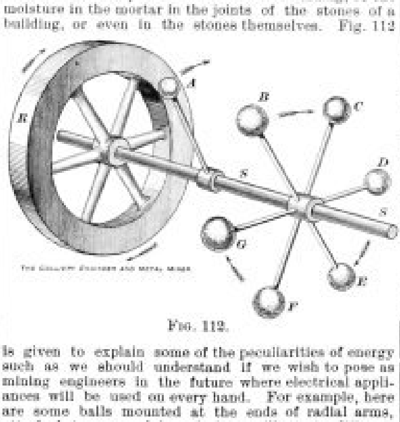

FIG. 112.

is given to explain some of the peculiarities of energy such as we should understand if we wish to pose as mining engineers in the future where electrical appliances will be used on every hand. For example, here are some balls mounted at the ends of radial arms, attached to a revolving shaft, to illustrate different electric voltages or pressures and the corelated coulombs or masses.

The particle A, may then be taken as one ampere, and its velocity may be such as to develop one joule of energy, which may be given out as pressure through a foot, an inch or less, or more, and what is said of A may be said of B, C, D, etc., with the correction in view that energy stored in six masses would be six times greater than that stored in one, and, therefore, the energy stored in the wheel R, would be as many times greater than that stored in the ball A, as R is times heavier than A. Here, however, is the puzzle. When these masses attain a stationary velocity they cease to accumulate energy, and they cannot give out ever so small a fraction of this energy without losing a portion of their velocity, so that for the balls and the wheel to take in and give out energy, their velocity must be alternately accelerated and retarded, or their motion, instead of being uniform, must be intermittent; and this peculiarity characterizes all electrical actions.

For example you cannot send an electric current through a cable, and the molecules of the wire remain at rest; and further we see, that if the molecules have a uniform rotary motion, they could not transmit energy; therefore, the molecules to continue the transmission must have an alternate vibration, and such is actually the case. Indeed the current is generated by the alternate movements of the poles of the armature of the dynamo. Fig. 113 is to illustrate the curious manifestations of continuity and alternation such as take place in an electric conductor.

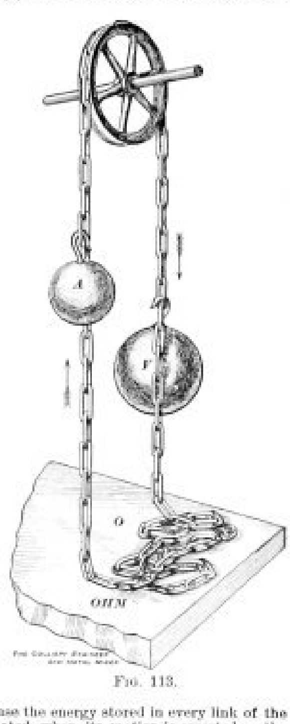

FIG. 113.

Here a chain passing over a pulley is used to illustrate the points before us. First we have an illustration of uniform velocity, the descending weight V does not accelerate in falling, because the energy stored in every link of the chain is dissipated when its motion is arrested on the slab O, and the energy of V is balanced by setting in motion the links in succession on leaving the slab, and the loss of energy due to the stopping and starting of the links is the analogue of that waste of electrical energy, that is measured by ohms, and is shown in a graphic manner by the piles of links at rest on the slab at *OHM*. We cannot close this lesson, however, without drawing attention to the great fact in relation to electric conductors, namely, they always consist of metals or their alloys, or simple bodies such a carbon, in which the vibrating or alternate movements of the molecules, can synchronize as electric waves.

MINING METHODS.

The Inertia of Moving Air.—The Pressure and Velocities of Air Currents.—Inertia of Air in the Shafts of Mines.—Measuring the Force of the Wind.—The Pressure of the Wind.—Regulator Experiments.

66. The Inertia of Moving Air.—Nothing is more important in the study of mining subjects than the acquisition of applied or practical knowledge in relation to the laws of air in motion, and we therefore now propose to so treat the subject as to make the numerical values we ought to know, clear and intelligible.

The force required to make air move or to arrest its motion, varies as the squares of the current velocities. That is, if you double the *square* of the velocity you require double the pressure to produce that result, and perhaps the best explanation will be found in applicate examples. First then, the square of the velocity of air rushing into a vacuum, is equal to 1,800,000, or it may be said that air rushes into a vacuum with a velocity of 1341.6411 feet per second.

Now as the pressures vary as the squares of the velocities of moving air currents, it is clear that if we knew the pressure per square foot at which air at atmospherit pressure rushes into a vacuum, we could with differenc pressures find the squares of the velocities coincident to to these pressures.

For example, the pressure of the atmosphere in pounds per square foot is 2120, and with the aid of a clear knowledge of the laws of energy and the values 1,800,000 and 2120, we can find the pressure due to the inertia of air moving at any velocity, or having the pressure given, we can find the velocity in every case.

67. The Pressures and Velocities of Air Currents.—Suppose the pressure per square foot of an air current is equal to 8 pounds, what is the square of the velocity that generated this pressure? The following simple statement will be sufficient to establish the conclusion by convictior, for it is clear, the 8 pounds are only a small fraction of the 2120 pounds and that 2120 will be in the same proportion to 8, that 1,800,000 is to the square of the required velocity, then $\frac{8}{2120} \times 1,800,000 = 6792.4516$ the required square, and the velocity in feet per second will therefore be $\sqrt{6792.4516} = 82.4166$.

We might ask the question, what pressure per square foot will set air in motion at the rate of 82.4166 feet per second? Now we know that the pressures vary, not as the velocities, but as the squares of the velocities in feet per second, and as the square of 82.4166 is 6792.4516., this square must be a fraction of 1,800,000 and therefore $\frac{6792.4516 \times 2120}{1,800,000} = 8$ nearly, or as the decimal portion of the number 6792.4516 in not finite, the result appears a very small fraction under its value.

68. Inertia of Air in the Shafts of Mines.—In the upcast shaft of a mine ventilated with a fan many experiments can be tried to demonstrate the laws of energy in relation to air currents, and to strengthen the evidence of the fact Fig. 115 is introduced. Now, let the round

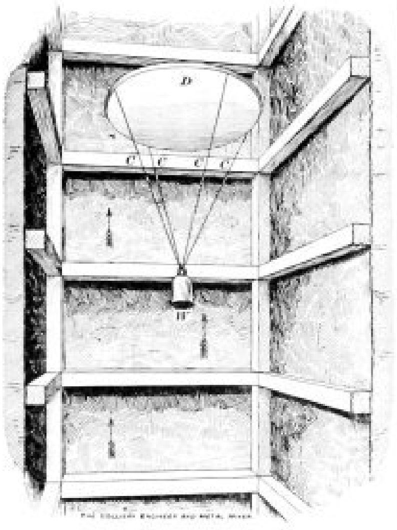

Fig. 115

disc of wood D be two feet in diameter, and let it and the cords c, c, c, c, and the weight W weigh all together 10 lbs.

From the standpoint of ordinary observation, say the flying of a kite, 10 pounds seems a great weight but in the open air the currents we most commonly observe are parallel to the plane of the horizon and therefore the direction of their motion is not favorable for lifting weights, but in the case before us, the current has a vertical upward motion, and therefore, advantage can be taken of the energy of this current for lifting the weight in question. First then, let us find the area of the disc in square feet and then from this number of square feet we will be able to find the weight per square foot to be lifted. The disk is 2 feet in diameter, then, $2^2 \times .7854 = 3.1416$ square feet and the weight to be lifted per square foot is $\frac{10}{3.1416} = 3.183$ pounds.

The velocity of the air in feet per second to lift this weight then is $\sqrt{\frac{3 \cdot 183 \times 1,800,000}{2120}} = 52$ nearly.

69. Measuring the force of the wind.—Fig. 116 is to illustrate the deflection of a board whose length $C A$ is 24 inches, and breadth 18 inches, and and total weight 7 pounds. This figure furnishes a good example for the training of the judgment to deal with questions relating to the inertia of fluids, and therefore let us suppose that the conditions of the problem are, in addition to those already given, that the board is by the force of the wind blown 30° out of plumb, and that we require the velocity of the air that produced this deflection.

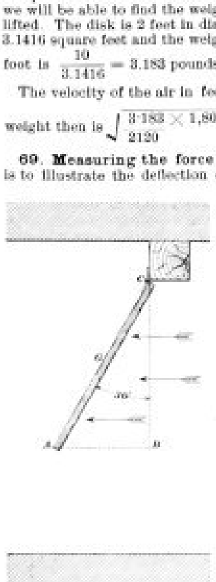

Fig. 116.

First find the weight per square foot of the board, thus $\frac{2 \times 1 \cdot 5}{7} =$ ·42857 of a pound.

Second as the board is suspended at the edge C, the wind will only lift half its weight, because the centre of gravity G is situated midway between C and A, therefore the weight lifted by the wind will only be $\frac{.42857}{2} =$ ·214285 of a pound.

Third the fraction of the weight lifted by the wind, will be directly proportionate to the sine of the angle $A C B$, then the force of the wind per square foot vertical will be, Sine 30° × ·214285.

Fourth, the length of the surface on which the wind impinges will be proportionate, not to $C A$ but to the cosine of the angle $A C B$, then the pressure deflecting the board per square foot vertical, will be

$\frac{\text{Sin } 30° \times \cdot 214285}{\text{Cos. } 30°}$ = the pressure required, but $\frac{\text{Sin}}{\text{Cos}}$ = Tan, then the Tan 30° is .5773503 and the pressure per square foot is .214285 × .5773503 = ·12372 of a pound, and the velocity of the air current that will deflect a board 2 feet long and 1.5 feet broad and weighing 7 pounds, from the plumb line, through an angle of 30°, must be $\sqrt{\frac{\cdot 12372 \times 1,800,000}{2120}} = 10 \cdot 25$ feet per second.

It is not necessary that the angle through which the board is deflected from the plumb line should be known, because if the horizontal distance through which the board is moved is found to be 12 inches as from A to B, and the length of the vertical or cosine line $C B$ is found to measure 20.7846 inches, then the tangent can be found at once, as $\frac{12}{20.7846} = .5773503$. All we have to do is to multiply half of the weight of the board by this tangent and then proceed to find the square of the velocity as already explained.

Suppose the length of the vertical line $C B$ is 12 inches and the length of the horizontal line $A B$ is 20.7846 inches, and the weight and dimensions of the deflected board are as before, then the tangent of the vertical angle $A C B$ is $\frac{\text{Sin.}}{\text{Cosin}} = \frac{20.7846}{12} = 1.73205$, and we find the pressure per square foot of the wind that would thus deflect the board is .214285 × 1.73205 = .3711523 pound, and the required velocity is therefore $\sqrt{\frac{.3711523 \times 1,800,000}{2120}} = 17.75$ feet per second.

70. The Pressure of the Wind.—Fig. 117 is an illustration that is co-related in principle with the other examples already given, and the aim of the figure is to

Fig. 117.

show how the volume of air passing through a regulator may be found with the help of the water gauge. Suppose then that the regulator shutter is open to the extent, that it uncovers an area of 2 square feet, and that the difference in pressure between one side and the other of the regulator stopping is equal to one inch of water gauge, what volume of air in cubic feet per minute will pass through this regulator?

To solve this problem, first find the velocity in feet per second that would generate a pressure of 5.2 pounds on the square foot, as $\sqrt{\frac{5.2 \times 1,800,000}{2120}} = 66.446$, the velocity in feet per second; second, the volume of air passing through the regulator can be found by multiplying the velocity per minute by the area uncovered in square feet, and by the equivalent of the *vena contracta* .65, and 66.446 × 60 × 2 × .65 = 5182.8, the cubic feet of air per minute passing through the opening in this regulator shutter.

71. Regulator Experiments.—To understand the principle of action of the regulator let us try an experiment with one, and discover what takes place when the shutter uncovers different areas for the passage of different volumes of air, and therefore in the first place let us assign values for the airway in which the regulator stopping is fixed.

1. The length of of the airway is 900 yards.
2. The section of the airway is 6 by 10 feet.
3. The volume of air passing before the regulator stopping was interposed was 36,000 cubic feet per minute.
4. The difference of pressure or the difference of potential between the opposite ends of the airway is equal to 1 inch of water gauge or 5.2 pounds pressure on the square foot.
5. The volume of air passing through the uncovered area of the regulator is 3,600 cubic feet per minute.
6. The vertical depth of the shutter is 16 inches.

Experiment one. Find how far open the regulator shutter must be for the passage of this quantity.

First notice that if 3,600 cubic feet pass through the shutter they also pass through the airway, and will therefore encounter a resistance from this cause, which will be proportionate to the squares of the quantities, and it follows that the difference of potential for the opposite sides of the regulator stopping will now be as $5.2 - \left(\frac{5.2 \times 3,600^2}{36,000^2}\right) = 5.2 - \left(\frac{5.2 \times 1}{100}\right) = 5.148$ pounds.

Second, notice that the velocity through the regulator must be $\sqrt{\frac{5.148 \times 1,800,000}{2120}} = 66.113$ feet per second, or per minute 3966.78 feet, and allowing .65 for the *vena contracta*, the square feet in the orifice of the regulator will be $\frac{3,600}{.65 \times 3966.78} = 1.3962$, and as the vertical depth of the shutter is 16 inches the amount it is open will be $\frac{1.3962 \times 144}{16} = 12.566$ inches.

Experiment second. Find how far the regulator shutter should be open for the passage of 20,000 cubic feet of air per minute, all the dimensions being the same as before. Then,

$$5.2 - \left(5.2 \times \frac{20,000^2}{36,000^2}\right) = 5.2 - \left(5.2 \times \frac{25}{81}\right) = 3.6,$$

then, $\sqrt{\frac{3.6 \times 1,800,000}{2120}} = 55.2865$, the velocity in feet per second, and the velocity per minute is 3317.19. The opening of the regulator then, is equal to

$$\frac{20,000 \times 144}{.65 \times 3317.19 \times 16} = 83.481 \text{ inches.}$$

Experiment three. Let the dimensions be the same as before, except those of the shutter, because the result will be too large for inch measure, and let us now calculate for a quantity of 30,000 cubic feet of air passing through the regulator per minute, then,

$$5.2 - \left(5.2 \times \frac{30,000^2}{36,000^2}\right) = 5.2 - \left(5.2 \times \frac{25}{36}\right) =$$

1.589 pounds, then, the velocity in feet per second must be as $\sqrt{\frac{1.589 \times 1,800,000}{2120}} = 36.731$, and the velocity per minute is 2203.847, then, $\frac{30,000}{.65 \times 2203.847} = 21$ square ft.

Experiment four. Continue the same dimensions, and let the volume passing through the regulator be 35,000 cubic feet of air per minute, then,

$$5.2 - \left(5.2 \times \frac{35,000^2}{36,000^2}\right) = 5.2 - \left(5.2 \times \frac{1225}{1296}\right) =$$

.285 pounds, and the velocity in feet per second will be $\sqrt{\frac{.285 \times 1,800,000}{2120}} = 15.556$, and the velocity per minute is 933.35, then, the opening required in this regulator is $\frac{35,000}{.65 \times 933.35} = 57.692$ square feet.

By these four experiments with the regulator, we learn the true principles of its mode of action, namely, the difference of potential on the opposite sides of the regulator stopping varies in the following proportion, when P is the difference of potential for the entire airway, and Q is the quantity through the unobstructed airway, and q is the quantity passing through the regulator, then $P - \left(P \frac{Q^2}{q^2}\right) = p$, for in this case p is the difference of potential at the regulator. It is clear then, that as the velocity in the airway increases, the difference of potential at the regulator decreases, and at last the constriction of the regulator vanishes, as in example four where we see, just as 35,000 is nearly 36,000 so 57.692 square feet are a very near approach to 60 square feet.

The most important lessons learned by these experiments are, first, as we have just seen, that the regulator vanishes into the equivalent orifice; second, that the volume of air passing through a regulator *cannot* be correctly calculated unless we can first determine the difference of potential, or the difference of current pressure on the opposite sides of the regulator stopping.

[TO BE CONTINUED.]

Pitch Glaciers.

Professor W. J. Sollas recently gave an address on "Pitch Glaciers or Poissiers," with illustrations of glacier movements, by the aid of lantern slides. He said that pitch and glacier ice strikingly resemble each other in behaving as solids or liquids according to their manner of treatment. On the sudden application of force they are very brittle, but behave as fluids when subjected to gradual pull and pressure. Hence it is possible to employ pitch in the construction of working models of glaciers, in order to get an insight into those internal movements of actual glaciers which are beyond the reach of direct observation. The study of glacial deposits has shown that many erratic boulders were transported during the glacial period from lower to higher levels hundreds of feet, and left stranded on the flanks of mountains. This standing difficulty in the way of physical theories of glacier movement has been explained by the study of pitch models, by means of which it is found that the lower layers of material, in approaching an obstacle, are carried up in an ascending current. The inference, which is confirmed by natural facts, is that similar movements would certainly take place in actual glaciers. Further, a glacier sometimes over-rides its terminal without disturbing it; and in one experiment this was exemplified, for pitch flowed for several months over a ridge of loose material, without carrying a particle of it away.—*The Colliery Guardian.*

The New York, New Haven & Hartford Railroad Company, New Haven, Conn., have recently added two more automatic railways of the Hunt type (C. W. Hunt Company, New York City, manufacturers) to their already complete system.

Mr. F. C. VanDuzen, late superintendent of the Stewart Iron Co's. plant at Uniontown, Pa., has been appointed general manager of the Crozer Coal and Coke Co., at Elkhorn, West Va..

MISCELLANEOUS.

THE SUN'S HEAT.

The Persian recognizes in the sun, not only the great source of light and warmth, but even of life itself and the advances of modern science ever tend to bring before us with more and more significance the surpassing glory with which Milton tells us the sun is crowned, and the prodigality with which it pours forth its radiant treasures.

An intelligent gardener once reasoned that the sun could not be a hot glowing body. He said:

"If the sun were a source of heat, then the closer you approach the sun the warmer you would find yourself. But this is not the case, for when you are climbing up a mountain you are approaching nearer to the sun all the time, but, as everybody knows, instead of feeling hotter and hotter as you ascend, you are becoming steadily colder and colder. In fact, when you reach a certain height, you will find yourself surrounded by perpetual ice and snow, and you may not improbably be frozen to death when you have got as near to the sun as you can; therefore, it is all nonsense to tell me the sun is a scorching hot fire."

I asked him wherein lies the advantage of putting his tender plants into his greenhouse in November. How does that preserve them through the winter? How is it that even without artificial heat the mere shelter of the glass will often protect plants from frost? I explained to him that the glass acts as a veritable trap for the sunbeams; it lets them pass in, but it will not let them escape. The temperature within the greenhouse is consequently raised, and thus the necessary warmth is maintained. The dwellers on this earth live in what is equivalent, in this respect, to a greenhouse. There is a copious atmosphere above our heads, and that atmosphere extends to us the same protection which the glass does to the plants in the greenhouse. The air lets the sunbeams through to the earth's surface and then keeps their heat down here to make us comfortable. When you climb to the top of a high mountain you pass through a large part of the air. This is the reason why you feel warmer on the surface of the earth than you do on the top of a high mountain. If, however, it were possible to go very much closer to the sun; if, for example, the earth were to approach within half its present distance, it is certain that the heat would be so intense that all life would be immediately scorched away.

The earth on which we stand is no doubt a mighty globe, measuring as it does 8,000 miles in diameter; yet if the earth be represented by a grain of mustard seed, then on the same scale the sun should be represented by a coconut. Perhaps, however, a more impressive conception of the dimensions of the great orb of day may be obtained in this way. Think of the moon, the queen of the night, which circles monthly around our heavens, pursuing, as she does, a majestic track at a distance of 240,000 miles from the earth. Yet the sun is so vast that if it were a hollow ball, and if the earth were placed at the centre of that ball, the moon could revolve in the orbit which it now follows, and still be entirely enclosed within the sun's interior.

For every acre on the surface of our globe there are more than 10,000 acres on the surface of the great luminary. Every portion of this illimitable desert of flame is pouring forth torrents of heat. It has indeed been estimated that if the heat which is incessantly flowing through any single square foot of the sun's exterior could be applied under the boilers of an Atlantic liner, it would produce steam enough for an entire record breaking voyage from Ireland to America. It would seem very presumptuous for us to assume that the great sun has come into existence solely for the benefit of poor humanity. The heat and light daily lavished by that orb of incomparable splendor would suffice to warm and illuminate, quite as efficiently as the earth is warmed and lighted, more than two thousand million globes each as large as the earth.

What should we think of the prudence of a man who, having been endowed with a splendid fortune of not less than $20,000,000, spent one cent of that vast sum usefully and dissipated every other cent and every other dollar of his gigantic wealth in mere aimless extravagance? This would, however, appear to be the way in which the sun manages its affairs, if we are to suppose that all the solar heat is wasted save that minute fraction which is received by the earth. Out of every twenty million dollars' worth of heat issuing from the glorious orb of day, we on this earth barely secure the value of one single cent, and all but that insignificant trifle seems to be utterly squandered. We may say it certainly is squandered so far as humanity is concerned. No doubt there are certain other planets besides the earth and they will receive quantities of heat to the extent of a few cents more. It must, however, be said that the stupendous volume of solar radiation passes off substantially untaxed into space, and what may there become of it science is unable to tell.

And now for the great question as to how the supply of heat is sustained so as to permit the orb of day to continue in its career of such unparalleled prodigality. Every child knows that the fire on the domestic hearth will go out unless the necessary supplies of wood or coal can be duly provided. The workman knows that the devouring blast furnace requires to be stoked incessantly with fresh fuel. How, then, comes it that a furnace, so much more stupendous than any terrestrial furnace, can continue to pour forth in perennial abundance its amazing stores of heat without being nourished by continual supplies of some kind? Prof. Langley, who has done so much to extend our knowledge of the great orb of heaven, has suggested a method of illustrating the quantity of fuel which would be required, if indeed it were by successive additions of fuel that the sun's heat had to be sustained.

Suppose that we extracted from the earth every ton of coal it possesses in every island and in every continent, and that this vast store of fuel, which is adequate to supply the wants of this earth for centuries, were to be accumulated in one stupendous pile and that an army of stokers were employed to throw this coal into the great solar furnace. How long, think you, would so gigantic a mass of fuel maintain the sun's expenditure at its present rate? I am but uttering a deliberate scientific fact when I say that a conflagration which destroyed every particle of coal contained in this earth would not generate so much heat as the sun lavishes abroad to ungrateful space in the tenth part of every single second. During the few minutes that the reader has been occupied over these lines a quantity of heat which is many thousands of times as great as the heat which could be produced by the ignition of all the coal in every coal pit in the globe has been dispersed and totally lost to the sun.

As the sun shines to-day on the earth, so it shone yesterday; so it shone in the earliest dawn of history; so it shone during those still remoter periods when great animals flourished which have now vanished forever, and during that remarkable period in earth's history when the great coal forests flourished; so it shone in those remote ages many millions of years ago when life began to dawn on an earth which was still young. There is every reason to believe that throughout these illimitable periods which the imagination strives in vain to realize, the sun has dispensed its radiant treasures of light and warmth with just the same prodigality as that which now characterizes it.

We all know the consequences of wanton extravagance; and the expenditure of heat by the sun is the most magnificent extravagance of which human knowledge gives us any conception. How have the consequences of such awful prodigality been hitherto averted? How is it that the sun is still able to draw on its heat reserves from century to century, ever squandering two thousand million times as much heat as that which genially warms our temperate regions, and draws forth the exuberant vegetation of the tropics, or which rages in the Desert of Sahara? This is indeed a problem.

It was Helmholtz who discovered that the continual maintenance of the sun's temperature is due to the fact that the sun is neither solid nor liquid, but is to a great extent gaseous. His theory of the subject has gained universal acceptance. Nature has not one law for the rich and another for the poor. The sun is shedding forth heat, and therefore, affirms this law, the sun must be shrinking in size. We have learned the rate at which this contraction proceeds, for among the many triumphs which mathematicians have accomplished must be reckoned that of having putting a pair of callipers on the sun so as to measure its diameter. We thus find that the width of the great luminary is ten inches smaller to-day than it was yesterday. Year in and year out the glorious orb of heaven is steadily diminishing at the same rate. For hundreds of years, aye, for hundreds of thousands of years, this incessant shrinking has gone on at about the same rate as it goes on at present. For hundreds of years, aye, for hundreds of thousands of years, the shrinking still will go on. As a sponge exudes moisture by continuous squeezing, so the sun pours forth heat by continuous shrinking. So long as the sun remains practically gaseous so long will the great luminary continue to shrink, and thus continue its gracious beneficence. Hence it is that, for incalculable ages yet to come, the sun will pour forth its unspeakable benefits; and thence it is that for a period, compared with which the time of man upon this earth is but a day, summer and winter, heat and cold, seedtime and harvest, in their due succession, will never be wanting to this earth.—*Condensed from Article by Sir Robert Ball in N. Y. Sun.*

THE WORLD'S TALLEST STRUCTURES.

The tallest chimney was built at Port Dundas, Glasgow, Scotland, 1857 to 1859, for F. Townsend. It is the highest chimney in the world (454 feet), and one of the loftiest masonry structures in existence. It is, independent of its size, one of the best specimens of substantial, well made brick work in existence. In Europe there are only two church steeples that exceed this structure in height—namely, that of the Cologne Cathedral (510 feet) and that of the Strasburg Cathedral (468 feet). The great Pyramid of Tizeh was originally 480 feet, although not so high at present. The United States outtops them all with its Washington Monument, 550 feet high, and the tower of the Philadelphia Public Buildings, which is 537 feet high.

The Eiffel Tower, at Paris, France, surpasses all other terrestrial metal structures with its altitude of nearly one thousand feet. The "Great Tower," for London, England, in course of construction from designs of Mr. Henry Davey, C. E., will outtop all metal structures, being built of steel, and its extreme height will be 1,250 feet when finished.

The highest and most remarkable metal chimney in the world is erected at the imperial foundry at Halsbrucke, near Freiberg in Saxony. The height of this structure is 452.6 feet, and 15.74 feet in internal diameter, and is situated on the right bank of the Mulde, at an elevation of 219 feet above that of the foundry works, so that its total height above the sea is no less than 711.75 feet. The works are situated on the left bank of the river, and the furnace gases are conveyed across the river to the chimney on a bridge through a pipe 3,227½ feet in length.

The highest artifical structure in America is the water works tower at Eden Park, Cincinnati, O. The floor of the tower, reached by elevators, is 522 feet above the Ohio River. The base is 404 feet above the stream. If the height of the elevator shaft be added to the observation floor the grand total height is 589 feet.

The highest office building in the world is the Manhattan Life Insurance Company of New York city; its height above the sidewalk is 347 feet, and its foundations go down 53 feet below the same, being 20 feet below tidewater level, making a total of 400 feet. The foundations consist of fifteen masonry piers, and are carried by the same number of steel caissons. The latter were sunk to bedrock by the pneumatic process. The cantilever system was used for the foundation. —*From Machinery.*

WHAT ALL BOYS SHOULD KNOW.

Don't be satisfied with your boy's education or allow him to handle a Latin or Greek book until you are sure that he can—

Write a good legible hand.
Spell all the words he knows how to use.
Speak and write good English.
Write a good social letter.
Add a column of figures rapidly.
Make out an ordinary account.
Deduct 16½ per cent. from the face of it.
Receipt it when paid.
Write an ordinary receipt.
Write an advertisement for the local paper.
Write an ordinary promissory note.
Reckon the interest or discount on it for days, months or years.
Draw an ordinary bank check.
Take it to the proper place in a bank to get the cash.
Make neat and correct entries in day-book and ledger.
Tell the number of yards of carpet required for your parlor.
Measure a pile of lumber in your shed.
Tell the number of bushels of wheat in your largest bin, and the value at current rates.
Tell something about the great authors and statesman of the present day.

If he can do all this, and more, it is likely he has sufficient education to make his own way in the world. If you have more time and money to spend upon him all well and good—give him higher English, give him literature, give him mathematics, give him science, and if he is very anxious about it, give him Latin and Greek, or whatever the course he intends pursuing in life demands.—*School Supplement.*

BENEATH THE FINGER NAILS.

There is something more than beauty and attractiveness to be considered in caring for the finger nails. Beneath them is a space which forms a nidus or resting-place for bacteria. Bacteriologists have found a score or more of different kinds of organisms under the nails, many of them harmless, it is true, but some of them exceedingly dangerous to health and life. Since they are microscopic in size, no one can tell whether they are innocent or harmful, or, indeed, whether they are present or absent.

Since a pin prick suffices to convey into the human system enough of the most poisonous germs of disease to cause death, it is easy to understand what evil results may follow a scratch with a germ-laden finger nail. An idea has gone abroad that the danger lies in being scratched by another person; but since the trouble is due to bacteria and not to any poison residing in the nail itself, it is easy to see that a self-inflicted scratch may be as bad as any other.

Many instances are recorded where a slight wound, like the prick of a needle under the nail, has been the means of introducing the germs which cause that painful trouble known as whitlow or felon.

He who bites the finger nails takes the risk of getting into his mouth and swallowing the germs of some infectious disease; for bacteria may be anywhere and the nails have a peculiar aptitude for scraping up particles of dust and dirt, which may be swarming with germs. The surgeon who goes to the performance of any cutting operation, realizing the danger which lurks beneath the nails, cleanses them in the most thorough manner.

Disease germs, once introduced into the human organism, become travellers. They do not stop at the point of infection, but once in the circulation, may go anywhere and live, even for years, waiting their opportunity for growth when the normal tone of the system is lowered by chill, by fatigue, or some other disturbing cause.

There is no better method of cleansing the nails than with a good brush and plenty of soap and water, and without the use of a brush it is impossible to have clean, wholesome nails. Not alone will the result obtained be pleasing to the eye, but the danger of becoming the bearer of disease to one's self is thereby lessened.—*Youth's Companion.*

SENSATIONS EXPERIENCED IN FALLING.

Dr. Heim, the celebrated geologist and professor of the Zurich University, declares that sudden death by a fall, by being run over, or by being swallowed up by machinery, water or by snow avalanche is the most beautiful way of leaving this life— is indeed preferable to any other mode or fashion of departure for the unknown regions.

He gives the following description of his journey down a mountain side, which, as he fully expected, would end in certain death:

"I was coming with two friends from the summit of the Santis in St. Gallen, when, at the height of 5,400 feet, we found ourselves opposite a snow field lying between two mighty rocks that had to be traversed. It was a perilous path, running apeak for several miles, it seemed. My companions hesitated to take it, but I decided to slide down on both feet, standing up boldly. I went down with unequalled velocity, but there was no danger until I made a movement to save my hat, which the current of air was carrying along. I fell and lost all control of my limbs.

"Quick as the wind I flew against the rocks to my left, rebounded, and was thrown upon my back, head downward. Suddenly I felt myself carried through the air for at least 100 feet, to finally land against a high snow wall. At the instant I fell it became evident to me that I was to be thrown against the rock, and I did my utmost to avert that calamity by digging with my fingers in the snow and tearing the tips of them horribly without knowing it. I heard distinctly the dull noise produced when my head and back struck against the different corners of the rock; I also heard the sound it gave when my body bounded against the snow wall, but in all this I felt no pain; pain only manifested itself at the end of an hour or so.

"I reckoned that my descent down the mountain side lasted five or six seconds. It would take me two hours to describe the thoughts and feelings I underwent during this short space of time. And all my thoughts, notions and ideas were thoroughly consistent and coherent, not mixed up and jumbled up as in dreams. First, as already intimated, I saw the possibility of my fate. I calculated to myself: Ten to one I will be a dead man upon my arrival at the bottom of the mountain. If, however, I find myself alive and fully conscious I will have to take some of the vinegar-ether, which, on leaving the Santis, I placed in my vest pocket. A good thing, I mused to myself, that it is where it is. I would scarcely be able to reach for it if it was still in my knapsack, where I used to carry it. I will take two or three drops of the ether on my tongue, I continued in my thoughts. That will revive me and keep me from taking cold. But what about my stick? Ah, that may be useful if I live, and besides, it is a beautiful Alpenstock. I will keep it. And, true enough, I held on to it. Then I thought that it might be well to take off and throw away my spectacles, that they might break and injure my eyes, I reached for them, but was unable to do as intended.

"Thus I spent several or maybe only one precious second in egotistical circumspection. After that my thoughts turned upon the consequences which my death would have for my family. I must try to save myself for the sake of my wife and children, I argued. The friends that were with me are probably lamed by terror, and I must double their energies by calling for help, if I can. A good way to spur them, I thought, would be to cry out, 'I am all safe, but must have a drink at once.' Then I managed to be present when the news of my death reached home. I heard my wife and children cry and lament, and I tried to condole with them. I even cracked jokes in this endeavor. Again I saw with my mind's eye the confusion that would reign in the university on account of my failure to begin lecturing. That brought back to me all my struggles, my early training, my trials and small triumphs. My life, from childhood to manhood, glided past my mental observation like a living picture, vivid, impressive, joyful and sorrowful, as it had been. Tableau followed tableau in quick succession, each figure being distinct, and incidents being perfectly and completely pictured. When I had arrived at my present state and condition I saw a magnificent blue heaven opening to receive me. All was serene happiness, while rosy and violet clouds marked the horizon. Into this heaven I floated with perfect equipoise, with beautiful anticipation, while my mundane eyes perceived my body flying through the air, and saw the snow field below. I heard a dull thud; I had struck the ground.

"It is an open question to me whether the above described sensation of going to heaven is not a very strong argument for the teachings of the Christian religion. The mind of man becomes clear and pure on the threshold of eternity; it becomes the most wonderful machinery for thought and observation. Its retrospective facilities are marvelous. Can its prognostics be waved aside?

"After finishing off all earthly affairs and making peace with man, the independent soul sees the heavens open; all around is beauty and happiness—a world steeped in blue and roseate tints. I should say here that I am far from being a pronounced religious man. At no period of my life have I been given to speculating much on the teachings of the Church, but when about to die I experienced all those sensations which are ascribed to deeply devout persons during their last moments on earth.

"To return to actualities, I will repeat that during my downward journey time seemed to stretch indefinitely, and the faculties of objective observation, subjective feeling and thinking worked simultaneously without interfering with each other. There was no confusion, no perplexity; my calculations were logical; I acted with lightning rapidity.

"I thought to do so, too, when I began to cry out, as intended, 'I am safe, bring me water,' or words to that effect, but I had actually lain perfectly still, without the least mental or physical performance, for over half an hour before I gave that sign of returning life. My friends who had watched me from above and afterward sat at my side for a considerable time say so. Without seeing them I took the vinegar bottle from my vest pocket, reached for my spectacles that rested at my side, and felt of my back and limbs to find out if any bones were broken. The fact that I failed to notice my friends, and did not even look at them, is explainable only on the theory that I continued thinking where I had left off my selfish calculations when unconsciousness overcame me; it was instinct of self-preservation that dominated my feelings upon regaining life. Forty minutes I had been dead to the world and to myself, and at the termination of this period I was the same selfish being as before. I cried for help, because, having no recollection of the comatose state in which I had been, I thought my friends at least a mile or two away, as they were at the time I reached the foot of the mountain."

And did the heavenly thoughts re-occur to you, also? the professor was asked.

"No," said Dr. Heim. "I experienced them only at the moment of standing on the threshold of eternity. Then my soul rose gloriously to the occasion, but the certainty of death being removed, my material instincts and spirits triumphed." —*The Inter-Ocean.*

HOW MACCARONI IS MADE.

Maccaroni is divided into thirteen classes, though each is the product of the same batch of flour and the same kneading, but vary they in size, shape and general appearance. Among Italian gourmets they are known as mezzani, forati, frenetti, trenetini, foralini, spaghetti, spaghettin, rigatoni, seme di melloni, rosa marina, stellini, tubetini and acine di fippi. The visitor to a factory is confronted by a big iron lathe arrangement with a cylinder the size of an ordinary snare drum at the business end. Through the center of this lathe slowly revolves a powerful screw.

Flanking the entrance are stands shoulder high, upon which rest strings of "maccaroni," strung over bamboo rods. The mixing trough is a box 6x4 feet. It has a depth of one foot. Here is where the first steps are taken.

With a regularity born of long practice flour is gradually mixed beneath the water faucets and kneaded by hand until it reaches a consistency and toughness that human strength cannot overcome. Then the batch, which is the size of a wash tub, is carried over to the "final kneader." This kneader is a curiosity. There is a solid block with protected sides, and into this the batch of dough is deposited. Hinged to the block, but getting a "spring" from a rope passed over a hickory stick braced to the wall, is a 14-foot "joist" of hard wood. For five feet of its length this joist is cut wedge shape. This wedge exactly covers the block upon which the "batch" rests. The remainder of the joint is squared and furnishes a seat for the "kneaders."

All being in readiness, the joist is swung to one end of the batch, and two or three men plant themselves on the square end. Then follows a performance that resembles the old-fashioned see-saw. Quickly, but with never failing regularity, the kneaders rise and fall on the joist, but each time push it in a circle a few inches. This is kept up until the "chief" is satisfied with the consistency of the mass. Without the loss of a minute the bare-legged and bare-chested kneaders carry the batch to the iron drum at the end of the lathe. In it goes with a rush. The "engineer" slips an iron disk that just fits the cylinder against the mass, and by the pressing of a button starts the electric dynamo.

Slowly the long screw revolves until its head is firmly against the disk. Then the mass is forced against the lower end of the drum, with irristible pressure.

This lower end is perforated at regular intervals with round openings the size desired, and from these openings come a miniature Niagara of sinuous dough. As the white stream reaches the accepted length it is broken off by a dexterous twist and doubled over a bamboo rod.

As quick as possible the rod with its 50 pounds of maccaroni is taken down into the cellar and put on the rack. There it remains about four days, or until thoroughly hardened. Then comes the packing and shipping.—*Boston Globe.*

SOME CURIOUS FACTS CONCERNING HEARING.

An inquiry was recently made in London as to the greatest distance at which a man's voice could be heard, leaving, of course, the telephone out of consideration. The reply was most interesting and was as follows: "Eighteen miles is the longest distance on record at which a man's voice has been heard. This occurred in the Grand Canon of the Colorado, where one man shouting the name 'Bob' at one end his voice was plainly heard at the other end, which is eighteen miles away. Lieutenant Foster, on Parry's third artic expedition, found that he could converse with a man across the harbor of Port Bowen, a distance of 6,696 feet, or about one mile and a quarter; and Sir John Franklin said that he conversed with ease at a distance of more than a mile. Dr. Young records that at Gibraltar the human voice has been heard at a distance of ten miles."

Sound has remarkable force in water. Colladon, by experiments made in the Lake of Geneva, estimated that a bell submerged in the sea might be heard a distance of more than sixty miles. Franklin says that he heard the striking together of two stones in the water half a mile away. Over water or a surface of ice sound is propagated with great clearness and strength. Dr. Hutton relates that on a quiet part of the Thames near Chelsea he could hear a person read distinctly at a distance of 140 feet, while on the land the same could only be heard at 76 feet. Professor Tyndall, when on Mont Blanc, found the report of a pistol shot no louder than the pop of a champagne bottle. Persons in a balloon can hear voices from the earth a long time after they themselves are inaudible to people below.—*From Harper's Round Table.*

NOVEL PROTECTION AGAINST FIRE.

A merchant of Gowanda has invented a most remarkable apparatus for saving stocks of goods from fire. Instead of of putting out the fire the apparatus opens the front of the store, and the counters, cases, and shelving roll out into the streets into their owner's arms.

The shelving and counters in the store are all portable, and mounted on rollers. Attached to the rear end of the shelving is a cable which runs forward and over a wheel below the floor in the front of the store. To this end of the cable are suspended weights sufficiently heavy to overbalance the shelving, cases, and goods in them. A break device keeps the weights from setting the machine going. Attached to the lever of the brake is a combustible cord which passes upward into the store and is carried along the walls and ceiling, where it will be quickly ignited in case of fire. The sundering of the cord looses the brake, the weights bear on the cable, and the shelves start helter skelter for the front of the building. At the same time the windows and doors open automatically outward, and the entire contents of the store are dumped on the sidewalk in a jiffy. To frustrate the designs of fire thieves the shelves fold up when they reach the street, presenting only blank wood and glass.

Those who have seen the apparatus tested say that it works admirably. One night a mouse found something palatable in the brake cord and gnawed it in two, whereupon, much to its consternation, the furniture, boxes, and shelves with one accord began a swift movement forward, and an automatic alarm attached to the machine began to rouse all the the inhabitants of Gowanda, the hour being 2 o'clock in the morning. The ingenious inventor was one of the first on the scene, and his disgust at being routed out by a false alarm was greatly mitigated by the spectacle of the smooth working of his machine. It seems to be a good thing, and pushes itself along with no help.—*From the Buffalo Courier.*

A BEDROOM "WIND-CURTAIN."

To get plenty of air into a sleeping room at night without the cold or damp wind blowing directly upon the bed is necessary alike for comfort and health.

The familiar device of a board fitted to set tightly into the window-frame underneath the raised lower sash answers for extremely cold nights; but it does not give enough air in moderate weather. On the other hand, if a severe wind is blowing upon the opened window, although the temperature may not be very low, the strong current is too trying for most sleepers.

To those who wish to enjoy the open window at night, and yet to be defended against a direct current of air, the wind-curtain will be valuable.

About a foot above the window-stool, on both edges of the casings, insert diagonally a pair of two-inch screw hooks. Being on the outside edges of the casings, they do not mar the wood, and are unnoticed during the day. Prepare a light curtain-pole, say an inch in diameter, and insert screw-eyes to correspond with the hooks. The pole may be a regular curtain-pole with brass knobs, or a bamboo pole, or a humble broomstick—painted, however, we will hope.

Hang upon this pole, either by rings, or by a broad hem through which the pole is thrust, a short curtain of burlap. This coarse cloth is suggested because of its very openness; while breaking the force of the wind, it admits much of it in a gentle way. This may be trimmed tastily with a half-inch hempen rope, or with cat stitching.

To prevent the curtain from flapping in the wind, sew to it a pair of small rings, which can be loosely attached to another pair of small hooks screwed on the under side of the window-stool at its extremities.

The chief admission of air will not be through the interstices of the coarse burlap, but above and around it, from the three or four-inch space between it and the sash. A shawl or an afghan may be thrown over the pole instead of a regularly hung curtain, and will answer the purpose equally well. In the morning the pole is lifted from its inconspicuous hooks, and stored away in the closet out of sight.

If it is preferred to have the window opened at the top, the same contrivance may be used—the window-shade being run up out of the way, and thus preserved from flapping or from damage by rain.—*Youth's Companion.*

SOMETHING ABOUT FIRE ENGINES.

What is, perhaps, the oldest known fire-engine for pumping water, is mentioned in the Spiritalia of Hero, about 150 B. C. This engine had two single acting pumps, the plungers of which were worked by a single beam pivoted between the two. The streams united in a single discharge pipe, passing up a trunk in which was an air chamber, and out at a nozzle which could be turned in any direction. This description might stand for a great many forms of hand fire-engines used even to the present day. The early Romans appear to have paid quite some attention to fire extinguishing apparatus, and had an organized fire brigade.

Something like the more modern fire engine appears to have been brought out in the early part of the sixteenth century; and is described as a "water syringe." This was mounted on wheels, and was worked by levers. Fire engines of this kind were apparently much used in Germany. In England, during the latter part of the sixteenth century, large brass syringes were employed, holding several quarts of water, and operated by three men, two holding the syringe at each side with one hand and directing the nozzle with the other, and the third operating the plunger. After having discharged the water, the syringe was refilled from a cistern or well near the fire, or from buckets. Later, these water squirts were fitted to portable cisterns or tanks.

In the latter part of the seventeenth century a portable engine, mounted on a cistern or tank, from which the water was drawn, was introduced in England by Newsham. This engine was, in many respects, similar to the modern hand fire engine, and continued in use in England up to 1832.

The Newsham engine was, perhaps, the first successful fire engine, and really was the pioneer of the modern, manually operated engine. The pumps were of various sizes and designs, and were, in most cases, operated by levers. Various forms of engines, similar to the Newsham engine, continued in use as late as 1850.—*Joseph Sachs in Cassier's Magazine.*

THE EVILS OF OVER-EATING.

I assert that it is the duty of the good housewife to keep down the appetite of her husband. Particularly is this necessary in the cases of well-to-do professional and business men. In the families of mechanics earning low wages such a warning is almost wholly unnecessary, but it may be said of most men in good circumstances that they eat too freely of rich food. If men would begin careful and systematic physical culture in early youth and continue the practice through life, good health would be the result. Beyond the age of forty—at a period when so many are physically lazy—the superior value of exercise is apparent; but ordinarily, this is just the time when the hygiene of athletics is neglected. There is no reason why a punching-bag, rowing-machine, pulley-weights and other apparatus should be relegated to college boys and clerks. But having done a good deal of work in his time it is almost impossible to persuade a business or professional man, turning forty, to give any sort of attention to physical culture if such training has been previously neglected. Hence, I say it is the duty of a woman to keep from her husband all rich compounds that will ultimately ruin his digestion. High feeding is occasionally neutralized by hard exercise; but in the absence of the latter it is mischievous in the extreme. If your husband will stand the treatment, begin by switching off from the heavy breakfast of steak, hot rolls, potatoes, etc. and set before him eggs-on-toast, oatmeal and coffee.—*Rev. F. S. Root, in Ladies' Home Journal.*

FLORIDA'S ALLIGATOR FARMS.

The attention of the United States Fish Commission has been called recently to a new and remarkable industry, namely, the artificial propagation of alligators. For supplying the trade in Florida curiosities there is a large demand for young reptiles of this kind. In Jacksonville, which is the centre of the traffic, from 8,000 to 10,000 alligators are sold to tourists annually—nearly all of them baby ones. The latter are collected in considerable numbers by professional hunters, who receive for them from $20 to $25 a hundred. Some of them are disposed of alive at retail, but many are stuffed. An infant alligator stuffed is worth twenty-five cents more than a live one. Saurians six to twelve feet long fetch $12 to $25.

The difficulty of securing young alligators in sufficient numbers has led to the establishment of the strange business described. To find the nests of these reptiles is comparatively easy, and the eggs are shipped in bulk by the hunters to Jacksonville. In that city there are twelve dealers in alligators, the best known of them being a man who has earned the sobriquet of "Alligator Davis." It was he who originated the incubator system, which is simple enough. The eggs, about the size of goose eggs, are placed in boxes of sand and covered up. The boxes are exposed on a roof to the torrid rays of a semi-tropical sun, and in a few days the lizards are hatched. They are six inches or so in length when they make their first appearance in the world. Some of them are killed and stuffed as soon as they see daylight.

A species of true crocodile is found in southern Florida on both coasts. It is hardly distinguishable from the alligator except by the shape of its head, though it grows bigger, attaining a length of eighteen feet. Dr. Hugh M. Smith of the Fish Commission says that young crocodiles are hatched for market in the same fashion. The mother crocodile lays her eggs in sand like a turtle, and simply covers them over. Somewhat different is the practice of the maternal alligator, who, in April or May, seeks a sheltered spot on a bank and there builds a small mound. The foundation of the mound is of mud and grass, and on this she lays some eggs. She covers the eggs with another stratum of grass and mud, upon which she deposits some more eggs. Thus she proceeds until she has laid from 100 to 200 eggs.

The eggs, in course of time, are hatched by the sun, assisted by the heat which the decomposition of the vegetable material generates. As soon as they have "chipped the shell" the baby alligators are led to the water by the mother, who provides them with food which she disgorges, showing much anxiety for their safety. At this early period of their existence they are exposed to many dangers, being a favorite prey of fishes and turtles. Alligators' eggs, by the way, are sometimes eaten by the Florida Crackers. The robbing of the nests for market is helping to hasten the inevitable destruction of the alligator fishery, which has been an important and profitable industry in Florida. Facts recently gathered by the Fish Commission show that the reptiles cannot long escape practical extermination. Already they are becoming scarce, and the price of hides has gone up.

It is estimated that 2,500,000 alligators were killed in Florida between 1880 and 1894. In 1889 three firms, located at Kissimmee for the purpose of buying skins taken in the region between Lake Kissimmee and Lake Okeechobee, handled 30,000 hides. During the same year twelve hunters brought to Fort Pierce 4,000 pelts. Two firms in Jacksonville handled 30,000 skins in 1889. A few years ago an expert hunter could easily secure 600 alligators in three weeks, and one man at Cocoa killed forty-two in one night. The skins are paid for in provisions and ammunition mainly. Dealers get sixty-five cents apiece for them from tanners in New York.

In 1890 about 250 pounds of alligator teeth were sold, hunters receiving from $1 to $2 a pound for them. They are removed by burying the head and rotting out the teeth. Of the best teeth about seventy make a pound. The stuffing of alligators and the polishing of the teeth give employment to forty persons. Unfortunately, alligators grow very slowly. At 15 years of age they are only two feet long. A twelve-footer may be supposed reasonably to be 75 years old. It is believed they grow as long as they live, and probably they live longer than any other animals.—*From the Washington Evening Star.*

EDUCATING POWER OF DANGER.

A writer on high mountaineering thus praises the good effects of danger in this pursuit:

"There is an educative and purifying power in danger that is to be found in no other school, and it is worth much for a man to know that he is not 'clean gone to flesh pots and effeminacy.' It may be admitted that the mountains occasionally push things a trifle too far. But grim and hopeless as the cliffs may sometimes look when ebbing twilight is chased by shrieking wind and snow and the furies are in mad hunt along the ridges, there is ever the feeling that brave companions and a constant spirit will cut the gathering web of peril.

"Something may surely be urged in favor of a sport that teaches, as no other teaches, endurance and mutual trust, and forces men occasionally to look death in its grimmest aspect frankly and squarely in the face. Amongst the mountains, as elsewhere, 'the unexpected always happens.' It is the momentary carelessness in easy places, the lapsed attention or the wandering look that is the usual parent of disaster."

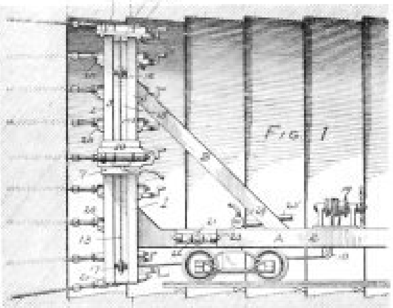
These words are worth remembering. There seems to be something enchanting in danger, and especially is this so to boys. What man now in mature life does not remember the dangers to which, as a boy, he has voluntarily exposed himself, and, after all, parents may comfort themselves that there is less danger to life in these dangers than in being shut entirely away from them. Danger educates boys to be careful, and this is very important to their lives in later years.—*Journal of Hygiene.*

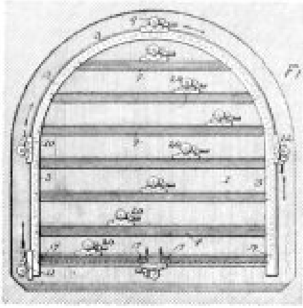
BIBLE MEASURES.

A day's journey was about twenty-three and one-fifth miles.
A Sabbath day's journey was about an English mile.
A cubit was nearly twenty-two inches.
A hand's breadth is equal to three and five-eighths inches,
A finger's breadth is equal to one inch.
A shekel of silver was about fifty cents.
A shekle of gold was $8.00.
A talent of silver was $538.30.
A talent of gold was $13,809.
A piece of silver, or a penny, was thirteen cents.
A farthing was three cents.
A mite was less than a quarter of a cent.
A gerah was one cent.
An ephah, or bath, contained seven gallons and five pints.
A firkin was about eight and seven-eighths gallons.
An omer was six pints.
A cab was three pints.—*Phila. Inquirer.*

TUNNELING APPARATUS.

No. 545,675. HARRY BRUNE, CHICAGO, ILL. *Patented Sept. 3rd*, 1895. Fig. 1 is a side view of the apparatus as it appears when at work in a heading; Fig. 2 is a rear view of the head frame. The method of driving a tunnel with this apparatus consists in cutting a channel groove around the sides and top of the heading, and blasting out the core thus left standing. The head frame 3, is shaped to suit the outline of the tunnel section, and it is tied together with a series of cross bars 4. It is supported upon a stout truck *A*, and is braced by bars *B*. The rim of the head frame has wide flanges, which are beveled on the edge to suit the saddles 7, of the channelling machines 9, 10, 11 and 12. These machines are connected to-

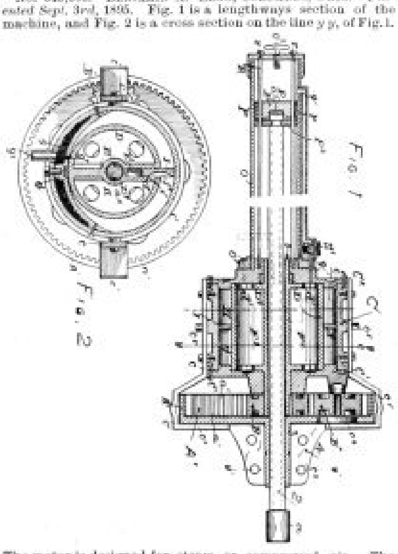




gether by means of a wire rope 13, which runs over suitable guide pulleys to a windlass 19. The whole set are thus fed laterally at the same time, by means of the windlass. The machines work at a sufficient angle to permit the drill cylinders to clear the standing edges of the preceding cuts, so that machines of ordinary make may be used. Shot holes are drilled in any number required, by drills 20, which are mounted on the cross bars 4. The air is received through the hose 25, into a manifold 24, from which a small hose leads to each machine. By closing the valve in 25 the entire machine is stopped. The machine is steadied when at work by side screw jacks 21.

MINE DRILL AND MOTOR.

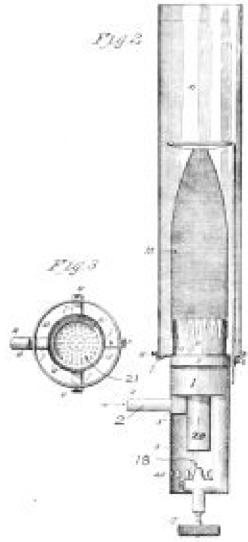
No. 545,596. BENJAMIN A. LEGG, COLUMBUS, OHIO. *Patented Sept. 3rd*, 1895. Fig. 1 is a lengthways section of the machine, and Fig. 2 is a cross section on the line *y y*, of Fig. 1.



The motor is designed for steam or compressed air. The drill spindle 2, is rotated by feathers in the hub 3, of the large gear *A'*, which is journalled in the bracket 4, and frame *C'*. The drill is fed up to its work by air or steam pressure acting upon the piston *P*, in the tube or cylinder *O*. The motor consists mainly of a barrel *D*, which revolves within the cylinder *C*. The chamber between them is divided by a partition *Y*. The barrel is turned by means of two pistons *J*, which slide back into suitable slots when passing the abutments *H* and *G*. The pistons are placed upon opposite sides of the barrel, so that when one is passing the abutment, the other is exerting full power. The steam or air is taken in through an annular groove in the cylinder head, and enters the barrel through the hole shown in its ends. When the piston *J*, is in good working position, a hollow *f'*, in its face, makes a communication from the interior of the barrel through the port *e'*, into the cylinder. The exhaust escapes at *g'*. The barrel has a projecting hub which carries a pinion *B*. Power is transmitted from this pinion to the wheel *A'*, by means of the idle wheel *B'*.

INCANDESCENT OIL LIGHT.

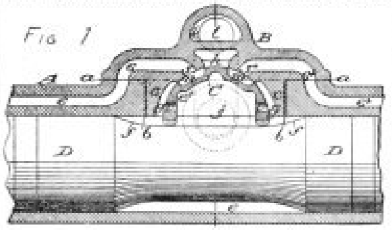
No. 545,398. CHARLES E. WHITE, KANSAS CITY, MO. *Patented Aug. 27th*, 1895. Fig. 2 is a side view partly in section; and Fig. 3 is a cross section near the top of the burner. Oil is supplied through the tube 2, to the chamber 1, which is maintained at a heat sufficient to vaporize it. The vapor escapes from the jet 18, and passes up the tube 20 accompanied by sufficient air to burn it. It is ignited above the burner cup 21, and burns with a thin pale flame which gives but little light, but which developes great heat. The burner

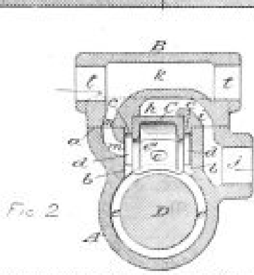


is enclosed by a cage or "mantle" 10, composed of a network of infusible threads. This is made by soaking a piece of coarse cloth of proper shape, in a solution of infusible earthy salts, and then destroying the cloth by incineration. The salts remaining form infusible threads. The heat of the burning gas causes the "mantle" to become highly incandescent, and to emit a strong white light. The light is free from all flickering, and the shadows cast by it are much softer than those from electric lights.

VALVE FOR ROCK DRILLS.

No. 545,738. HENRY C. SERGEANT, WESTFIELD, N. J. *Patented Sept. 3rd*, 1895. Fig. 1 is a section lengthways of the cylinder, and Fig. 2 is a cross section at the middle of the steam chest. The valve *C*, is circular in form and works on a concave seat. The valve comprises a little more than a half circle, and its ends are shaped to suit the shoulders *f*, of the drill piston *D*, which moves it at each end of the stroke. The steam or air is admitted to the annular chamber *c*, and passes

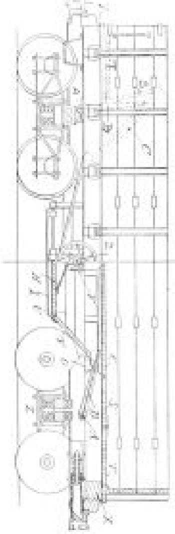




through the passages *g*, *g'*, to the ports 6, 6', according to the position of the valve. The exhaust passes out through the port *n*, and passage *i*, to the outlet *j*. Steam is received through either inlet *t*. By making the valve a full half circle, with its center at the outside of the bore of the cylinder, the working surfaces are brought nearly square to the direction of the pressure upon them, and the wear is greatly reduced, thus making the parts very durable.

ORE CAR.

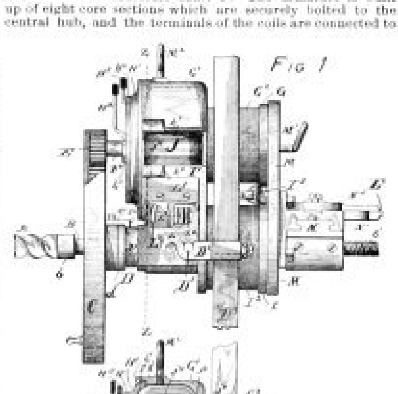
No. 542,831. DANIEL C. MULVIHILL, MARQUETTE, MICH. *Patented July 16th*, 1895. The drawing is a side view of the car, partly in section. The object of this invention is to provide a freight car for carrying ore or coal, having a suitable hopper bottom therefor; and which may be readily converted into a flat bottomed gondola, suitable for lumber or ordinary freight. The car frame has the usual side and middle sills, and two end sills. The middle cross sill *F*, is made of channel iron, having the flanges down. That part of the hopper which is below the frame is of ordinary construction. The sides *V* are permanent. The trap doors *H* are held up by chains, which are wound upon the shaft 2,

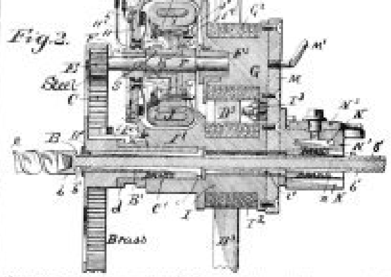


beneath the sill *F*. The end sections *T*, of the car floor are permanent. The hopper is covered by two lifting sections *C*, which are attached to the ends of the arms *B*. When it is desired to use the car for coal or ore, the arms *B* are raised by turning the rockshafts *A*, and the sections *C* are raised to the position shown by dotted lines at the left end of the car, thus forming an extension of the hopper. The lower edge of *C* then rests in pockets *O*, and the upper part is sustained by the sections *S*, which are turned up on edge for that purpose.

ELECTRIC MINE DRILL.

No. 545,570. HENRY H. BLISS, WASHINGTON, D. C. *Patented Sept. 3rd*, 1895. Fig. 1 is a side view of this machine, and Fig. 2 is a vertical section of the same. The drill spindle *B* is rotated by means of feathers *B'* in the hub of the main gear *C*. The feed motion is obtained by means of two half nuts *N*, which slide in a T groove in the bracket *N'*, and are closed or opened by means of a cam plate *N²*. The wheel *C* is of brass, and is driven by a steel pinion *E*, on the outer end of the armature shaft *F*. The armature is built up of eight core sections which are securely bolted to the central hub, and the terminals of the coils are connected to

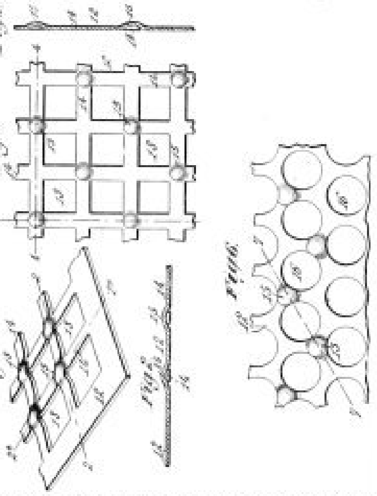




the commutator segments *S*, thus forming a "Gramme ring." The shaft is journaled in a brass block *F'*, which is sunk in the core *G* of the field magnet. The pole pieces *I'* and *G'* nearly enclose the armature, and the commutator is closed in and protected from dirt or injury by the plate *H*. The brushes *K* are attached to this plate, and means are provided for adjusting the pressure of the brushes from the outside and while running. The plate is turned to any desired extent by means of the handle H^1. By placing the armature out of center with the field magnet, the lower core J can be utilized to support the drill spindle, and the width of the machine, or the room required between the sides of the drilling post D^2, is reduced to a minimum.

SCREEN SEGMENT.

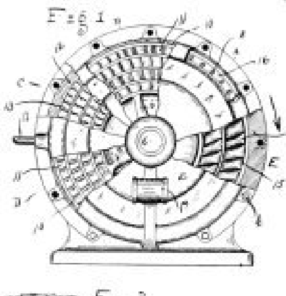
No. 543,780. John N. Pott, Chicago, Ill. *Patented July 30th, 1895.* Fig. 1 is a perspective view of a square meshed segment having this improvement; Fig. 2 is a section along the line 2; Fig. 3 is top view of another variety of mesh; Fig. 5 is a section through the same; and Fig. 6 is a top view of a round meshed segment. The object of this invention is to provide the working surface of a perforated-metal screen-plate with an effective arrangement of rounded protuberances, distributed at suitable intervals and located at intersections of the portions of metal left between the holes. By this construction there is provided an uneven screening-surface

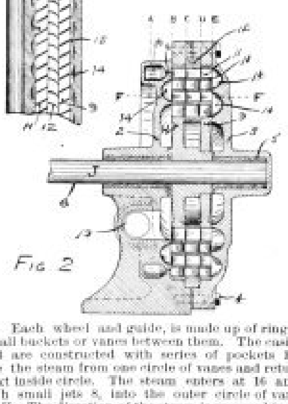


which will prevent the material being screened from passing over it in mass, and that will cause a slight undulatory movement in the said material, thereby assisting the smaller particles to descend to the surface of the screen, so that such as are small enough may readily pass through. The protuberances will also prevent the larger lumps of material from coming in contact with the sharp edges of the holes in the screen-plate, thereby avoiding considerable waste, as frail materials are liable to be broken by striking against such edges.

STEAM TURBINE.

No. 543,791. George C. Pyle, Indianapolis, Ind. *Patented July 30th, 1895.* Fig. 1 is a side view, having parts broken away to show various parts of the interior; Fig. 2 is a vertical cross section through the center; and Fig. 3 is a section on the line F. The two wheels H and 9 are similar in construction, and are keyed to the shaft J. Any number of wheels may be used. Between each pair of wheels there is a guide plate 12, having vanes which deflect the steam in a direction contrary to that in which it leaves the preceding

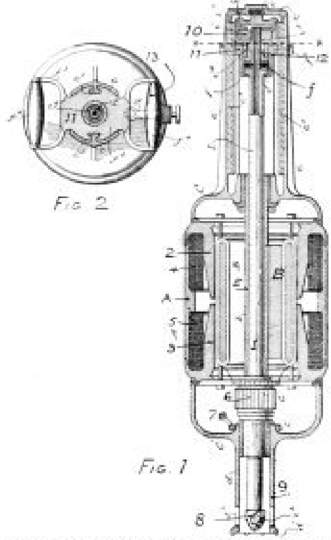




wheel. Each wheel and guide, is made up of rings 10, having small buckets or vanes between them. The casing plates 2 and 3 are constructed with series of pockets 14, which receive the steam from one circle of vanes and return it into the next inside circle. The steam enters at 16 and passes through small jets 8, into the outer circle of vanes in the wheel H. The direction of the steam is reversed in the guide plate 12, and it then passes through the outer circle of vanes 11 in wheel 9, and thence into the pockets 14, in casing 3. Here the steam is transferred to the next inner circle of vanes, and is then forced through the wheels to the opposite casing 2. It is thus forced through from side to side of the wheels, as often as desired, until it escapes into the central chamber, and into the exhaust 19. It is claimed that this construction utilizes a large and satisfactory percentage of the power of the steam.

ROCK DRILL.

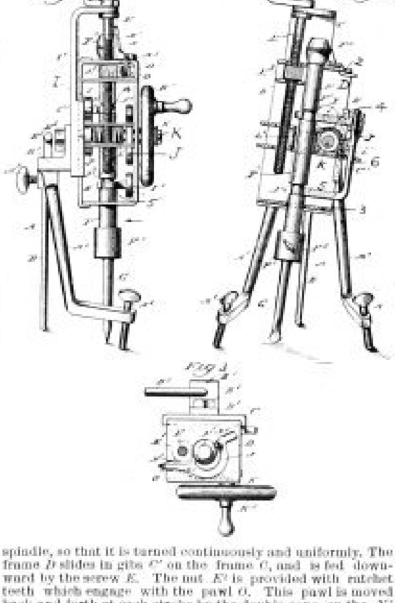
No. 545,109. Isle E. Storey, Boulder, Colorado. *Patented Aug. 27th, 1895.* Fig. 1 is a section lengthways of the machine; and Fig. 2 is a cross section at the line x, x. The movement of the drill is rotary, and it is propelled by electricity. The field magnet is composed of the cores 2 and 3, coils 4 and 5, and casing A. The armature B is secured to a



long sleeve E, which is journalled in the heads C and C'. The commutator 6, and brushes 7 are contained in the lower head. The drill spindle I is driven by means of a feather in the sleeve E. When it is drawn up to the limit of its stroke, the drill bit 8 comes inside of the foot piece 9, and is thus protected from accidental injury. Water is driven through the hollow drill spindle by means a rotary pump 10, which is built with the crosshead 11. The drill spindle is connected to the crosshead by a stuffing box 12 and a ball bearing f. To use the machine, it is stood up on the foot 9, the water hose is connected to the nozzle of the pump, and the electric wires are connected and the current turned on. The drill is pressed downwards by means of the handles 13 which are attached to the crosshead. A full sized drill weighs about 100 lbs., and may be operated by one man.

HAND ROCK DRILL.

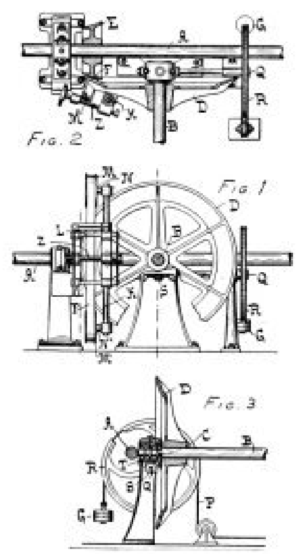
No. 545,335. Robert Binnie, Bolivar, Penna. *Patented Aug. 27th, 1895.* Fig. 1 is a front view; Fig. 2 is a side view partly in section; and Fig. 3 is a top view. The drill spindle F slides through the top and bottom bars 2 and 3 of the frame D, and it is moved up and down by means of two collars 4 and 5, which have arms H united by a bar 6. These arms carry rollers I, I', which are lifted by cams J, on the shaft K. There is a worm on the widdle part of K which turns the worm wheel L'. This is secured by a feather to the drill



spindle, so that it is turned continuously and uniformly. The frame D slides in gibs C' on the frame C, and is fed downward by the screw E. The nut E^1 is provided with ratchet teeth which engage with the pawl O. This pawl is moved back and forth at each stroke by the double cone on the N^1 of the drill spindle, which alternately strikes the fingers top and N^2, as shown in Fig. 3. The cams are double acting, moving the drill positively both ways, so it can be used in any position.

VARIABLE SPEED GEARING.

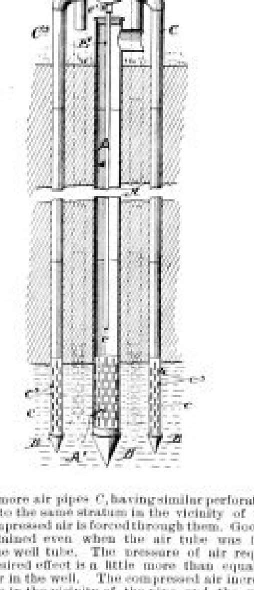
No. 546,060. Christian Seybold, Zweibrucken, Germany. *Patented Sept. 10th, 1895.* Fig. 1 is a rear elevation; Fig. 2 is a top view partly in section; and Fig. 3 is a section along the shaft B. The power is transmitted by friction from the wheel E to D, or the reverse, by means of a belt F, which is pinched between them. The face of the wheel E, is made concave, and that of D is made convex to suit. If these faces were made straight, the belt F could not be kept in place by any practicable means. By shifting the belt F, the contact between the two wheels is made



on differing radii, consequently the relative speeds are varied accordingly. The belt runs over flanged guide pulleys M, and it is shifted by moving the frame which supports them by means of the hand wheel and screw Z. To throw the wheels in or out of gear, the shaft B is moved endways, by means of a thrust box C, rack T, pinion S, shaft Q and wheel R. The weight G turns the wheel R and causes D to press upon the belt with sufficient force to drive properly; and by pulling on the rope P the wheels are disengaged.

RAISING WATER.

No. 546,125. Silas W. Titus, Brooklyn, N. Y. *Patented Sept. 10th, 1895.* When well tubes are sunk to water bearing strata, lying at considerable depths, it is frequently found that the pressure is insufficient to raise the water to the top of the well, or within reach of a suction pump. The object of this invention is to convert these wells into "flowing" wells, or to increase the depth of standing water in them to such an extent that the "air lift," process of pumping may be successfully applied to them. A represents the well tube, having its lower end provided with a strainer A', and being sunk to a water bearing stratum B. To drive the water into the well tube and thus raise its level therein, or to cause it to over-



flow, one or more air pipes C, having similar perforated ends, are driven into the same stratum in the vicinity of the well tube, and compressed air is forced through them. Good results have been attained even when the air tube was fifty feet away from the well tube. The pressure of air required to obtain the desired effect is a little more than equal to the head of water in the well. The compressed air increases the local pressure in the vicinity of the pipe, and the well tube affords the readiest escape for the extra pressure, consequently the water ascends in the well tube, mixed with fine air bubbles. Thus the water will flow as long as the supply of air is continued.

The Colliery Engineer

AND

METAL MINER.

VOL. XVI.—NO. 5. SCRANTON, PA., DECEMBER, 1895. WITH WHICH IS COMBINED THE MINING HERALD

Written for THE COLLIERY ENGINEER AND METAL MINER.

PROSPECTING FOR PLACER GOLD.

ALMA PLACER, SOUTH PARK, COLO. A TYPICAL GOLD PLACER.

Showing how Large Quantities of Gold Bearing Soil is Handled to obtain Gold Economically.

(By Prof. Arthur Lakes, Golden, Colo.)

Placer mining will become more and more popular the more the present demand and search for gold is kept up.

At present prospectors with their habitual search for vein mines are hunting mainly for them; placers however are beginning to receive some share of attention; old long-forsaken placers are being looked up again; new ones are being opened, and large enterprises and in some cases novel ones are being started.

Whilst a gold-bearing vein in place may or may not lead to a rapid fortune, a placer when found, if fairly good, offers a chance for slow, but steady returns.

We have thousands of acres of placer ground in Colorado, more or less rich, scattered amongst the mountains, or by the banks of river and canyon. The origin of these deposits is mainly due to the glaciers that once held sway in these mountains. They mined the gold veins and the gold-bearing rocks on a gigantic scale, and carried down the debris of their work into the canyons and dumped it in their moraines along the sides. Floods and streams afterwards winnowed, sorted and rearranged these piles of rubbish, and the gold was distributed through the mass of material, or by its gravity found its way down to "bed rock."

Such morainal placer banks we often see especially among the river courses and ravines in the higher portion of the mountains. They are generally rolling banks of pebbles, often covered with grass and trees.

Besides these well known and more modern placers, experiments may be tried hereafter upon beds of coarse conglomerate sandstone of various geological ages and dates which we have been in the habit of looking upon as primeval solid rocks, but in reality they are ancient consolidated placers, and may or may not carry gold. In Colorado it might be well to look into such conglomerates, especially such as are made up of andesitic lava pebbles, also into loosely compacted andesitic breccias and tuffs, such for instance as form a large portion of the Conejos range. Cripple Creek has shown us that andesite is an eminently gold bearing rock.

The largest deposits of gold at the Homestake Mine in the Black Hills is derived from an ancient consolidated placer of Cambrian age. The hard gold placers of California are old placers hardened by time and pressure and covered by a protecting cap of lava.

The difficulty in the hard material of these ancient placers would be the process of crushing them on a large scale.

In modern placers the difficulty often lies in bringing a sufficient head of water for a sufficient length of time during the summer months to bear upon and work the material. Many a bank in some dry region has shown "good colors," but absence of water rendered it valueless, and in other localities thousands have been expended in bringing water by flume and ditch for many miles upon a placer bank known to be rich.

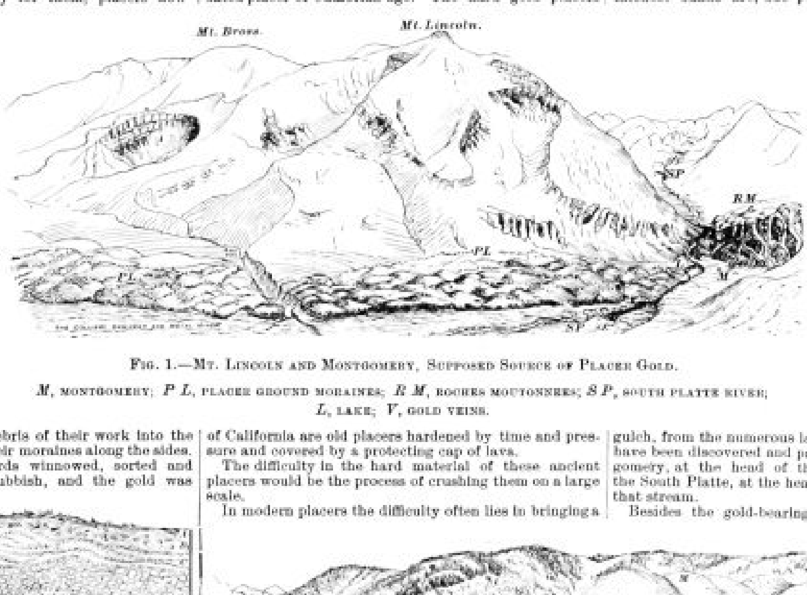


FIG. 1.—MT. LINCOLN AND MONTGOMERY, SUPPOSED SOURCE OF PLACER GOLD.

SOUTH PARK PLACER BEDS.

In South Park, Colorado, at an altitude of 10,000 feet above the sea and 5,000 above the plains is an extensive area of placer ground, along the banks of the South Platte, stretching from Mt. Lincoln to Fairplay, a distance of twenty miles. This area consists of rolling banks of pebbles, boulders and sand, on both sides of the stream, covered with grass and trees, and sloping up gently toward the mountain sides for an average width of half a mile.

Portions of these placer-banks have been worked both at Alma and Fairplay, but are far from exhausted.

The principal workings are at Alma, where also the thickest banks are, due perhaps to the confluence of tributary canyons at that point.

There is a powerful body of water on hand, and the beds are being worked both night and day by the Green Mountain Company, under the superintendence of Mr. J. Fortune. Happening to be staying with a friend in South Park, we ran up to Alma and spent a week at the placer mine, for the purpose of mastering the subject in all its details as one of the most typical, extensive, and successfully worked placers in the state.

THE SOURCE OF THE GOLD.

To begin at the beginning of things, our first care was to take a trip with Mr. Fortune to the source whence we may suppose the gold came from originally.

This was doubtless mainly from the head of the gulch, from the numerous large gold-bearing veins which have been discovered and partially worked above Montgomery, at the head of the ravine above the valley of the South Platte, at the headwaters and main sources of that stream.

Besides the gold-bearing veins, the quartzites and porphyries of the adjacent region may have contributed a certain amount of gold to the placer, from gold disseminated through their mass.

The head of the canyon, below Mt. Lincoln, is the head also of the South Platte River, and was the starting point of the glacier that carved out the valley upon which the Alma Placers lie. The character of the predominant pebbles in the placer, viz.: quartzites, granites and porphyries indicates that the rocks at the head of the canyon were their principal source.

Mt. Lincoln is 14,400 feet above the sea. The peak is about 4,000 feet above the valley of the Platte. (See Fig. 1). The wall of the east face of the peak descends to the valley at Montgomery in a magnificent cliff of massive granite capped by quartzite and limestone beds with intercalated beds of porphyry.

The face of the granite cliff is traversed by an extraordinary number of large white parallel fissure veins composed of quartz and feldspar, having a general northwest and south-east direction.

The valley below is of a U shape, cut out of granite by the glacier. The rocks over which the glacier passed are rounded, polished and grooved, forming what the

FIG. 4.—DUMPING GROUND. MODE OF DUMPING REFUSE.

French call "*roches moutonnees*" or sheep-backs. These are exposed as the pavement of the upper part of the valley. And here over steps cut by the descending glacier, a violent stream tumbles in waterfalls—the source of the Platte.

Below, where the fall plunges into the valley, is a small shallow lake on a bench above the stream, which continues its course through a narrow ravine, and thence more slowly, down the valley to Alma.

This shallow lake half filled with gravel and pebbles is eyed hungrily and prophetically by the prospector, as a probable source of untold wealth, if it were only drained and worked, because here they think the gold accumulated by the glacier, by scooping out the upper part of the canyon and veins above the falls, must have first been deposited. A scheme has been projected by Mr. Fortune to drain this lake by "coffer-dam" and an underground sluice tunnel, the water of the lake with its debris passing through the coffer dam and tunnel, the giant nozzles blowing the sand and gold through the coffer dam and out through the sluices in the tunnel. Miners aver there is enough gold here to pay the national debt.

The veins in place in the cliff above have been tunnelled upon and worked with some profit. One in North Star Mt. shows bodies of solid iron pyrites together with a certain amount of free milling gold in decomposed sandy matter. Very little quartz is associated with the solid ore.

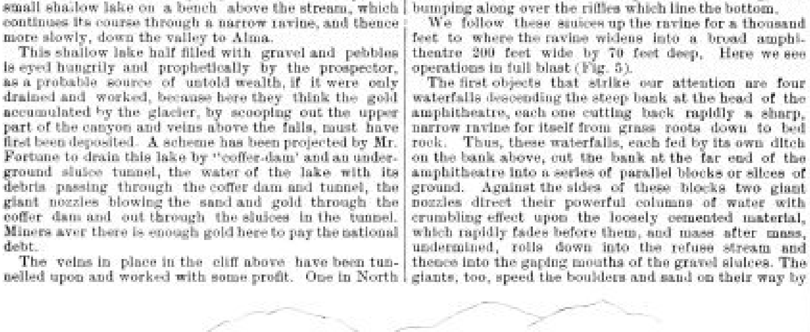

FIG. 5.—ALMA PLACER. *G, G*, GIANTS.

THE PATHWAY OF A GLACIER.

From this point we look down on numerous traces of the work and pathway of the ancient glacier. Vast bodies of great bowlders rise on the slope of the cliff 1,000 feet above the stream, with here and there an exceptionally huge block as big as a house dropped by the ice on the lateral or side moraine on either side the stream. The *roches moutonnees* fill the bottom of the upper part of the valley with their smooth rounded outlines like the bellies of a school of whales, grooved with long parallel grooves traceable from rock to rock, and many smaller scratches or "striæ." Between the moraines, the river runs in a long meadow with continuous banks of placer material on either side to a height of two hundred feet or more and downward to 50 feet. The surface of these morainal placer banks is very undulating, rising and falling in smooth grassy swells like the long swells of mid-ocean.

These banks are composed of what may be called modified drift, that is the rough, angular, original blocks left by the glacier have been worked over again by the stream, rounded and broken up, together with sand, gravel and flattened striated pebbles, the latter caught by the ice and ground down between it and the rock bottom under the ice mass.

SECTION OF A PLACER BED.

These banks when exposed in section, as at Alma, (Fig. 2) show a structure as follows, beginning from grass-roots. First a foot or two of black turf in which there is no gold, below that a foot or two of clay with pebbles in it, then a few feet of sandy layers irregularly bedded in streaks, as if formed by eddies and currents, this also is commonly barren or poor. The remainder to bed rock, from 30 to 50 feet, is composed of subangular pebbles and boulders of all sizes, from that of a marble to masses a yard or more in diameter. These are cemented together by gravel and sand which time, pressure and solutions of lime and iron-oxide have cemented into a firm conglomerate, which can only be attacked by the pick or by the all-destroying giant nozzle. Such are the placer beds for which we are indebted to glacier and stream.

ALMA PLACER BEDS.

These banks are continuous down both sides of the stream for 14 miles, but appear thickest on the East side and especially near the village of Alma and opposite the outlet of the tributary canyon of Buckskin Creek.

This is the site of the oldest and largest placer workings in Colorado. The banks have been cut back for a long distance, presenting a line of vertical cliffs 70 feet in height for about half a mile in length, channelled by narrow ravines and gashes, as shown in our illustration (Fig. 3), by the inroads of the giants and the cutting back of the flume waterfalls. Some of these cuts are short gashes not penetrating far into the hill, others lead through long narrow ravines into wide open amphitheatres, surrounded by channelled cliffs, whilst the center is occupied by tall piles of large boulders thrown out and piled up in the course of the work.

Wending through these piles of debris may be seen the pathways of the old abandoned gravel sluices, telling of the great work done and long since abandoned.

It is into one of these amphitheatres where work is still actively going on that we enter through a cut and ravine on the southwest end of the hill. From this ravine issue two long snake-like gravel-sluices debouching onto the open river bottom by many radiating mouths and shorter branch sluices (Fig. 4).

The water rushes rapidly along the bottom of these sluices and we can hear the big boulders rolling, and bumping along over the riffles which line the bottom.

We follow these sluices up the ravine for a thousand feet to where the ravine widens into a broad amphitheatre 200 feet wide by 70 feet deep. Here we see operations in full blast (Fig. 5).

The first objects that strike our attention are four waterfalls descending the steep bank at the head of the amphitheatre, each one cutting back rapidly a sharp, narrow ravine for itself from grass roots down to bed rock. Thus, these waterfalls, each fed by its own ditch on the bank above, cut the bank at the far end of the amphitheatre into a series of parallel blocks or slices of ground. Against the sides of these blocks two giant nozzles direct their powerful columns of water with crumbling effect upon the loosely cemented material, which rapidly fades before them, and mass after mass, undermined, rolls down into the refuse stream and thence into the gaping mouths of the gravel sluices. The giants, too, speed the boulders and sand on their way by adding their force to that of the refuse stream flowing from beneath the the waterfalls. So, sand and gravel and boulders are washed into the gravel sluices, the bottoms of which are lined with "riffles" or short cross-sections of the trunks of trees placed together like a lot of lozenges, or like a Nicholson block pavement. Both big and little boulders roll rapidly over this block pavement, and the gold by its gravity drops into the interstices between the blocks and is retained there. Its retention and deposition are further assisted by quicksilver thrown in, which has an affinity for gold and collects the finer particles in its soft, heavy mass.

Whilst the boulders and gravel soon find their way to the dumping ground on the open river bed, the gold in its travel stops long before this point is reached.

In the center of the amphitheatre a tall derrick moves a long arm around over the area by the power of a ten feet diameter Pelton wheel worked by water, and an undershot nozzle. The use of this derrick we see presently.

One of the flumes is stopped and its waterfall ceases, the giant nozzle is directed elsewhere, and the pathway of the stream becomes comparatively dry. Men gather into it and pick up the larger boulders, which are too large to pass conveniently through the gravel sluice. Some of these are so large they have to be blasted. The long arm of the derrick swings around and the boulders are placed in a large tray or stone boat suspended from the arm of the derrick and swung around to a convenient dumping ground on either side of the sluices. The larger boulders being removed, the gravel and finer pebbles become more exposed, and the nozzle is again brought to play on these, till at last bed rock sandstone appears beneath, full of cracks and crevices, forming by its gentle dip and irregularities natural riffles and catching places for the gold.

Now, the bed rock cleaners go to work and dig up and shovel into the sluice the rotten surface of the sandstone to a depth of a foot or so, below which, experience has shown, no gold passes. They also probe the cracks with their knives and pick out any stray nuggets that may be concealed there. (Fig. 6.)

Again, in the bed of the stream that descends from the flume, men are at work with long handled shovels "ground sluicing," *i. e.*, helping along some of the boulders, so as to keep the water in as definite a channel as possible and prevent it from spreading. (Fig. 6.)

Such is what the visitor learns in a general way at his first visit, leaving details for another time.

He is struck, however, with the magnitude of the work accomplished in so comparatively short a time, as well as with the enormous power of the giants and the cutting flumes, when he learns that, the whole ravine

FIG. 6.—"GROUND SLUICING" AND CLEANING BED ROCK.

and amphitheatre, the former 1,000 feet long and the latter 200 feet wide by 70 feet deep, has been worked out within the past six months.

After a day spent in an examination of the works we pass the evening with Mr. Fortune in his little cottage built on the bank above the placer and interview him over a pipe as to his mode of working the placer and the details of his work. He said:

MODE OF WORKING A PLACER.

"In undertaking a new placer enterprise the ground should first be well prospected and the certainty of the presence of gold assured. Shafts and prospecting holes must be dug down to bed rock to ascertain the depth of the formation. Prospecting and panning should also be done upon the sides of the gulches and other exposures.

"Then the water supply should be considered and water ditch and flume planned with a view to its power over the underlying bed rock. The grade of this ditch is a matter of consideration. If the grade is too great the water cuts and breaks banks, I have found a good average grade to be three-eights of an inch to a rod. 'Penstocks' or 'sand boxes' must be made and pipes attached. Pipes used here are 14 inches diameter.

"The giant nozzles, being attached and firmly braced to a platform on the ground, begin to play on some exposed part of the bank, also the ditch flume cuts a little canyon and blocks off ground, as you have seen, to be later broken down by the giants.

"The gravel sluices are then constructed for carrying the pebbles, gravel and gold with a general fall and inclination towards the dumping ground. In some cases the sluice is sunk down into the underlying bed rock. The sluices have curves and branch at the ends. The bottom of a sluice is lined with round riffles made out of sections of pine trees wedged tightly together with small stones in the interstices.

"After a ditch flume is let out over a bank it begins rapidly to cut a small ravine. The material, large and small, rolls down into the stream. To prevent the water of this stream from spreading too much and scattering the gold, men ground sluice it as you saw.

"The giant after a while is brought to bear and wears down the debris dislodged by the flume and drives pebbles, gravel and sand down into the gravel sluice.

"Water is shut off from one of the cutting flumes and made to play on another section, leaving the old channel dry. The 'ground sluicers' now remove all the big stones they can by help of the derrick and by blasting, till bed rock is reached, which is carefully washed and opened up with pick and shovel and searched with knives for a depth of two or three feet to a clay layer, below which no gold has been found to pass. Much of the decomposed bed rock is shovelled into wheel barrows and sent through the sluice.

"A smooth bed rock is not usually so rich as a rough one full of crevices. Bed rock is better, too, when on a

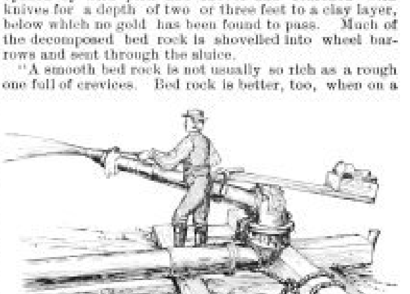

FIG. 7.—GIANT NOZZLE.

rise than in a hollow the gold being caught by its natural riffles.

"The richness of the bank depends on various conditions. The fine eddy top sand in the section is seldom rich. The best gold is generally in the coarser material or on bed rock. Sand is cemented by iron rust and pressure to the consistency of rock. 'Black sand' occurs here and there, and when it is rusty it is richest.

"There are often peculiar courses in the sand currents and turnings and windings, as in river courses. I think I have observed as many as three different periods of deposition in the material of the placer. The best explanation of the various changes, etc., in the deposits of a placer are to be found in studying those of a modern stream.

"The reservoir up the river supplying the ditches covers about five acres and is 10 feet deep. The dam is made out of gravel and brush cribbed with timber with a gate. The ditch is two miles long leading to the highest gravel banks and carries about 2,000 miner's inches of water flowing through it. It is 12 feet wide and 3 feet deep. It is flumed at one place on raised trestles for 240 feet. The flume is of boards 12 feet in length forming what are called boxes built with frames of 4″x4″ sawed

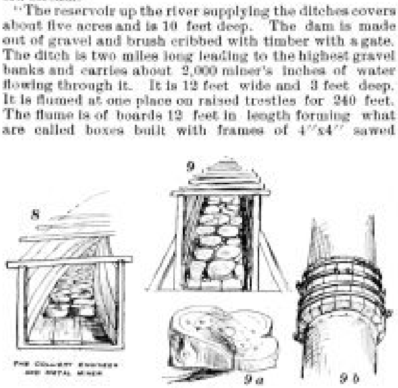

FIG. 8.

8, 9, SLUICES PAVED WITH RIFFLES; 9 a, WORN OUT RIFFLE BLOCK, ROUND SPOTS ARE PEBBLES FIRMLY STUCK IN IT; 9 b, STRENGTHENING A 16-INCH PIPE ACROSS A STREAM.

timber floor boards 1½″, sides 1½″. The flume is 6 feet wide and 3 feet deep. I had also in one place to cross a deep ravine of the old workings for 200 feet on trestles 50 feet high. At the end of this wooden flume on the solid rock is a flume 50 feet long at right angles to the trestle flume, from which there are four openings to ditch flumes which distribute the water to the general workings. The grade of the ditch was three-eighths of an inch to the rod. (Fig. 9)

"From the main ditch a branch ditch leads to the penstock or sand box. From that, two pipes are laid which at the penstock are 22 inches diameter but taper gradually down to the monitor or giant to 10 inches diameter. This pipe is 500 feet long. The giants also called "chiefs" or "monitors" are two in number and belong to the size known as No. 2. The discharge pipe is 9 feet long. The deflector by which the man in charge directs the nozzle in whatever direction he pleases (See Fig. 7) is attached to the end. The nozzle screws onto the deflector. The deflector works on the principle of a ball and socket, where the discharge pipe connects with the main casting there is also a ball and socket so that it too can be moved to right or left, up or down. Leather is used to prevent leakage at joints and saw dust is thrown into the sand box to stop leaks in the pipe at the joints. The "chiefs" are used for cutting down banks. The surplus water not used by the pipes is allowed to run over the highest part of the gravel bank to cut down and carry away gravel to the sluices. The pipes use 200 inches of water to each "chief." The ditches carry 2,000. The volume carries the gravel into the sluices."

GRAVEL FLUMES OR SLUICES FOR WASHING GRAVEL.

"These flumes or sluices are three feet wide by 4 feet high or deep paved with riffles 8 inches thick of varying width packed in the bottom of the sluices with small rock like a Nicholson pavement, Fig. 8.

So great is the force of the water in these sluices that boulders half a ton in weight are sometimes carried along from end to end. The velocity is about 25 miles an hour the dip, slope or grade is 4 inches to every 12 feet and 33″ to every 100 feet. This sluice is laid down on bed rock which is sometimes cut into to admit it.

"The curves of the flume are made like those of a railroad, raising on the outer part of the curve. There are two parallel sluices 30 feet apart.

"When these two main arteries reach the bed of the river which is their natural dumping ground, branches are formed (See Fig. 3), so as to spread out the material in a fan shape and these branches are extended as the material accumulates.

"The sluices are 4,000 feet each in length. The riffles protect the boards on the bottom from the wear and tear of the gravel and boulders. Old riffles are left in the bottom of the branches were no gold is collected for this purpose. The gold is mostly found deposited in the first 400 feet of each sluice.

"The derrick or hoisting gear is run by water when it hoists up the big rocks with a 'cab' or 'stone boat' by a 'gin-block' and chains. The water is led in an 8-inch pipe from the sand box to an undershot Pelton wheel with 1⅝-inch nozzle. The wheel is 10 feet in diameter. The drum is worked on the V friction principle.

"Quicksilver is thrown into the flume among the riffles from a bottle, we estimate about 2 oz. of quicksilver to one of gold.

"In a 'clean up' which occurs at irregular intervals, we first take out the riffles and let on water to wash everything clean. We take out the packing of small rock with twelve-tined forks. The floor is then quite clean, the gold being all collected by the quicksilver, usually at about 200 feet from the entrance of the flume. The quicksilver is shovelled out and separated from black sand and carried in kettles to the retorting office, retorted there and prepared for the mint."

After our talk, as Mr. Fortune had to see to the "night shift" of workmen, we went out on the hill to look at the placer by star light. It was a weird sight to look down on to the dark abyss of the plain with elfin light flickering to and fro from the men at work, and the great giants shooting columns of flame as it seemed into the abyss, the water from these reflecting the flames of a bonfire built on the bank. The main danger at night is the fear of flumes bursting or breaking their banks.

TREATING AMALGAM AND RETORTING.

The following epitomized from Lock's gold mining is the process for extracting the gold from the mercury amalgam.

The amalgam as collected, whether from sluices when working alluvial deposits or from plates and riffles when dealing with veinstuff, in large establishments and is carried into an apartment containing a table slightly inclined with a grooved surface near the lower end, and a hole at the lowest point opening into a receptacle for catching any mercury that may escape.

On this table is an iron kettle large enough to hold all the amalgam collected in a single "clean up." Into the collected amalgam and mercury some sodium amalgam—one ounce to each flask of mercury—is introduced, and the whole is stirred. After some time, water is poured into the kettle above the mercury, and stirred. Sand and mud rise to the surface and are removed with a large sponge. Washing and stirring continues until the surface is comparatively clean. The mercury is then made as dry as possible with the sponge and the whole stirred again with the hands. Some dirt generally arises which is scraped of with a dry card or piece of leather drawn gently edgewise over the surface. This is repeated till the mercury seems clean.

It is then poured into conical bags of canvas or chamois leather, through the pores of which the mercury runs, or is squeezed leaving the gold amalgam in the bag. A certain quantity of gold is retained by the mercury which can only be recovered by retorting but it is not desirable to do this if the mercury is to be used for further amalgamation, as the presence of gold increases its activity. The retort is a deep cast iron vessel shaped like a bowl; on top is a jointed iron from which an iron tube rises and bends downward. A mixture of wood ashes and clay is prepared. The balls of amalgam are placed in the bowl and the ashes put thickly around the edge. Cover is fitted. Clamp adjusted. The retort is placed in a furnace over a moderate fire. The end of the pipe dips just below the surface of water placed in a vessel. When the retort has attained a dull red heat and no more mercury distiles over, the retort is allowed to cool. The cover is taken off and the bullion removed. The amalgam after retorting has a gold metallic color. It is ready for the melting pot as soon as taken out. Gold from a placer is usually deposited in the local bank and thence goes to the mint for refining.

The sodium amalgam must be freshly made to be effective. If kept long it oxidizes. Metallic sodium may be kept in wide mounted bottle covered with coal oil. Enough for a single "clean up" can be made in a small frying pan.

A small quantity of mercury from a fresh flask is poured into the pan and dried with a sponge and then heated beyond boiling point but not enough to volatilize the mercury.

A piece of sodium is cut into one-half inch cubes and the mercury taken out into the open air. A cube of sodium is placed with tongs in the center of the warm

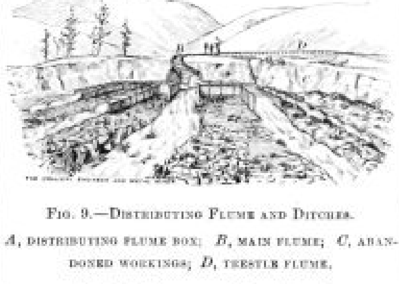

FIG. 9.—DISTRIBUTING FLUME AND DITCHES.

A, DISTRIBUTING FLUME BOX; *B*, MAIN FLUME; *C*, ABANDONED WORKINGS; *D*, TRESTLE FLUME.

mercury. A flash follows, a small portion of mercury is volatilized, another cube of sodium is placed with less flash. This is repeated three or four times when the sodium sinks down gently. At the proper moment a solid mass of amalgam will appear in the center. The contents of the pan are then stirred and a few more added cubes change the whole to a mass of crystallized sodium amalgam.

Meritorious Machinery Appreciated.

The Robinson Machine Co., of Monongahela, Pa., inform us that their foundry and machine shop are running full time and with a full complement of men, in the construction of hoisting, haulage and ventilating machinery and tipple arrangements. Among the recent orders received by the Robinson Co. are the following: A three drum hoisting engine for the Clipper Sand Co.; a two drum haulage engine for the California Coal Co., of California, Pa.; endless haulage machines for the Oliver Coke and Furnace Co., Pittsburgh, Pa., and the Royal Coal and Coke Co. of Knoxville, Tenn. A single friction drum haulage engine for the Hopkins Coal Co., of Perryopolis, Pa., and a large ventilating fan for the P. J. Forsyth Coal Co., of Coal Centre, Pa.

Among the orders received for complete tipple rigging are those from the following companies: The Equitable Coal Co., Webster, Pa., Hopkins Coal Co., Perryopolis, Pa., and the Belle Bridge Coal Co., Pittsburgh, Pa.

Written for THE COLLIERY ENGINEER AND METAL MINER.

A FLUME CONVEYOR.

By L. S. Ropes, B. S.

Your space permitting, I will add a few words on the subject of Mr. Lloyd's interesting article in the October COLLIERY ENGINEER AND METAL MINER.

At one of the old corundum mines at Corundum Hill, Macon Co., N. C., such a conveyor has been in use for a number of years and the experience here has suggested means of overcoming some of the difficulties met with in the above case.

A flume is just about completed from the Foster Mine on Ellijay Creek from the top of the mountain to the mill on the creek (now under construction). This flume is about a mile long and its fall about 800 or 900 feet.

Briefly the troughs are 10 and 12 ft. long, the bottom boards are sawed 10″ for the upper end and eight for the lower, so that the joints telescope and are nailed together with 10d. nails and a cleat 1″ x 4″ nailed across the top of the outside trough to prevent spreading, and with some a collar is made about the middle of the trough. The plank used is one inch oak and the sides are eight and ten inches high. In turning a curve or angle the side boards are beveled, one side of the lower trough inside, and the opposite outside, of the upper trough. At every joint is a one inch fall which should be changed as excessive wear, comes at this point. As the bottoms wear false ones are put in.

With plenty of fall but little attention is paid to grade except where a noticeable change occurs, then, to prevent damming of the material a vertical drop of two feet or more is made by fixing to the lower end trough of an even grade, a tight box opening at the bottom into the upper trough of the next regular grade. Should the following grade be the flatter one a small head may gather in the vertical column and give velocity to the material.

Where possible, a high "jump off" is given, this assisting in breaking up the loosely compact sand, clay and vermiculite which make up the gangue of the corundum vein and further in separating by allowing the light material to race. The troughs are charged at intervals. In this way there is no damming and overflowing. The climate being mild, no covering is used over the trough.

As a post script allow me to note that the Foster-Ellijay mines are nearly developed and will commence milling from stockpiles which have been accumulating for a number of months past. This with the old Corundum Hill mine are the only two in operation; many prospects in this and adjoining counties are being brought before mining men and with the advent of the railroad it is thought that some of the grand water powers and forests of these mountains will be turned to the use of man.

A wealth of power and timber with raw material lies dormant awaiting the key, a railroad, where capital will quickly discover the advantages. An abundance of good food and most healthful climate will bring the laborer.

But must capital await a railroad? We are but twenty miles away and have the chief factors to the economical production of aluminum and calcium-carbide, viz. the raw material and the *water power*, the latter with high heads and abundant flow.

Pressure Recording Instruments.

Bristol's Recording Pressure Gauge is rapidly coming into great favor among mine managers, as a medium through which the condition of the ventilation of a mine can be accurately and constantly checked. Every mine fan should be supplied with some appliance by means of which the work of the fan can be accurately and constantly gauged. In some States the mine law requires that either a speed or pressure recorder be applied to each fan. Speed recorders are far better than nothing, and as they were placed on the market before pressure recorders, they were adopted by mine managers who desired the best possible method of gauging the work of a fan. The pressure recorder is far more efficient than a speed recorder, because it furnishes constant and direct evidence of the efficiency of the ventilating current. A speed recorder does not do this with the same degree of accuracy. It merely records the revolutions of the fan. If an open door, or a fall of roof occurs in a mine, the fan may continue running at normal speed, and the volume of air may be reduced to a remarkable, and in some gaseous mines, to a dangerous degree. The pressure recorder acts differently. If there is any derangement of the air passages it immediately records a change in the pressure of the air current, and the degree of change as compared with the normal pressure gives an idea of the extent of the derangement. If the speed of the fan changes from its normal number of revolutions, the pressure recorder records it by noting the change of pressure due to the change of the periphery speed of the fan. When these features of the recording pressure gauge are considered, it becomes evident to every practical mine manager, that it is a far more efficient and valuable appliance than a speed recorder.

The same principles that are embodied in the construction of the recording pressure gauges for use in connection with ventilating machinery, are applied by the Bristol Co. to recording pressure gauges for steam, gas, etc.

Thesame company also manufacture recording vacuum gauges, recording thermometers, recording volt meters, recording amper-meters for both direct and alternating currents, and recording watt meters.

The value of each of these appliances in the various fields for which they were designed is obvious to every reader.

In laying out the holes in a belt for the lacing, do not get them too near together, for while this practice makes the finished lacing stronger, it makes the belt weaker, on account of the large amount of material cut away in making the holes.—*Power.*

Written for THE COLLIERY ENGINEER AND METAL MINER.

GOLD AND SILVER MINING.

TIMBERING FOR PRECIOUS METAL MINES IN COLORADO.

The Methods of Working and Conditions Which Influence the Methods of Timbering.

By Francis T. Freeland, B. S., C. S. S., A. S. M. E., A. I. M. E.; Gen'l Mgr. Aspen Contact Mg. Co., Lenado; Durant Mg. Co., Aspen; Isabella Gold Mg. Co., Cripple Creek, Colo., etc., etc.

The styles of timbering for precious metal mines differ materially from those used in coal and base metal mining and also show variations in different sections of the country. The Nevada practice is described by Hague and Curtis, and that of California by Storms. Ricketts refers briefly to some designs used at the Morning Star mine, Leadville, Colo.*

I have shown in the accompanying plates a number of patterns largely and successfully used in Aspen and Leadville. The drawings are to scale and dimensioned so that they may be used for working drawings if so desired. No attempt has been made to illustrate forepoling or spiling, breast-boards, stulls and cribs, as they have been often given, nor to describe methods necessary in unusual or difficult cases. In treating of timbering it was found inadvisable to avoid all reference to methods of mining, as is sometimes done, for success depends not entirely upon knowing how to set a stull, erect a square set, or plumb a shaft. It is just as important to know what style and dimensions of framing to use with the various kinds of ground, shapes of ore bodies, methods of mining, plans of development and the hoisting appliances adopted.

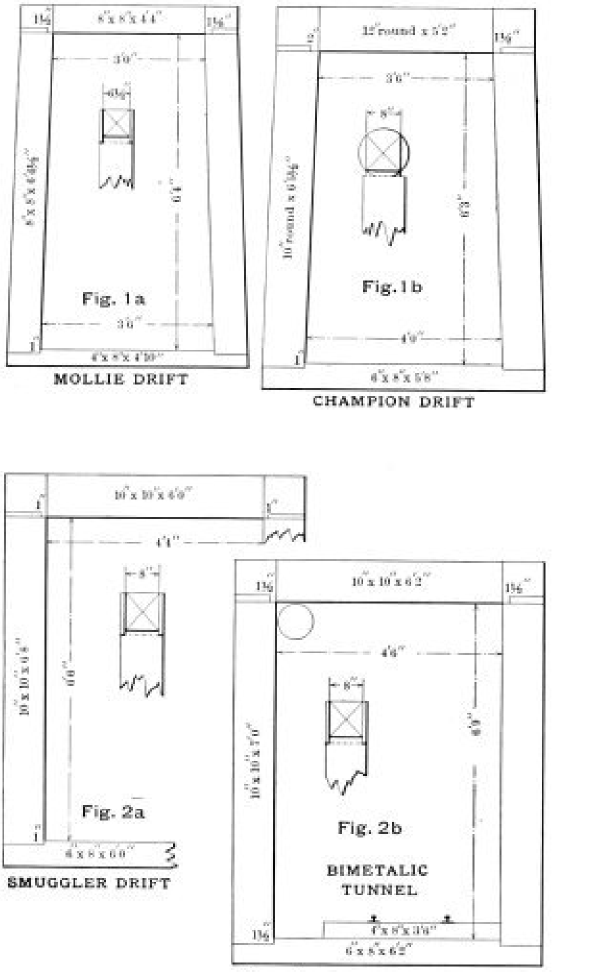

Plate I.
Scale [illegible]

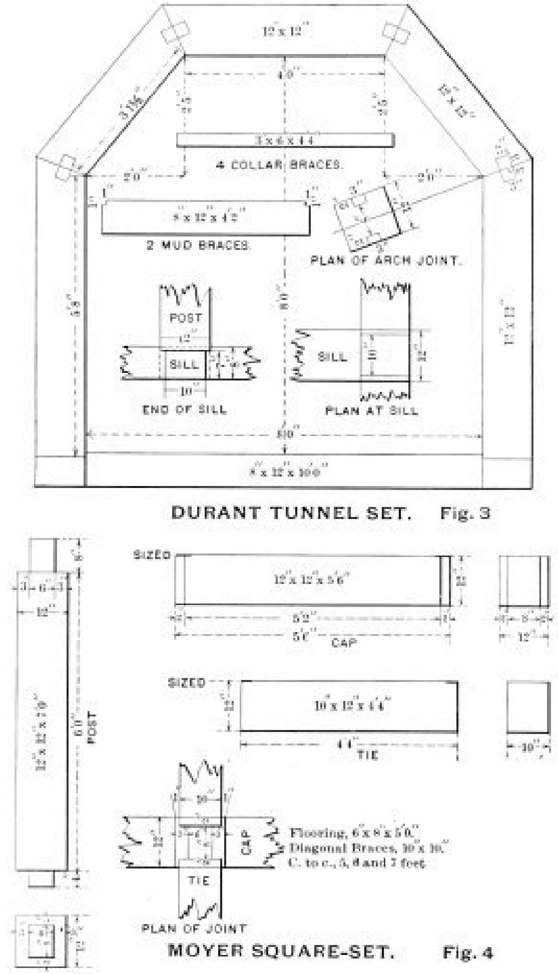

Plate II.
Scale [illegible]

DRIFTS.

The usual mining cage-car is square bodied, turns and dumps at the end. The box is 2′ by 2′ 2″ by 2′ 6″ and contains 15 cubic feet. The car stand 3′ 3″ from the track and runs on 10″ loose wheels upon 8 lb. track of 18″ gauge. Plate I, Fig. *a* shows the smallest size drift in which such a car can be worked conveniently. This is the standard drift set in the Mollie Gibson mine at Aspen, W. J. Cox, Supt. The height will allow for a sheet-iron ventilating pipe overhead. In that mine in the wet drifts the track is laid on 4″ stringers to form a waterway all over the floor. Otherwise 6′ height would be the minimum.

The drift set of the Bohn mine, Leadville, is rectangular, 3′ 6″ by 6′ of 8″ by 8″ squared timber with 4″ by 8″ sills. The posts are 6′ 4″ over all and the tenon at the top is 6″ by 6″ by 2″, flush on the outside of the set, with a plain foot. The boxes on the sill are 8″ by 2″. The boxes for the collar braces are 1″ deep. I also have used this set largely in the Durant mines in medium ground. In heavier ground, 10″ by 10″ timbers are used with the same size of jogs but with a 6″ by 10″ sill. Plate I, Fig. 1*b*, shows the standard drift set used by the Mineral Farm Cons. Mg. Co., Aspen, designed by the writer. This mine is worked through the Cowenhoven tunnel, and the drift could not be smaller and yet take the tunnel cars, (See description of Cowenhoven tunnel below.)

Plate I, Fig. 2*a* shows the standard drift set used in the Smuggler mine, Aspen, S. I. Hallett, Supt., a more roomy design and suitable for main levels. The Aspen mine uses a cage-car, 2′ 6″ by 2′ 6″ by 4′, but they are rather large for a high grade mine. The Aspen Contact standard drift set is 3′ 10″ by 6′ 4″. The El Paso standard drift set, Leadville, is 3′ 6″ by 6′ 3″, timbers 10″ by 10″ and sill 4″ by 10″ or 8″ by 10″, squared and rectangular.

TUNNELS.

Plate I, Fig. 2*b* was designed by the writer for a single track tunnel in the Bimetallic mine at Lenado near Aspen, ½ mile long. It contains a water way over the sills and is as small as can be worked with a mule. The standard single track section of the Compromise tunnel, Aspen, ½ mile long is 5′ x 7′. The cars have boxes 3′ by 3′ by 5′ and one mule will pull 4 in a train.

Plate II, Fig. 3 shows the standard section of the Durant tunnel, Aspen, 1 mile long. A boxed waterway 12″ by 16″ of 3″ plank runs under the sills. The grade is 5″ to 100′. The cars have turning scoop beds holding 20 cu. ft. and run on 12″ fixed wheels with 22″ gage on 30 lb. rails. The draw-bars are on the trucks. One horse will pull 10 cars. It will be seen that the collar braces lock the arch. The Castle Creek tunnel, ½ mile long, resembles this set, but is 7′ 6″ high by 8′ wide. The drain is 16″ by 16″ and the grade 6″ to 100′.

The Cowenhoven tunnel at Aspen, about 2 miles long, designed by D. W. Brunton, Mgr., is about 6′ 6″ by 7′ and is timbered with octagonal and trapezoidal sets. The gauge is 18″ double track, 22 lb. rail. The waterway 12″ by 14″ is under the sills between the tracks and covered by a plank walk. The grade is 6″ in 100′. The cars turn and dump from the end and have the bumpers on the box. They are 3′ 2″ by 2′ 4″ by 4′ 1″ holding 20 cu. ft. They stand 4′ 4″ above the track and run on 12″ loose wheels. Full throw switches were found an advantage on the main line for then no frogs interrupt the continuity of the rail. One mule with a driver pulls 10 cars.

The Revenue tunnel, Ouray, H. W. Reed, Supt., about 8,000 feet long is 8 by 8 feet with 14 inch caps and 12 inch legs. The track is double, 2 feet gauge and the cars are 4′ 11½″ by 3′ 3½″ wide by 2′ deep on 12″ wheels. The air pipe is 4″ and the ventilating exhaust pipe 15″. Rack-arock powder was used as giving less smoke.

The Newhouse tunnel, Idaho Springs, designed by W. H. Wiley, Mgr., is similar and 7′ by 8′, timbers 10″ by 10″ and sill 6″ by 10″. The water drain is under the sills and 12″ by 24″. The mud braces are rough and the collar braces 6″ by 6″. The track is double of 18″ gauge and 30 lb. rails. Grade is 5″ to 100′. The cars have a capacity of 27 cu. ft.

The arch form is stronger only where the pressure is uniform. Space must be allowed for the various pipes and wires the tunnel is to contain. For a single track tunnel the waterway may be formed over the main sills by laying a floor on plank stringers set on edge, having made proper allowance in the height. A tunnel can be driven faster if it is wide enough for two air drills to be set on columns abreast. A 7′ by 9′ or 10′ section can be driven faster than 8′ by 8′ as the center cut breaks better.

Bad ground often occurs in depth as crevices or chambers filled with loose material carrying water under pressure. They can usually be penetrated by spiling and breast boards; or by setting the cap first, supported on temporary longitudinal stringers. With a large section, flanking small drifts may be sent out to drain and thus consolidate the ground. In continually swelling ground a second light set may be erected outside of the main set, the ground to be eased when the lagging bends and the light set to be replaced when broken. This will save the main set and prevent interruption of traffic. It is better to use light open lagging in heavy ground so that it may break before the set.

In this sort of mining no heading machines are used, and no application of the shield, or pneumatic processes have been made in driving. The drilling is done by percussion drills driven by air.

Long tunnels may be ventilated by an exhaust fan or steam jet, to keep the bad air out of the tunnel. But in most cases and especially for raises forced ventilation by fan or jet driven by compressed air is best as the fresh air goes to the place where most needed and at once. The air drills themselves will supply a certain amount of fresh air, but the practice of opening the

* The Ores of Leadville, by L. D. Ricketts.

compressed air pipes for ventilation after shooting leads to waste.

Tunnels and drifts are aligned by sighting over two plumb-lines to a light at the face. The hubs are set a convenient distance from the face by a transit or special tunnel instrument. The sills are set by a grade stick and carpenter's level checked by a surveyor's level from time to time. The grade of an ordinary drift is usually from 6 to 9 inches in 100 feet.

RAISES.

Plate VI, Fig. 13 shows a prospecting raise, about the smallest that can be driven and timbered, containing a manroad and chute. The ends are made to overlap the sides to reduce the weight of the heaviest piece. These raises may follow the contact and change grade with it by altering the length of the posts. A common way of timbering raises is to place two lines or stulls about 4′ apart with a loose plank on each pair, but it is neither safe nor convenient for a considerable height.

In Aspen a number of important raises have gone up from the Cowenhoven tunnel, some of them 500′, at an elevation of 50 to 60 degrees. Plate VII, Fig. 15 shows one on the Mineral Farm property, containing chutes for ore and waste and a manway. In the manway runs a timber truck straddling the ladder road and hoisted by a windlass or engine. These raises follow the contact nearly and are run at a uniform grade. Levels are turned off at intervals of 50 to 100 feet and the rock is dumped down the chutes which are lined on the bottom and sides, direct to the tunnel cars from bins.

SHAFTS.

A small bucket shaft or shaft winze may be 3½ by 7 or 4 by 8 feet with a square bucket way and solid partition. The buckets will usually hold ½ ton of rock. The principal shafts are provided with cages, and the great majority of hoist ways are 4 by 4½ or 4½ by 5 feet. Two compartment shafts vary from 4½ by 9 to 5 by 10 feet, and three compartment shafts from 4½ by 13 to 5 by 16 feet. The largest shaft in the state is the Bobtail, above Central City. It is 8 by 16 feet, with four compartments, hoisting cars containing 32 cu. ft.

Shafts are usually either cribbed or setted. Plate III., Fig. 6, shows a crib used at the A. Y. mine, and Plate VII., Fig. 16, the Jamie shaft, Leadville. The size of the timbers varies with the character of the ground from 4 by 8 to 8 by 10 inches, often 6 by 8 inches. The new Star shaft on the Penrose mine, Leadville, is 4′ 6″ by 9′, cribbed with 8″ by 8″ timbers. Each side and end piece is boxed four times at the corner 1½″ by 8″. The partitions are solid of 3 or 4 inch plank confined by 2 by 4 inch strips or angle pieces of diagonally sawed 4 by 4 inch. The cribs are built up in stretches of 8 to 12 feet on hitched special end pieces, or in smaller stretches hung up by iron dogs, when in firm ground. Cribs are nearly as cheap, are easier to frame, require less space and are stronger in bad ground than sets. But they can only be relieved by cutting them out and cannot be aligned anew without replacing them, and are not so convenient for hanging pumps, pipes, or setting platforms.

IRON ORE MINING.

The Mining and Washing of Iron Ores at Scotia, Pennsylvania.

(By H. H. Stock, E. M., State College, Pa.)

The recent development of the Mesabi range in Minnesota, in the United States, quite largely by the use of the steam shovel or excavator, has attracted unusual attention to this tpye of mining. While it has been used somewhat in other localities in the eastern and southern portions of the United States, for the stripping of coal beds and the mining of the soft, brown ore deposits, the use of the steam shovel in connection with iron ore mining is generally considered a novel departure. It may therefore be of interest to recall that for the past fifteen years it has been in almost constant use in the very center of the great Commonwealth of Pennsylvania, and that before a single ton of ore had been taken from the Mesabi field, over half a million tons had been thus mined at Scotia in that State and shipped to Pittsburgh, for smelting.

The mining and smelting of iron ores in Central Pennsylvania is by no means a recent industry, and the history of the same is intimately and almost inseparably connected with the general local history from a period antedating the opening of the present century. On all sides, and often in the most unexpected places are found the evidences and relics of a former busy industry, in the form of an overgrown cinder bank, an old stack or open hearth, a mossy water wheel or whatnot. The mountain sides, denuded of their trees, tell a similar story of former activity, for long ere the much blamed lumber interests had begun their campaign of deforestation the charcoal burner had begun, and ofttimes, completed the work of destruction. The life of many an early furnace was determined by the distance to which it was economical to carry the needed charcoal, for the limestone and ore were abundant and easily obtainable, while the latter, easy to smelt and of exceptional purity, produced an iron deservedly celebrated for its working qualities.

The old Centre furnace, situated about one mile to the east of State College, but abandoned thirty years ago, serves as a very good type of one of these early workings. At first ore, limestone and charcoal could be gotten within almost a stone's throw of the stack, while the power for turning the water wheel came from a huge spring near by, still used for a saw mill and a flour mill, the former situated nearly on the site of the old furnace. The pig iron was hauled down the mountain to Bellefonte and there either converted into muck bar or shipped away over the canal. The area from which came the charcoal supply gradually widened until the long haul of two days for each load of charcoal became prohibitive. The foundations of the old furnace still stand, suggesting and recalling the characteristic scenes of old forge life and activity which are now so rapidly disappearing. In those good days it mattered little in these mountain valleys whether a single or double money standard ruled the country, as the only currency seen in the community was that brought in by an occasional traveller, while wages and all local wants were satisfied by barter through the medium of the company store.

The numerous charcoal furnaces of the region have been replaced and supplanted by two modern blast furnace stacks located in Bellefonte and owned by the Valentine Iron Company and the Collins Brothers.

The Scotia mine was formerly owned by the Centre Furnace Company, but was purchased in 1881, by Carnegie Bros. and Co., now the Carnegie Steel Co., and has since been operated by them.

The geological relations of the Centre county deposits are very like the many similar surface formations found in eastern Pennsylvania and extending parallel to the Atlantic seaboard until finally lost in the extensive deposits of brown ores in Alabama. These deposits have been described in detail in the reports of the Second Geological Survey of Pennsylvania, but in brief they may be said to be pocket deposits occurring in the lower Silurian limestones and irregular both in form and distribution.

Two varieties of ore occur, the wash and the lump hematite ores, which constitute the bulk of the Scotia ore, and the pipe ore found in other sections intimately connected with the first variety. The designation "wash ore" suggests the theory of formation advanced by the geologists of the State Survey, who suppose these beds to be wash deposits of rolled ore, stiff clay, sand, etc., which have been transferred from other localities, and finally imprisoned in the huge caverns existing in the native limestones.

The ore banks of Centre county have been divided into seven groups, the most important probably being the "Barrens Group" of which the Scotia deposit forms a part. This property comprises 430 acres and before the change of ownership in 1881 it was thoroughly prospected by the present owners by means of pits and drill holes. These tests showed only a portion of the property to be underlaid by the ore bank, but in a number of instances pits sunk eighty feet in depth were still in the ore body. According to the calculations of the owners, one million tons of washed ore will be taken from the bed, of which six hundred and fifty thousand tons have been already mined, while at the present rate of working the bank will be exhausted in about six years from the present time.

The ores vary both in color and value, the darker colored pitch like ore being richer than the lighter liver colored and more compact ore.

A mine classification to size is also made in the lump ore, which is shipped in the form in which it is

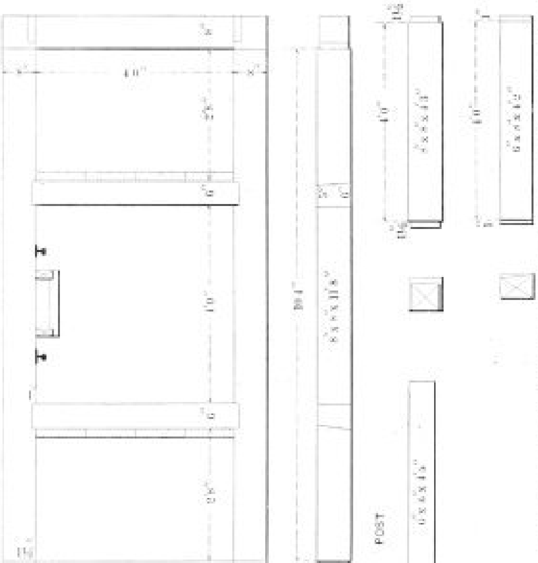

PLATE VII.
Scale $\frac{1}{40}$.

mined without further breaking or washing, and the "fine ore" which is that passing through bars placed six inches apart is broken, washed, and picked before shipment.

ANALYSES OF SCOTIA ORES.

	Sample No. 1.	Sample No. 2.
Bi-Sulphide of iron		
Protoxide of iron		
Sesquioxide of iron	75.443	64.821
Sesquioxide of manganese	0.578	0.392
Sesquioxide of cobalt	0.020	0.010
Alumina	1.851	2.973
Lime	0.860	0.650
Magnesia	0.336	0.280
Sulphuric acid	0.225	0.275
Phosphoric acid	0.116	0.116
Carbonic acid		
Water and carbonaceous matter	9.669	9.184
Silicious matter	11.450	20.730
	100.348	99.651
Metallic iron	52.950	45.374
Metallic manganese	0.403	0.273
Sulphur	0.091	0.170
Phosphorus	0.051	0.051
Phosphorus in 100 parts of iron	0.096	0.112

In the earlier reports of the State Survey the heavier ores are stated to lie at the bottom of the deposit but the later development of the Scotia bed has shown the character of this deposit, at least, to be very uniform throughout.

The foregoing analyses of the Scotia ore were made in 1881 by the chemist of the Second Geological Survey, Mr. A. S. McCreath:

Sample No. 1 represents 490 pieces selected from different parts of the ore pits and thoroughly dried.

Sample No. 2 was of thoroughly washed and dried ore taken from different parts of the ore pile.

The early estimates of the State Survey gave the iron content of these ores as 44–52%, and the phosphorus as 0.08–0.20%, but according to the developments up to the present time, while the iron has averaged only 40%, the phosphorus content has likewise been lower, 0.05%, thus compensating somewhat for the smaller amount of iron. The lump and fine ores are kept and shipped separately, as the former contain 40–50% of metallic iron, and the latter only 35–40%, while the amount of phosphorus is constant, and neither contain sulphur.

Mining is carried on with the steam shovel, three excavators of the Otis type, made by John Souther & Co., of Boston, being in active and continuous operation at the present time, two working in the older, or northern portion of the mine, and a third opening up the southern extremity of the deposit, near the old "Red Bank" mine, belonging to the Collins Bros. of Bellefonte, formerly also operated with the steam shovel. These excavators are of the ordinary scoop or drop bottom bucket type, with a lateral reach of 17–18 feet, thus giving a cut 35 feet in width. A vertical cut of 16 feet is taken, but an allowance of from four to nine feet is made for the topping, which falls when undermined, thus making the actual vertical excavation 20–25 feet in height. The track upon which the excavator runs is laid in sections two feet in length, and the excavator is moved forward over one or two sections at a time, depending upon the character of the ground being worked. The ore and accompanying clay and sand are removed in mine cars with a capacity of 32 cubic feet each, and as the excavator scoop shovel holds about the same amount, a car can be filled at each swing of the bucket. A single track runs parallel to the excavator track, on which the cars are removed and put in place with a mule driven by a small boy. Considerable time is lost in the loading of the cars, as a single track only is laid near the excavator, and the empty car must thus wait until the loaded is switched to the side track, where it forms part of the train of 24 cars, which is drawn to the washer, half a mile distant by a small "dinkey" locomotive. The estimated capacity of the excavators working under the conditions at Scotia is 350–400 cars per day (415–474 cubic yards) and they are assumed to replace 25–30 laborers shoveling and loading by hand, though these figures are very much smaller than those given by Mr. Robinson in his article upon the steam shovel in the January number of Cassier's Magazine, and also by the manufacturers of the shovels. The crew of the excavator consists of the engineer, the cranesman and the fireman, while working about the machine are a foreman, two pit shovelers, track layers, etc., and two mule drivers. Assuming a laborer's wages to be $1.00 per day, and that it takes half a ton of coal per day to fire the excavator boiler, (the makers estimate only 700 lbs. per day), with the above force of workmen and with the usual difference between the wages of engineers, firemen, etc., taking the value of coal as $2.00 per ton, the cost of operating an excavator will be $10.55 per day of nine hours, or 2.64 cents per cubic yard of material excavated. If the excavator displaces only thirty men, as assumed above, the wage account of the same, including a foreman, would be at least $31.50 per day, or nearly three times as great as steam shovel work. If, on the other hand, we assume, as does Mr. Robinson in the article before quoted, that a laborer can dig and load not more than four cubic yards per day, the Scotia excavator can be assumed to replace 100 men, with a probable wage account of $105.00 per day, or 26 cents per cubic yard. The above figures are not given as the actual results attained at Scotia, which cannot be secured for publication, but are merely estimates based upon the wages paid in this locality.

The mining is carried forward by the simple open cut method, sections 20–25 feet thick and 35 feet wide being taken at each cut. The ground having been thoroughly prospected in advance, it is possible to avoid barren spots, and numerous pinnacles and ridges of this description will be found distributed over the worked out area.

The excavation is carried on in levels or terraces, a single excavator generally working upon each level. In this way one shovel will be mining the first cut including the necessary surface work, while a second will be taking off the second cut at a level 25 feet below the first, and possibly a third will work at a still lower level. This regularity of working has not been generally observed, and the greater portion of the ore-bearing area has been now gone over by the first cutting, while a considerable area has been second cut, and a smaller area third cut. It is estimated that about three cars of run of mine material will produce one of washed ores.

A partial hand separation takes place at the mine where the largest and purest lumps are picked out, laid aside until sufficient have accumulated and then shipped without further treatment. During the early days only the large lumps were used for smelting in the neighboring furnaces, the finer ore being separated by screening at the mine and left where it fell from the revolving screen or trommel. As a result many of the first cuts now made by the shovel include these old screenings and consequently yield an unusually rich ore product.

The systematic and extensive washing of the ore dates from a comparatively recent period, for in former times it was only where streams were available that the washing could be carried on. These mountain valleys are not well-watered, and not until about twenty-five years ago was it discovered that an abundant supply of water could be secured by sinking so called artesian wells. This discovery gave a new impetus to the mining of these surface ores, and now the country is dotted here, there and everywhere with the old derricks used in driving and operating these wells, the derricks being in many instances the only remaining evidences of the former scene of activity, or of an unsuccessful mining venture.

At the washer the cars are hoisted and lowered by an inclined plane, on which are three tracks, two for the loaded and a third between them for the empties, which are lowered by a tail rope, while the full cars are hoisted by a reversible endless rope, both ropes being worked by engines located in the washer building. At the top the cars run upon revolving dumps, of which there are two, one for each track. These dumps, which turn the cars upside down are necessary on account of the sticky character of the ore, which could not be readily dumped from the end of the car. From the revolving dump the empty cars are dumped off by the loaded and run upon a transfer platform which carries them to the empty track located midway between the loaded tracks and at a slightly lower level. This transfer truck is merely a platform car running upon a depressed track and moved by hand, being so counterbalanced that it will return to its position in line with the loaded track as soon as the empty car has been run off and the truck thus released.

Directly below the two dumps are inclined hoppers from which the ore passes over a grizzly composed of iron bars slightly inclined to the horizontal and placed 5—6 inches apart. At the foot of this grizzly is a platform upon which workmen stand and with large iron hooks prevent clogging of the bars, at the same time drawing the large lumps which will not pass between them onto the platform, where the clay balls are separated from the large lumps of ore, the former being thrown upon one side and carried to the mud bank, while the lumps of ore are thrown into a small car and from that loaded directly into the R. R. car for shipment, together with the lump ore which is separated at the mine as previously mentioned.

The small ore passing through the grizzly bars goes next to a pair of toothed rolls thirty inches in diameter, and 48 inches in length, set 2 inches apart and running 40 revolutions per minute.

A revolving screw washer 23 feet 2 inches in length made with iron arms bolted to an iron axis, receives the crushed material coming from the rolls together with a stream of water. At the end of this first washer or "mixer" as it is sometimes called, are placed three parallel troughs containing screws similar to the first and with their axes parallel to the axis of the mixer, but only 19 feet 2 inches in length. The material from the mixer passes through the first of these parallel troughs, then through a lateral opening in the end into the second trough of the series which it traverses in a direction opposite to that taken in the first, then through another lateral opening located diagonally from the other into the third washer of the series, which is traversed in the the same direction as the first, the washed material from this last screw emptying into a circular trough provided with a perforated bottom through which the muddy water drains, and from this trough the particles of ore and flint rock are raised by an antique revolving bucket elevator and delivered into a double-revolving trommel. This is made up of two concentric punched screens, the inner having circular holes one-half inch in diameter, and the outer oblong slots one-half inch long by one sixteenth broad. Through the trommel axis runs a pipe and from it jets of water play upon the ore as it passes over the screen, while the well-washed ore and rock are delivered by the trommel upon a traveling picking belt 30 feet long and inclined at an angle of 10 degrees, along which stand men and boys who pick the flint and the clay balls from the ore, which then drops over the head of the picking belt into a chute and thence passes directly into the cars for shipment. The refuse flint and clay from the picking belt are thrown aside upon the floor and subsequently shoveled into a small car for transfer to the dirt bank. This car runs upon the same track with the one previously mentioned as carrying away the large clay balls from the first cobbing platform. The foregoing description applies to but one half of the washer, but the other half is an exact duplicate.

The muddy water from the washer runs into a well located outside of the building and across the railroad tracks from the loading chutes. From this well it is raised a height of 25 feet by a bucket elevator, and discharged into a wooden launder which carries it to the settling pond several hundred feet away. These ponds cover an area of 25 acres, which has however been prospected and found to contain no ore, but to be underlaid by a deposit of sand.

Formerly the material was jigged before shipment, but the present owners have not found this to be economical nor necessary, so that the jigging of the ore has been discontinued.

The present output of the washer is 300 tons per day, but it is designed to wash 350 tons, while as much as 425 tons have been washed in a single day. From Scotia the shipment is made over the Lewisburg & Tyrone R. R. to Tyrone, whence it goes over the main line of the Pennsylvania R. R. to the furnaces of the company at Braddock.

Written for THE COLLIERY ENGINEER AND METAL MINER.

ELECTRIC PLANT AT ESSEN MINES.

THE LARGEST ELECTRIC MINING PLANT IN AMERICA.

A Description of the Mining and Haulage Plant at the Essen Mines, at Federal, Pa.

The largest electrical coal mining plant in the world has been in operation during the past summer and fall in the mines of the Essen Coal Co., at Federal, Pa. The magnitude of this plant renders it of especial interest to coal operators. Electrical coal mining plants having a capacity of a few hundred tons of coal a day and employing one or possibly two hundred horse-power have become quite common, and one or more such may be found in almost any coal field of this country. But the Essen mines are equipped to produce by electrical machinery over two thousand tons a day, and the plant installed is capable of furnishing six hundred horse-power.

This power plant is in reality a central station, from which two mines are operated. The mines are both "drifts" into the hillside, the openings being about 1,700 feet apart, and known as Essen mines No. 2 and No. 3.

The power house itself is located close to the mouth of No. 3 mine, as the accompanying map shows. This location was chosen for several reasons; it concentrates the entire plant at No. 3 tipple, which is a quarter of a mile nearer the town of Federal than No. 2. It also makes a simple matter of supplying the boilers with slack coal, since a car load from the tipple has to be pushed but 200 feet to the boiler room. And furthermore, the location puts it equally distant from the point of utilization of the power in the two mines, the workings in No. 3 being much farther from the drift opening than in No. 2.

From the power house a line of three No. 0000 bare copper wires extends to each mine and then down the slope and underground, a distance of 2,000 feet in No. 2 and 4,000 feet in No. 3. In each mine this constitutes the main feeder, and from it current is supplied to the trolley wires and the machine wires, which ramify throughout the workings.

The map, Fig. 1, shows the plan of the wiring for the entire plant. The main feeders in each case extend from the switch board to the points marked by a cross.

Throughout the underground workings the rails are used for the return conductor; they are bonded at the joints and cross-bonded at intervals of 100 feet. All of the main entry track is of 40 lb. steel rail, well laid, and makes an exceptionally good road bed for the locomotives.

Turnouts are provided as shown and the trips are made up at these points in either mine and pulled by the electric locomotives to the main partings, where they are taken by a rope up the inclines to the respective tipples. Mr. Baldwin, the mine superintendent, has shown excellent judgment in making the main partings at the foot of the inclines of very ample capacity. In each mine there is about 1,200 feet of track at this point and this liberal allowance renders unlikely delays from the accumulation of either empties or loads.

The pit cars weigh about 1,200 lbs. each and carry 2,500 lbs. of coal. The locomotives pull trains of from 40 to 50 of these cars, and with this load they run eight miles an hour. Their normal draw-bar pull is 3,500 lbs. at this speed, but in starting a train, or in pulling up a grade or around a curve, they exert a much greater pull, although at a reduced speed. A test was made on one of them at the mines, to determine just what was their maximum pull; a train of 50 loaded cars was started on a reversed curve and a dynamometer registering up to 9,000 lbs. was put between the locomotive and the first car. When the machine was started up the indicator went beyond the extreme end of the scale, indicating a draw bar pull of over 9,000 pounds. The track was, of course, well sanded, but the true secret of this enormous pull will immediately become apparent to any one who is fortunate enough to have the opportunity of personally examining one of the locomotives. The large heavy drive wheels, the soft steel tires, and the single 85 H. P. motor geared to both axles, explain the whole matter. The locomotive weighs ten tons in all and 20% of the entire weight is in the wheels. The two pairs of drivers, moreover, are not built into one rigid truck but each pair is at liberty to follow the track irregularities, regardless of the other pair, this results in keeping all of the four wheels on the track all of the time and is one of the features making possible the 9,000 lb. draw bar pull above referred to. Each locomotive will easily haul out 1,200 tons of coal in 9 hours, pulling it a distance of 4,000 feet.

A striking feature of the locomotives is the head-light. It is in reality a miniature electric search light and consists of a 1,000 candle power arc lamp fitted out with a parabolic reflector. It can be seen down the entry as far as the entry is straight and as a source of light, there is no comparison between it and an oil or incandescent lamp; it is in a class by itself. This strong light is of the utmost importance, since it enables the motorman to see any track obstruction in ample time to bring his train to a standstill before reaching it, even though running at full speed.

The locomotives come out of the mines every night through the manways, which are practically level, and run into the the motor room which is at one end of the power house. Here they are given a supply of sand for the next day and whatever oiling and general cleaning up they may require. The manways are also used by the locomotives when bringing out slate or taking in props and other supplies. Fig. 5 shows a locomotive coming out of No. 3 Mine at the close of a day's work.

The coal at the Essen mines is the "Pittsburg" vein and contains considerable sulphur, especially in the lower parts where the machines cut. This made the mining of the coal by machines a serious problem.

The "Independent" Chain machines, illustrated by Fig. 3, which were put in, have, however, proved entirely capable of the work, notwithstanding the sulphur, and they have made as high as 54 cuts each 3½ feet wide, per shift of 10 hours, from 30 to 40 cuts being an ordinary occurrence. Sixteen of these machines are now in daily use, and, running double shift, are capable of producing 2,400 tons of coal a day from this 5½ ft. seam.

The reason of this machine's success under these most exacting conditions, is found in its general strength. Both in the electric motor and in the mechanical parts there is an ample margin of safety, and this fact reduces the repairs and their attendant delays to a very small item.

The nature of the "feed" on the machines also renders them especially applicable to work in coal containing sulphur or other impurities.

The machine is fed in by a sprocket wheel receiving power from the motor, and working on a sprocket chain which is on the stationary frame. This chain has a very stiff spring at either end, and, therefore, when the cutters strike something unusually hard, this spring is compressed, allowing the machine to stop feeding for a small fraction of a minute, thus permitting several cutters to pass over the obstacle before the machine again advances; whereas if the feed were absolutely positive, each cutter would be compelled to cut as much of the harder substances as of the coal. If the impurity is sulphur, and, therefore, quite impossible to cut, the machine will stop feeding until the spring is entirely compressed, and then with the energy of the spring added to that of the "feed," the cutters are frequently forced behind the obstacle, jerking it out bodily. The practical working of this feature of the machine is evidenced by the large flakes and layers of sulphur band that are frequently pulled out by the chain.

The machines make a cut 4 inches in height and work in rooms approximately 30 feet wide, about nine cuts being necessary to finish up a room. The cut is 5 feet deep, and this makes a total undercut of 150 sq. ft. per room. The machine, in advancing under the coal, travels 5 ft. in three and one-half minutes and backs out in a minute and a half. About 250 rooms are wired in each mine. It is, however, impossible to cut every room, every shift, as the room, after being cut, must be blasted, have the coal loaded out and the gob thrown back before the machine comes in for the next cut. While this work is going on the room wire is entirely disconnected from the entry wire and is, therefore, "dead." At the foot of each entry there is a switch whereby the current may be entirely cut off from the

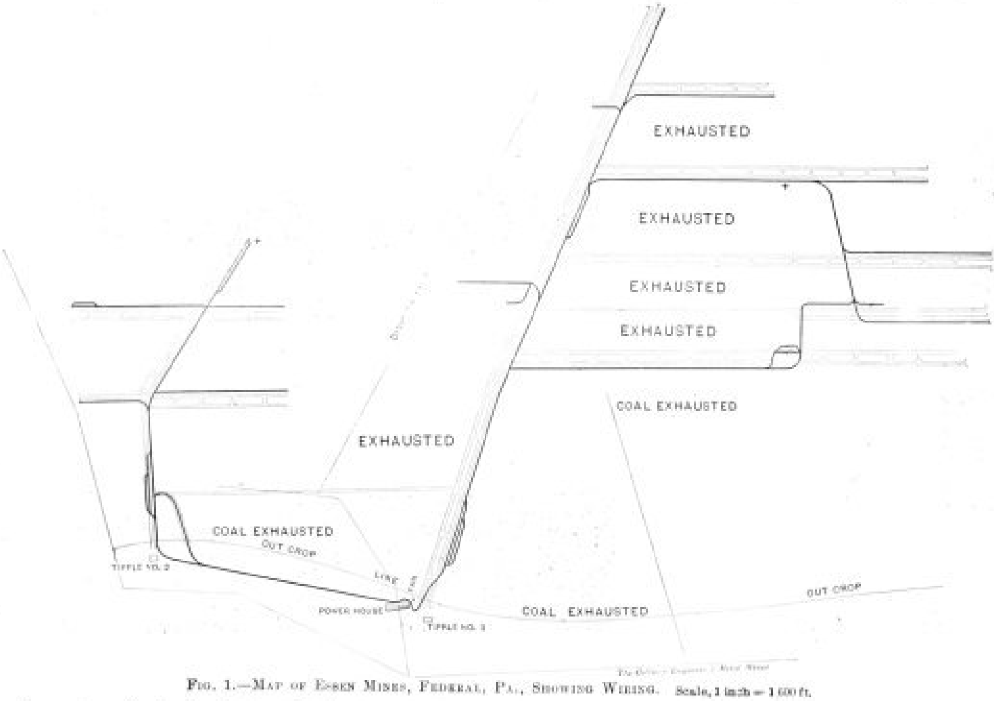

FIG. 1.—MAP OF ESSEN MINES, FEDERAL, PA., SHOWING WIRING. Scale, 1 inch = 1 600 ft.

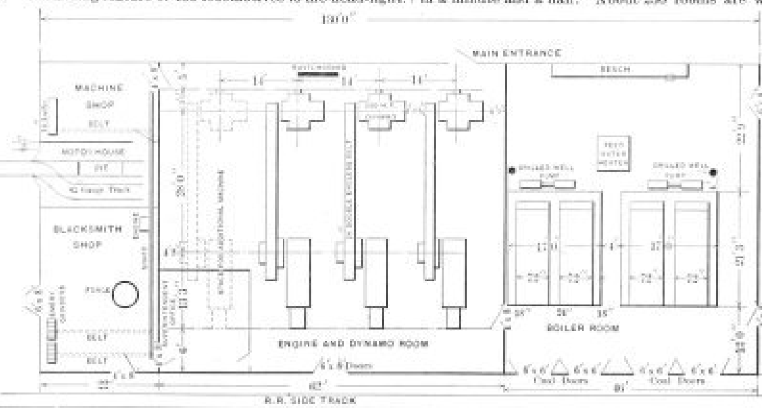

FIG. 2.—PLAN OF POWER PLANT, ESSEN MINES, FEDERAL PA.

entry, and in combination with this switch there is a safety fuse which any abnormal current will melt, thereby opening the circuit and cutting off the current. This arrangement of switch and fuse renders every entry independent of every other entry, and an accident, such as a fall of roof, on one will not interfere with work on any other. At the main parting in each mine there is a large switch, whereby the power may be instantly cut off from the entire mine.

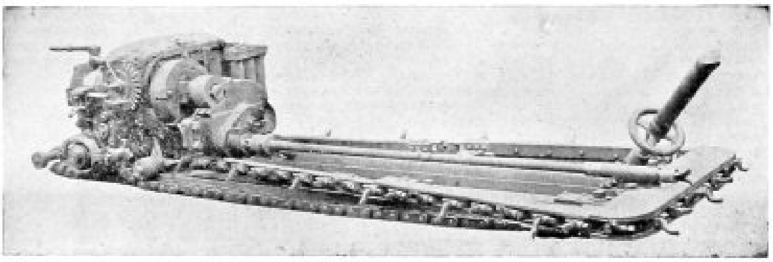

FIG. 3.—"INDEPENDENT" ELECTRIC CHAIN BREAST MINING MACHINE.

FIG. 4.—MINE ARC LAMP.

The main partings are extremely well lighted, the "Independent" mine arc lamp, shown in Fig. 4, being used for the purpose; this is a thousand candle power lamp and burns off the same wires that furnish current to the machines. It is only 12″ high, and may, therefore, be hung from the roof without interfering with work on the entry. The light is the lowest thing on the lamp, and, therefore, all of the shadow is thrown on the roof, giving an unobstructed light on the floor.

The building, illustrated by Fig. 2, which supplies the power for all of this machinery is an iron structure 56 ft. wide by 130 feet long. Forty-six feet of one end are occupied by the boilers. There are four of these grouped in two banks of two boilers each. They are tubular boilers 72″ in diameter and 18 ft. long. In front of them is a space for coal, and behind them the feed-water pump, heater and the injectors are located. There is also bench space, used for pipe fitting. The water for the boilers is taken from two wells drilled for the purpose, in this part of the boiler room.

The middle portion of the power house is occupied by the engine dynamos and switch board. This part of the plant consists of three medium speed 17 x 24 Corliss type Russell automatic cut off engines. The engines run 150 revolutions per minute, and each one is belted directly to a 150 K. W. "Independent" mine type generator. The belts are 24″ wide and the centers of engine and dynamo pulleys are 28 ft. apart.

The three dynamos are slow speed, bi-polar machines, and especially impress one with their extreme solidity and simplicity. They are absolutely free from sparking, even when operating under heavy over loads, and their armature temperature under full load never exceeds 40 degrees Centigrade above the air, while the fields heat up less than 20° Centigrade above the surrounding atmosphere.

The switches, instruments, etc., are mounted on three panels of white Italian marble, shown in Fig. 6, and present a very handsome appearance. The arrangement of the switches is such that any or all of the dynamos may be thrown onto both mines, or either of the mines may be shut off at will. The current to each mine is controlled by an automatic circuit breaker, whereby an accident in one mine will automatically open the circuit there, without interfering with work in the other mine.

Three Weston ammeters and one Weston voltmeter indicate at all times just the amount of power being used on the line.

The normal voltage at the switchboard is 275; the dynamos are over compounded so as to raise this to 300 at full load, and the working voltage underground is from 240 to 250. This combines a perfectly safe current with one that does not necessitate the use of a prohibitory amount of copper, even where the workings are as extensive and as far from the power house as in this case.

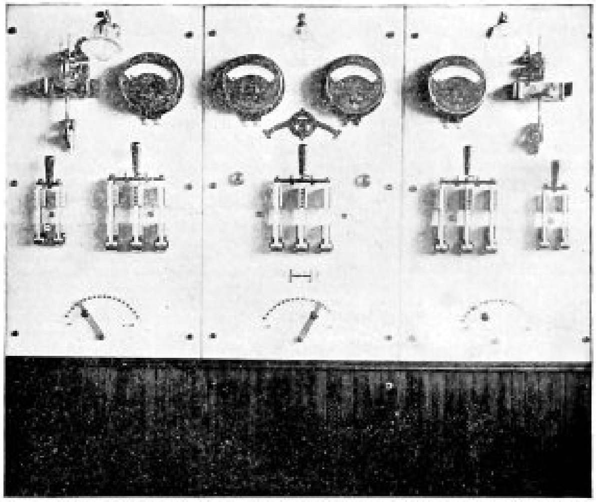

FIG. 6.—SWITCHBOARD FOR DISTRIBUTING 600 ELECTRICAL HORSE POWER AT MINES OF ESSEN COAL CO., FEDERAL, PA.

The cables connecting the dynamos with the switch board have across section of 400,000 circular mils and are three-fourth of an inch in diameter. They pass from the dynamos overhead to the switch board. This method has the very great advantage of keeping the wires where they are in sight and easily accessible and is greatly to be preferred to the altogether too common practice, in small plants of running the cables under the floor where they are out of sight, out of mind and inaccessible.

FIG. 5.—80 H. P. "INDEPENDENT" ELECTRIC LOCOMOTIVE WITH TRAIN OF COAL, AT MINE OF ESSEN COAL CO., FEDERAL, PA.

The engine room is provided with a good brick floor, all of the steam pipes are covered with asbestos, and the whole air of the place is that of a thoroughly first class plant.

The east end of the power house is divided into three rooms, one of these contains a lathe and bench room; one is used for a motor room; and the third is fitted out with forges and emery wheels for dressing up and sharpening cutters.

The plant was first started up in May and soon after starting, a very comprehensive system of keeping track of the work was inaugurated. Each machine runner immediately upon coming out of the mine at night filled out a blank in duplicate, showing the number of cuts made, number of feet of face cut, the number of hours he worked and the nature and cause of delays, if any. The number of his machine was added and the report signed by himself, his helper and pit boss. One of the reports was filed at the mine and the other sent to the Chicago office of the Link-Belt Machinery Co. A photographic reproduction, (Fig. 7) of one of these blanks is shown and will make the whole system very clear. Later, these reports were merged into a general monthly report (see form, Fig. 8.) from which the average results for each machine and each runner were readily obtainable. To this thorough system for keeping track of the work, as well as to the inherent excellence of the machinery, the splendid results of the plant are attributable.

The contract for this, the largest electric mining plant, was let to the Link-Belt Machinery Co. of Chicago after a thorough investigation of all the leading electric mining plants of the country by Mr. Dysart the General Manager and his Superintendent, Mr. Baldwin. That they did not err in their judgement is attested by the fact that the plant was in operation two days ahead of the contract time and every stipulation and guarantee of the manufacturing company regarding the capacity of their machines not only met but surpassed. And the fact that the plant was formally accepted and paid for in full in accordance with the

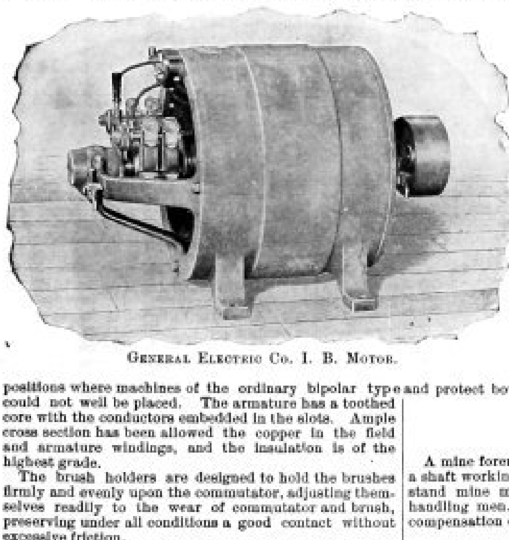
N. B.—1st. Make up this report weekly, attach it to daily report blanks for that week, and mail to Mining Department.
2d. Daily report blanks must by signed by some representative of Coal Company from time first machine starts and all delays and breakages noted thereon.
3d. Furnish Coal Company with copy of this report when requested.

terms of the contract, is evidence that Pickands, Mather & Co, who control the Essen Mines, were satisfied that the plant was all it was represented to be.

Ironclad Generators and Stationary Motors.

The list of slow and moderate speed four pole dynamos and motors of the General Electric Company, has been supplemented by a series of machines adapted to smaller output than is practicable with the four pole type. They are classed under the head I. B. from the fact of having an ironclad bipolar frame, and are built for various outputs—from ¾ to 4½ kilowatts as generators and from 1 to 5 horse-power as motors.

The frames are cylindrical and are supported on short legs. This brings the center of gravity very low and conduces to stability and steadiness when running. The space occupied by the machine is small for its output, and its shape and construction allow of its use in



GENERAL ELECTRIC CO. I. B. MOTOR.

positions where machines of the ordinary bipolar type could not well be placed. The armature has a toothed core with the conductors embedded in the slots. Ample cross section has been allowed the copper in the field and armature windings, and the insulation is of the highest grade.

The brush holders are designed to hold the brushes firmly and evenly upon the commutator, adjusting themselves readily to the wear of commutator and brush, preserving under all conditions a good contact without excessive friction.

The speeds are comparatively low varying from 1,800 to 1,000 revolutions per minute according to the size of the machine.

They are especially adapted to the requirements of small motor service. Their small size, low speed, high efficiency and simplicity of construction render them peculiarly valuable in printing, wood turning and establishments of a similar character, and for the operation of small pumps, ventilating fans, machine tools, etc. A large number of these I. B. motors are already in use.

The generators are successfully used in isolated plants and in cases where a small amount of current economically generated is desired.

To Mine Managers.

Among the new advertisments in this issue of THE COLLIERY ENGINEER AND METAL MINER, are the following.

The Bloomsburg Car Mfg. Co. of Bloomsburg, Pa., manufacturers of freight, mine and dump cars of every class, and also manufacturers of the well known "Bowden" self-oiling mine car wheel. This company has extensive works at Bloomsburg, and has won an enviable reputation for excellency of work, promptness in shipment and reasonable prices. Their circulars and catalogues are of interest to every mine manager.

The well known pump manufacturers, The Geo. F. Blake Mfg. Co., and The Knowles Steam Co., make their debut as advertisers in THE COLLIERY ENGINEER AND METAL MINER in this issue. The use of Knowles and Blake pumps for many years in every mining field on the continent attests their reliability and efficiency. The pump user who does not possess their catalogues should send for them at once. Their is no telling when a new pump of some description from a small boiler feed to a large mine pump for heavy duty is required. When it becomes necessary to order a pump the wise mine manager will at least consult the catalogues of such well known manufacturers even if he has "almost made up his mind to purchase some other make." The immense number of Knowles and Blake pumps in use for many years is the strongest testimonial of their excellence.

Messrs. Wyckoff, Seamans and Benedict, also make their debut in this issue as advertisers. Their specialty is the Remington type-writer. The office of the present that is not equipped with a type-writer of some kind, is the one in which either the amount of business done is exceedingly limited or the cost for clerical work is excessively high. There are more Remington type-writers in use in large railroad and other corporation offices, as well as in the various governmental departments at Washington, than any other. They are well made, convenient and easy to operate, and they are the best manifolding machines we can get for use in our own offices. This latter feature alone is a valuable one in a mining office. Their catalogues are sent free on application, and we advise every mine manager in want of a machine to look into the merits and advantages of the Remington before purchasing any other.

Another new advertiser this month is the Allison Coupon Co. of Indianapolis, Indiana, whose coupon books are described in another column. These books are a decided advantage at mines where stores are run in connection with the mines. They absolutely prevent mistakes in accounts and protect both the operator and miner.

Wanted.

A mine foreman to go to Colorado to take charge of a shaft working 7 feet of bituminous coal. Must understand mine machinery and have had experience in handling men. Address, stating experience, age and compensation expected,

413,
Care THE COLLIERY ENGINEER AND METAL MINER.

PRIZE CONTEST.

PRIZES GIVEN FOR THE BEST ANSWERS TO QUESTIONS RELATING TO MINING.

For the best answer to each of the following questions, the value of $1.00 in any of the books in our book catalogue, or six months' subscription to THE COLLIERY ENGINEER AND METAL MINER.

For the second best answer to each question, the value of 50 cents in any of the books in our book catalogue, or three months' subscription to THE COLLIERY ENGINEER AND METAL MINER.

Both prizes for answers to the same question will not be awarded to any one person.

Conditions.

First—Competitors must be subscribers to THE COLLIERY ENGINEER AND METAL MINER.

Second—The name and address in full of the contestant must be signed to each answer, and each answer must be on a separate paper.

Third—Answers must be written in ink on one side of the paper only.

Fourth—"Competition Contest" must be written on the envelope in which the answers are sent to us.

Fifth—One person may compete in all the questions.

Sixth—Our decision as to the merits of the answers shall be final.

Seventh—Answers must be mailed us not later than one month after publication.

Eighth—The publication of the answers and names of persons to whom the prizes are awarded shall be considered sufficient notification. Successful competitors are requested to notify us as soon as possible as to what disposal they wish to make of their prizes.

Competition Questions for December.

QUES. 193. As we are trying to make our new patent safety lamp the best in use, we cannot be over careful in avoiding the errors that may spring from our own ignorance. Now there were two of the primitive lamps that were furnished with glass chimneys, and one had it set within the gauze cylinder, as in the Stephenson lamp, and the other had the chimney set over and outside of the gauze, as in the Jack lamp, and to make the use or intention of these glass chimneys so clear that we may discover any essential principle in them that should be incorporated in the structure of the new lamp, will you please explain to me four things?

First. What was the use of these glass cylinders in promoting safety?

Second. Did these glass chimneys increase or diminish the light from the lamp?

Third. Did these glass cylinders increase the motive column and make the lamp burn where other lamps would go out?

Fourth. Was the safety of the lamp increased or decreased when by accident the glass cylinder was broken?

QUES. 194. Before commencing to sink we are boring to find the thickness of the seams, and those of the intervening and overlying strata, and the general direction and amount of the dip. We have two good seams, and the top one A, according to the prevailing thicknesses east of us, should be 4.5 feet, and that of B the lower seam 3.75 feet, and in addition we know that the thickness of the rocks between A and B should be 104 feet; but if the excited story of our master borer is to be believed, these thicknesses will be found to be quite different for the following reasons:

At 2 o'clock this morning our house door-bell rang most violently, and running to the stairs I shouted, "Whose there," when a voice replied, "It is me, the master borer from Hardrock," and he continued, "I bring good news, we have cut seam B with the bore tubes at 57 feet instead of 104 feet," and I said "Good, that will save the expense of boring the other 47 feet," but he replied, "That is a trifling consideration, and this is what you should know. The thin intervening rock indicates a thick seam, and instead of 3.75 feet, the B seam will most likely be 6 feet." Now this is good hope if it is not good news, and I will be obliged if you will tell me on what geological facts or principles the master borer founded his opinion. I may say that all the mines east of us are deeper to the A seam than we are.

QUES. 195. Will you calculate for us the quantity of air in cubic feet per minute we will obtain with a 2 inch water gauge. The fan is 30 feet in diameter and runs with an angular velocity of 90 revolutions per minute, the diameter of the central orifice of intake is 12 feet the area of the throat of the fan is 130 square feet the area of the orifice of discharge is 60 square feet and the radial length of the blades is 9 feet.

QUES. 196. We are passing 86,400 cubic feet of air per minute through an airway 10 feet high, 12 feet wide and 3,000 yards long with a water gauge of 3.29 inches, and as we do not now require such a large quantity for this district, we are going to reduce the supply with a regulator and pass instead only 36,000 cubic feet per minute and we will be obliged to you if you will calculate for us the area required in square feet to pass the stated quantity through the regulator. Make the co-efficient for the *vena contracta* .65, and the co-efficient of friction .00000001.

QUES. 197. We have sold a conical heap of coals to three persons A, B and C, and to prevent injustice of any kind we will be obliged for your assistance in furnishing us with the heights at which each purchaser will have obtained his correct weight. For example, the cone is 42 feet high, and the diameter of the base is 90 feet, and as a cubic foot of these broken coals weighs 53 pounds, will you first tell us what is the total weight of the heap, in tons of 2,240 pounds, and as each of these persons have paid for one third of the weight of heap, we have arranged to surround the heap at the height you give us with a platform, so that A can only cut off the top of the cone to get his share, and then we will erect the platform to allow B to obtain his share, and the remainder will be C's share. Now please tell us how high the platform should be set for A's share to cut off a cone, and for B's to cut off a frustum, and leave C his just share as the remaining frustum.

QUES. 198. Why is anthracite coal broken in pieces before it is sent to the market for sale and for use as fuel?

Answers to Questions which Appeared in October and Previous Issues, and for which Prizes Have Been Awarded.

QUES. 174. My Uncle George is a mine superintendent and he asked me to-day if I had given due attention to the study of mine machinery, and steam engines and boilers? and I said oh! yes, I know all about them, and nobody can teach me any more than I know; and he said, "hem," and continued, "Solve me this question and let me have the answer in a few days."

We have a semi-portable hauling engine in the Burdock mine, and it it rather light for the work, and therefore, always runs with full steam. It is 80 horse power, and the highest pressure of the steam at blow-off is 90 pounds on the square inch.

The train has a speed of 10 miles an hour on the level road when the steam pressure falls to 50 pounds on the square inch, and on coming within 850 yards of the shaft the train of cars has to ascend an incline, when the speed reduces and the pressure of the steam in the boilers rises to 90 pounds on the square inch. Now the boiler fire (before the start) is banked up to keep the horse power of the boiler uniform throughout the journey.

The question makes three demands:

1st. Why does the boiler pressure vary?

2nd. What is the gradient of the incline?

3rd. What is the speed of the train on the incline?

I frankly confess, I have made a mistake in bouncing to my uncle George, and I hope you will help me out of the dilemma by answering the questions for me.

ANS. First. The pressure varies because the boiler is making its maximum output of steam when the train of cars is running at 10 miles per hour with a pressure of 50 pounds on the square inch above the pressure of the atmosphere.

Second. The grade of the incline can be found as follows: Let there be 2,240 pounds in a ton, and let the co-efficient of traction for cars, ropes, rollers, engine, etc., be .018 of a ton in pounds; then $2,240 \times .018 = 40.32$ pounds per ton for traction due to level only; and for level and incline it will be 50 : 90 :: 40.32 is to 72.576, that is $\frac{40.32 \times 9}{5} = 72.576$ pounds for traction, and force required to overcome that of gravitation. Therefore the force required to pull every ton up the incline will be $72.576 - 40.32 = 32.256$ pounds. The grade of the incline then is $\frac{2,240}{32.256} = 69.4$, that is an upgrade of 1 in 69.4 feet.

Third. The velocity up the incline will be inversely as the pressure of the steam, because as the volume of the steam reduces, the pressure increases, and as the speed of the engine is directly proportionate to the volume of the steam consumed, $\frac{10 \times 50}{90} = 5\frac{5}{9}$ the velocity of the cars up the incline in miles per hour.

CHAS. E. BOWRON,
Tracy City, Tennessee.

Second, HUGH CAIRNS,
Elco, Washington County, Pa.

QUES. 181. I am about to invent a new miner's safety lamp, and I intend to make the capacity of the tank or oil vessel large enough to supply sufficient vegetable oil for a consumption of 8 cubic inches per day of 10 hours, and as I require your valuable assistance, will you answer me three questions, as follows:

1. What volume of air will be required to supply the necessary oxygen to burn the oil?

2. If only 20 per cent. of the oxygen of the air entering the lamp is consumed, what volume of air is necessary to feed this flame?

3. If, after allowing for the *vena contracta* and the interference of the wires, the available aperturage is in the ratio of .3, and if the velocity of the air on entering is equal to 3 feet per second, how many square inches of gauze covered entrance must I provide for the admission of air?

ANS.—

(1.) Taking $Sp. G$ of the oil at 0.92, the weight of 8 cu. in. would be $\frac{8 \times 0.92 \times 62.4}{1728} = 0.265$ lbs.

Assuming the oil to produce all gas, and if it were rape seed oil, with the formula $(C_{10}\, H_{18}\, O_2)$ 0.265 lbs. of oil would require 3.03 lbs. of air to completely burn it.

From the formula, Wt. Air = 12 × Wt. Carbon + 36 (Wt. Hydrogen — $\frac{1}{8}$ Wt. Oxygen.) In this case, C being $\frac{120 \times 0.265}{170}$; H, $\frac{18 \times 0.265}{170}$ and O, $\frac{32 \times 0.265}{170}$ lbs., as

$$\begin{aligned} 10\,C &= 120, \quad (C = 12) \\ 18\,H &= 18, \quad (H = 1) \\ 2\,O &= 32, \quad (O = 16) \\ C_{10}\, H_{18}\, O_2 &= \overline{170} \end{aligned}$$

3.03 lbs. of air ÷ .0807, Wt. 1 cu. ft. air, = 37.55 cu. ft. Ans.

(2.) It would take $\frac{100}{20} \times 37.55 = 187.75$ cu. ft. Ans.

(3.) With assumption in second question,

$$\frac{187.75 \times 1728}{10 \times 60 \times 60 \times 0.3} = 3 \times 12 \times A, \text{ whence}$$

$A = 0.83$ sq. in. Ans.

CHAS. E. BOWRON,
Tracy City, Tenn.

QUES. 182. We have found a large fault in one of our coal seams, and the cheeks or sides are 6 inches apart, and the interspace or vein is filled with calcite and galena. Our mine foreman says that galena always contains gold and silver, and his statement has so excited me with surprise that I have been trying to extract the metal by raising the ore to a high heat on an open fire, but it all wasted away in white smoke. I will, therefore, be obliged to you if you will tell me what I must do to obtain about seven pounds of the metal, and while you are busy please say what I must do to separate the silver from the lead.

ANS. Cut out a representative sample of the vein stuff and break it up into pieces about the size of hickory nuts and after spreading it out evenly, divide the layer into 4 equal parts and with the part taken, continue breaking it smaller, and dividing it still further and further until it is reduced to about 1 pound or less. Next pulverise it small enough to pass through a sieve of 100 meshes to the square inch. Now, take a crucible and roast and reduce with an oxidizing flame, when the metal will be obtained as a button. We now know the weight of metal per pound of vein stuff tested, and the percentages of lead and gold and silver can be found by burning off the lead with an oxidizing flame when a small button of gold and silver will remain. After this we can tell exactly how much vein stuff would be required to obtain 7 pounds of the metal.

P. H. CARROL,
Vivian, W. Virginia.

Second, H. K. MOBERLY,
West Newton, Pa.

QUES. 183. We have 1,000 acres of a seam of good and clean coking coal, 2 feet, 10 inches thick, and at an average depth from the surface of 600 feet; the roof consists of 30 inches of bad shaley coal, or bone; the mean inclination or dip of the seam is 4° 16′ to the east. How do you think I should work this seam to obtain all the coal, as I can only sink the shafts on the western side of the estate, the eastern side being all under water?

ANS. First drive the main haulage roads straight to the eastern boundry and then take out the coal by longwall retreating. The bad top coal would just stow the gob after it had been brushed to make height. The danger of gob fires would be great with such a roof, but the gob could be kept full of water and altogether this mode of working would, I think, best meet the requirements of the case.

P. H. CARROL,
Vivian, W. Virginia.

Second, GEO. BROWN,
Falls Creek,
Clearfield Co., Pa.

QUES. 184. I am engaged by a powerful syndicate to be the chief of a large staff of prospectors to search for useful minerals in Asiatic Turkey, and my instructions are to confine the work to be done to the valleys of the great rivers, the Euphrates and the Tigris, and the valleys of their tributaries, the reason for the restriction being, that the country is not opened up with railways, and therefore the water-ways are the only routes open for transport. In the North of Asia Minor where the great rivers take their rise the stratified rocks belong to the Cenozoic period, and nearly all the exposed rocks found in the valley of the Levant belong to the Mesozoic period such as those that are found on the east of the Tigris and the west of the Euphrates; and between the great rivers, as west of the Tigris and east of the Euphrates, the rocks are mostly of the Eozoic age, although rocks of later ages are found in patches. Now the great stone records of Babylon and Nineveh are cut on slabs of gypsum taken from their near hand quarries, and I will be obliged if you will give me such information as I require.

First.—We know that salt, coal, lignite, copper, lead, silver, gold, and iron abound within the rocks of the valley of the Levant, then please tell me where to send my men to search for them.

Second.—Tell me briefly what class of tools I ought to give each set of prospectors to find the particular minerals they will be sent in quest of?

ANS. *First.*—To find coal and iron ore, send one set of prospectors to search the rocks in the region east of the Tigris, and another set to search west of the Euphrates. To find salt, send a set of prospectors to examine the regions of the gypsum quarries in the neighborhoods of the cities of Babylon and Nineveh, as the salt rock may be expected to overlie the gypsum beds at the dip of the horizons of the quarries.

Between the great rivers locate the prospectors for gold, silver, copper, tin, lead, etc.

Second.—Each set of prospectors would require guides and a bodyguard of well armed men, tents, blankets, and cooking utensils. The tools for the metal prospectors should be picks, shovels, hammers, drills, blasting tools, iron ladle, pan, blow-pipe outfit, bellows, hammers, tongs, anvil, carpenters' saws, nails, hammers, etc., microscope, chain, transit instrument, and mapping tools and paper. The prospectors on the Persian side of the Tigris, and those on the Arabian side of the Euphrates, and the set sent into the neighborhoods of Babylon and Nineveh, should have in addition to the tools given to the prospectors sent to operate between the rivers, a complete set of deep bore rods to be worked by hand with a brake staff.

P. H. CARROLL,
Vivian, W. Virginia.

QUES. 185. As I am anxious to obtain a good example of a magnetic survey. Will you give me your notes of one where the figure only has seven sides, also the plot, and the results of the traverse to prove its accuracy?

ANS. In an actual magnetic survey, where the readings of fractions of degrees cannot be made as accurately as on a transit, to obtain better results in the calculations, it is necessary to balance the survey. This is done by distributing the differences of the sums so obtained in the latitudes and departures among the courses in proportion to their lengths.

L. A. O. GABANY,
Civil and Mining Engineer,
Brookwood, Ala.

Second, WILLIAM WYLIE,
Civil Engineer,
Washington, Pa.

QUES. 186. We have a pump that forces with two six inch plungers the drainage water of the mine to an elevation of 660 feet. From the commencement, this pump had a heavy "knock" and it was found to occur at the moments when the plungers began their advance on the forcing stroke and it seemed to result from the chambers not being filled close with water during the suction or intake stroke, and the consequence was the knock by the plunger advancing on the force, and the heavy strain that destroyed the packing of the glands and ultimately the "skin" of the plungers that became scored and fluted. Some mechanical engineers declared that the cause of the knock was the softness of the iron plungers that became fluted and leaky, and that the only cure would be found in getting nickel steel or bronze plungers; our engineer, however, thought differently and said the only cure would be found in slacking the glands and drowning them with water. He then fixed cases over the outsides of the glands and filled them with water when the knock was completely cured. Will you then explain to me the cause of the knock and how or by what means it was cured by drowning the glands?

ANS. During the intake stroke the vacuum was neutralized by the entry of air between the sides of the plunger and the leaky gland, consequently the pump chamber was never close filled with water, and, therefore, at the beginning of the forcing stroke, the plunger attained a high speed before it struck the water that had to be suddenly set in motion with a jerk.

The drowning of the gland entirely prevented the entry of air, because a little water entered instead, and thus the pump chamber was always closely filled with water, and, therefore, at the beginning and all through the stroke, the engine had force against a solid column.

HUGH CAIRNS,
Elco, Washington Co., Pa.

Second, CHAS. ED. BOWRON,
Tracy City, Tennessee.

PERSONALS

Mr. T. B. Corey, of Seattle, Washington, resigned his position as mine superintendent of the Oregon Improvement Co. on the first ult., after an incumbency of nearly seven years. Mr. Corey's relations with the company were most cordial, and in his resignation it loses the services of an official who was faithful to its interests under all circumstances.

Mr. A. D. W. Smith, late Assistant Geologist Pennsylvania Geological Survey, has opened an office for the individual practice of his profession as a geologist and engineer at No. 74 Coal Exchange, Wilkesbarre, Pa.

Waste Packed Mine Car Wheels.

The Hockensmith Wheel and Mine Car Co. of Irwin inform us that their works are running full time, and that they are in continual receipt of large orders for their new patent waste packed mine cars wheels. In fact this wheel has met with such favor that the Hockensmith company is arranging to increase its plant so as to enable them to promptly fill all orders. Reports from dozens of users of this wheel show that it is giving universal satisfaction.

This department is intended for the use of those who wish to express their views, or ask, or answer, questions on any subject relating to mining. Correspondents need not hesitate to write for supposed want of ability. If the ideas are expressed, we will cheerfully make any correction in composition that may be required. Communications should not be too lengthy, and personal reflections should be carefully avoided.

All communications should be accompanied with the proper name and address of the writer—not necessarily for publication, but as a guarantee of good faith.

The Editor is not responsible for views expressed in this Department.

☞ *Correspondence should be in as simple language, and as free of technical terms and formulae as possible, consistent with clear solution.*

Questions on subjects not directly connected with mining will not be published.

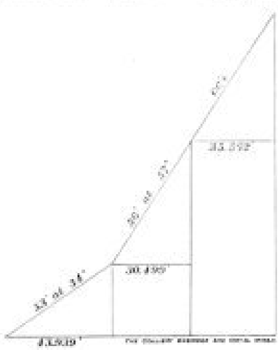
Surveying.

Editor Colliery Engineer and Metal Miner:

SIR:—I submit the following solution to problem propounded by "Tom," Minersville, Pa. in November issue of this journal.

I am working a seam of coal that outcrops on a piece of land which I cannot enter. The horizontal distance of the land line from the high side of the gangway is 110 ft. I have driven a hole up on a pitch of 34° for 53 ft. from the high side of the gangway, and at this point the pitch changed to 57°. I have driven on this last pitch a distance of 56 ft. How much farther can I go on the same pitch before I reach the land line?

ANS. If the horizontal distance is 110′ to line, the horizontal distance of the first 53′ at 34° = 53′ × cosine = 43.938′ + Then the second 56′ × cosine of 57° = 30.499′ + then 30.499′ + 43.939′ = 74.438′, then 110′—



74.438′ = 35.562′ from line on a horizontal distance? Then 35.562′ ÷ .54464 = 66′ nearly. He can drive at work up 66′ feet on the dip of 57° to strike land line.

Yours, etc.,
J. G. LEWIS.

Minersville, Pa.

This question can be solved by forming three separate right angled triangles. And taking a part of the total horizontal distance for the base of each triangle.

Then horizontal distance for first triangle = cos. 34° × 53 = .82904 × 53 = 43.93912 ft.; second triangle, horizontal distance = cos. 57° × 56 = .54464 × 56 = 30.49984 ft. Then the horizontal distance for the third triangle = 110 − (43.93912 + 30.49984) = 35.56104 ft. And as the pitch is the same as the second triangle or 57°, then the distance that the hole can be driven will

$$= \frac{35.56104}{\cos. 57°} = \frac{35.56104}{.54464} = 65.29 + \text{feet farther.}$$

Yours, etc.,
ARCHIE LAFFERTY,
Wampum, Pa.

[We have also received answers similar to one or the other of the above from David P. Thomas, Miner's Mills, Pa.; Alfred Powell, Scranton, Pa.; E. W. Bailey, Rock, W. Va.; Adolph Cook, Houtzdale, Pa.; W. A. Goodspeed, Nelsonville, O.; Geo. H. Winter, Joint, Pa., and 'Carbon," Oskaloosa, Iowa. ED.]

Pumping.

Editor Colliery Engineer and Metal Miner:

SIR:—Please insert the following question in your valuable paper for some of the readers to solve.

In putting in a new line of pipe 640 ft. from steam plant I could not hold pressure for more than twenty minutes at a time for four or five hours. And after that time it was quite easy to hold pressure.

Please state cause of increase and decrease in pressure.

Yours, etc.,
DAVE HOLSTEAD,
Krebs, I. T.

How to Mine.

Editor Colliery Engineer and Metal Miner:

SIR:—I write the following in answer to question asked by "Inquisitive," Mammoth, Kanawha, Co., W. Va. in the November issue.

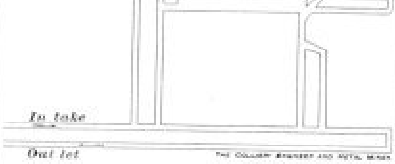
By mining the lower seam first and taking out the pillars, the upper seam would be affected very much. It would be the best to work the upper and lower seam at the same time with the upper seam a little head of the lower; then by taking the pillars out of the lower seam it would not affect the upper seam. I speak from experience, having tried this plan. I worked a 4 foot seam on the stall and pillar system and drew the pillars and then mined a seam which was 5 feet thick, 60 feet higher up the mountain, and I found it to be affected very much where I had drawn the pillars out in the lower seam. Then I tried working the upper seam a little head of the lower seam and I found then by taking the pillars out behind me I was all right.

Yours truly,
GEO. BLEWITT,
Vintondale, Cambria Co., Pa.

Ventilation.

Editor Colliery Engineer and Metal Miner:

SIR:—I wish to submit the following drawing of double entry system and request that some of your



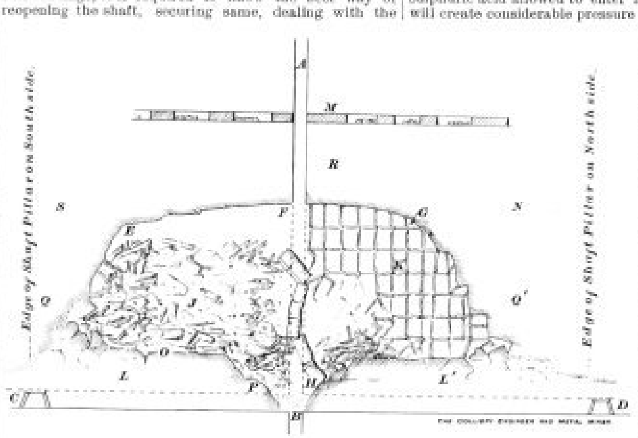
readers give plans for ventilating the same with the least number of doors and without doors.

Yours, etc.,
AJAX.

Reopening a Caved Shaft.

Editor Colliery Engineer and Metal Miner:

SIR:—Given the extent and character of this cave and its surroundings, it is required to know the best way of reopening the shaft, securing same, dealing with the



cave, cleaning up and putting in the permanent shaft and main entries running north and south from it to connect with the interior of mine.

Referring to the section, AB is the bottom 200 ft. or so of the main shaft. This is a rectangular timbered shaft, about 18′x8½′ timbered throughout with 6″x8″ stuff. It is divided into three compartments, 2 cage ways and 1 airway. The shafts longest diameter is in a west and east direction. S and N stand for south and north, B is the sump about 15′ deep, M is a 5′ seam of coal, in which some rooms were worked several years ago and then the seam was abandoned. CB and DB are where the main lyes or roads were before the shaft caved in. The points C and D can be reached to-day by descending the escapement shaft which is intact. There is a small fan on it and from it the workings are kept in repair.

Some 6½ years ago the timbering of the lyes on both sides of foot of shaft broke down and with it the roof caved to about the height O and for 50′ or 60′ inbye from bottom of shaft. These falls were cleaned up and heavily retimbered and no trouble was experienced until a year ago. In Nov. '94 the tower on top burnt, and falling down the shaft, set fire to the timbering about H. This fire went clear up the shaft to the surface and consumed the timbering around top of shaft until the surface for 35′ around it, and to 40′ deep ran in with a rush and smothered the fire below.

In May last the shaft was reopened and made safe down to about F, which is 120′ from the bottom B. The cavity EFG (about 150′ long x 20′ wide) was timbered up, the shaft built or extended downwards through the cave hole as the work proceeded. Slice after slice of debris was removed (hoisted) and by Oct. last timbered securely down to about 35′ from rail level B. LL' shows the quantity of debris not yet taken out, K represents timbering in cave on north side, and south side J was similarly timbered.

On about Oct. 1st, actual fire (red hot rail guides etc.), was met with at O and P. The hose was vigorously applied to it. Doing this seems to have created large quantities of steam, which got up into the timbering and loosened some, as well as the exposed strata (shales chiefly) on that side, the result was this side of the cavity fell in (see JEF) and with it fell the lower 95′ or so of the newly put in shaft. (See F to A). The settling down of the shaft also damaged the timbering K on north side, but which, when last seen was most of it standing in good shape.

The width of the cave as explored and when timbered was reported at from 25′ to 40′ (it got wider as followed downwards). This shaft stands or stood in the middle of a pillar of coal measuring about 350′ N and S x 300′ E and W. The seam is 3½′ thick and worked entirely on the longwall system (Scotch method). The hoisting capacity was 1500 tons of lump coal per day of 10 hours, and when the fire of Nov. '94 occurred this mine was just about at its best having been growing larger and larger since sunk about 12 years ago.

After the fire of Oct. 1st, all was reported cool and quiet in the cave until Oct. 5th, when the fire again and very suddenly broke out about 1 A.M. Water was again turned into top of shaft, but the fire gained on them, until, at 6 A.M. the top of shaft had to be sealed up. Timbers 6″x6″x18′ with 2 layers of 2″ plank on top were used and over these 2′ of puddle and then a layer of sand. The fire in the cavity is so far confined thereto, because there is no sign of it in the mine at C or D, but hot water trickles out on floor at D. Thermometer 200′ deep registers 110° F. This shaft is practically dry and the workings are quite dry. Whether the top of cave F has run up any higher towards R or M is not known, nor whether timbering is intact or not.

Besides the roads CB, and DB, the shaft pillar has been driven through in at least three other places E and W of C B D. Total depth of shaft is 341 ft. from surface to coal.

Yours, etc.,
G. S. W.

Nov. 8, 1895.

Chemistry.

Editor Colliery Engineer and Metal Miner:

SIR:—Will you kindly publish the following questions for answer in your early issues, as it will be a kindness to me.

(1.) If one ounce of bicarbonate of soda and one ounce of sulphuric acid be mixed with 12 ounces of water, the soda and water may be mixed first, then the sulphuric acid allowed to enter in a small stream this will create considerable pressure if confined. What will be the pressure and temperature and how many cubic feet of gas will be generated from these chemicals and what kind of gas will it be. If it will not be convenient to give pressure and temperatures, please give the number of cu. ft. and kind of gas.

(2.) My question in last March issue has never been answered. With your kind permission will repeat it here, as follows: If one pound of carbon from bituminous coal produces 14,500 units of heat, how many atoms of oxygen would be required to form complete combustion under a boiler of moderate draft and at what degree of temperature would the above carbon and oxygen ignite.

Yours, etc.,
WM. M. MORRIS.

Pueblo, Colo., Nov. 22, 1895.

Safety-Lamp Experiment.

Editor Colliery Engineer and Metal Miner:

SIR:—Will some fire-boss who is a reader of your valuable paper give me a correct answer to the following experiment? To test gas with a safety-lamp without a gauze. Removing the gauze from a safety-lamp using soap to close all holes in shield except *one*, I received same indications inside shield as I did when gauze was placed in the lamp. It gave me light but not quite sufficient to work with.

Now explain why the gas did not explode outside the shield, remembering that the mixture was highly explosive.

Yours, etc.,
D. L. AINSLEY.

Mining Tools.

Good tools are essential both inside and outside at mines. Quality is a prime requisite. Tools made of second-class material and in a second-class manner are dear at any price, especially when used at mines. First-class tools can be made to compete in price with second-class goods if the purchaser knows where to buy. The Fulton Tool Works, which were established in 1882, make a specialty of mining tools. Their tools are not pressed but are *strictly hand made*. They are in use in almost every mining region, and their record is first-class. Large purchasers will profit by sending to the Fulton Tool Works of Canal Fulton, Ohio, for catalogues, and small purchasers can be sure of first quality by insisting on their local dealers giving them Fulton Tool Works tools.

Heretofore the deepest sounding of the ocean has been forty-six hundred and forty-five fathoms, near Japan. But the surveying ship *Penguin* sent out by the British government, has found a deeper spot. The sounding wire broke at forty-nine hundred fathoms, when bottom had not been reached. This was exactly south of the Tonga, or Friendly Isles, and almost on the Tropic of Capricorn.—*Ex.*

THE PENNSYLVANIA MINE INSPECTORS' REPORT.

As usual, the report of the Inspectors of Mines of Pennsylvania for 1894 is nearly a year behind time. It has just been issued. We have had the reports of almost every other State for some months and even the report of distant Victoria (Australia) has been in our office for at least two months. Other foreign reports were received still earlier.

Why the report of the Inspectors of Mines of Pennsylvania, which is one the most important of the State publications should be so far behind time is a question that has never been satisfactorily answered by the State Printer.

The report has been received too late for us to analyze the statistics and prepare a summary of them for this issue. Such a summary will appear in our January number.

As usual the work of editing the reports, and the proof reading has been done in a manner that, to say the least, is disheartening to the Inspectors, who have worked hard to make them models of completeness, and is discreditable to the department from which they are issued.

Mr. Edward Roderick, Inspector of the First Anthracite District includes in his report some useful information and hints on pillar robbing, which show that his attention to this subject in 1893, produced good results in 1894, and at the same time points out dangers that can only be avoided by the personal watchfulness and care of the men engaged in the work.

Mr. Patrick Blewitt, of the Second Anthracite District limits his reports to the statistical tables and a brief summary of their contents in his letter of transmittal.

Mr. Hugh McDonald of the Third Anthracite District explains why the number of fatalities per thousand employees is greater in the anthracite regions than in the bituminous mines of Great Britain. His reasons are based on the greater use of explosives in mining the coal, together with the greater disturbance of the overlying strata by blasting in mines, the greater thickness of the coal seams making inspection of the roof less positive, and the difference in the average intelligence of the men employed, due to the influx of workingmen from Southern and Eastern Europe in the past few years. Mr. McDonald's description of the electric machinery at Mt. Lookout colliery is spoiled by having a number of the illustrations mixed up with others in the centre of the Eighth Bituminous District Report.

Mr. G. M. Williams of the Fourth Anthracite District, as usual, presents a report that is not only complete from a statistical point of view, but which contains a vast amount of good practical data and information for the guidance of miners and mine officials. He gives a very complete summary of his investigations at the collieries in his district during the year, and on the subject of ventilation gives the Lehigh & Wilkes-Barre Coal Co. the following commendatory notice:

"This company is the largest coal producer in this district. It operated ten collieries, consisting of seven shafts and five slopes in 1894. All are large collieries having workings of wide extent in several seams. With the exception of one, all are working in deep parts of the coal basin, where explosive gases are evolved in large quantities, requiring immense volumes of air currents and great care in management. They are excellently ventilated and carefully conducted, and liberal provisions are made to insure safety in the event of an accident occurring which would disable the ventilating fans. No standing gas is permitted to remain in any part of the workings, and where such a large volume of air circulates, no satisfactory excuse can be presented by any foreman for the presence of standing gas."

In commenting on the mines of the other large companies, and on those of smaller companies, he states that, in general, they are well ventilated and in safe condition, though he points out one or two minor instances in which changes can be made that will enhance the safety of the men.

The mines in Mr. Williams' district taken as a whole are probably the most gaseous mines on this continent, and when he commends their management for efficient ventilation, it necessarily follows that great attention has been given the subject. A peculiar feature noted in Mr. Williams' report was the discovery that the electric current used on trolley car lines in the neighborhood of collieries can be and is carried into the mines by water pipe or other continuous lines of iron and is a new element of danger that must be guarded against in gaseous mines, owing to the fact that the electric spark will ignite fire-damp.

Mr. John M. Lewis of the Fifth Anthracite District furnishes a very complete statistical report, and includes in his text a report on colliery improvements in his district during the year 1894, and a review of the fatal accidents.

Mr. Wm. Stein of the Sixth Anthracite District, in addition to complete statistics, publishes a large amount of useful information. In speaking of mine accidents he says:—"I herewith assert, without fear of contradiction, that if our workmen would observe the law in the same manner as mine officials do, we would have very few accidents to record. I speak thus from practical experience, and not because I would uphold the assertions of either operators or mine officials at the expense of the character of our employes." He describes in detail Hempel's Apparatus for Quick Determination of Gases, but the description is rendered worthless by the illustrations being inserted in the report of the Eighth Bituminous District. He also describes in detail the fire at Packer No. 5 Colliery and the methods employed in extinguishing it. This is accompanied by a map that is inserted in a pocket in the back cover.

Mr. Edward Brennan of the Seventh Anthracite District presents a very complete statistical report, and describes the fire at Lake Fidler mine and the methods used in extinguishing it. He was more fortunate than his colleague Mr. Stein, as the map and section illustrating his article is in its proper place.

Mr. John Maguire of the Eighth Anthracite District furnishes, besides his complete statistics, an account of the mine fire at the Lehigh Coal and Navigaton Co's. No. 11 Shaft, and detailed descriptions of the extensive improvements made at old and new collieries in his district.

The Inspectors for the Ten Bituminous Districts each present reports that are statistically as near counterparts of those of the anthracite districts as possible. They are also very complete and comprehensive.

In addition to his statistical report, Mr. Henry Louttit of the First Bituminous District notes six prosecutions brought during the year against violators of the mine law in his district. He also reports specifically as to the condition of each mine in his district at the time of his last visit in the year under consideration. His reports on each accident are full and complete.

Mr. Wm. Jenkins, of the Second Bituminous District has a full and complete report, in which he gives a brief description of each mine, with the average quantity of air circulating per minute in each. In commenting on the accidents in his district Mr. Jenkins says:

"The stricter the officials are, the fewer accidents they will have to report. This much I have discovered in my official capacity, that no matter how often the officials visit the working places, they will always find some one working in danger who needs to be warned and severely reprimanded for his carelessness. One of the most fruitful causes of accidents is from falls of slate, and care should be taken in setting posts. The posts should always be set at a right angle with the roof and floor. The cap pieces should always be set across the slips in the slate.

Mr. Thomas K. Adams, of the Third Bituminous District reports all the statistics and the condition of of each mine in a clear and concise manner. In commenting on the causes of accidents Mr. Adams says:

"We cannot emphasize the fact too strongly that miners, no matter how poor they may be, or what their circumstances are their first duty is to have their working places made safe, no matter what time it requires to do it. They must be compelled to use all proper and necessary precautions in protecting their lives and limbs. The performance of this duty must not be left optional with the workingmen. It must be rigidly enforced by men in authority.

Mr. James N. Patterson of the Fourth Bituminous District confines his report closely to statistical information and to the conditions of the mines in his district.

Besides the usual matter found in all the reports, Mr. Chas. Connor of the Fifth Bituminous District, gives his correspondence with Deputy Attorney General Stranahan regarding the correct interpretation of the law as to an applicant for examination as a mine foreman being able to read and write. The opinion of Mr. Stranahan was that such a qualification was necessary. Mr. Connor also gives some interesting and valuable information regarding the working of a Stanley heading machine at the H. C. Frick Coke Co's Leisenring No. 2 mine. He also dwells on the carelessness of workmen, and says: "Neither legislation nor instruction will prevent accidents unless the persons employed in or about the mine will exercise common sense and take precautions to protect themselves." He also describes the draining of the gas from about ten acres of "gob" at the Oliver mine, by a bore-hole from the surface.

Mr. J. T. Evans of the Sixth Bituminous District, in his report, emphasizes the remarks of his colleagues on the lack of care on the part of workmen as a frequent cause of accidents. He notes four very important changes in opening and conducting mines at the present time that give excellent results as to economy, safety and sanitary conditions. They are (1) Haulage by machinery; (2) The method of drainage by which the water flows out through the main airway driven parallel and to the dip of the hauling roads; (3) The driving of wider headings; (4) The drawing back of pillars as soon as the room reaches its limit of length.

Mr. James Blick of the Seventh Bituminous District confines his report to the statistical tables, reports on the condition of each mine, with improvements made during the year and detailed accounts of all fatal accidents. He announces a decided improvement in the sanitary conditions of the mines, which he ascribes as due to the beneficent influences of the mine law of 1893.

The report of the Eighth Bituminous District is made jointly by Messrs. J. T. Evans, and R. Hampson. The district was under the supervision of the late D. H. Thomas, who died Jan. 27, 1895, and Messrs. Evans and Hampson of the adjoining district prepared the report from Mr. Thomas' notes. The report is complete with the exception of the fact that Messrs. Evans and Hampson did not have the data from which to report on the condition of each mine. In connection with this report some views of electrical machinery at Mt. Lookout colliery in the Third Anthracite District, and views of the Hempel apparatus described by the inspector of the Sixth Anthracite District are mixed up with some views of electrical machinery, etc., at Smoke Run mine, in the Eighth Bituminous District. There is, however, not a line descriptive of the latter views in the text, and we are only able to locate them by our knowledge of the plant.

Mr. Bernard Callaghan of the Ninth Bituminous District confines his report to statistical tables and descriptions of the condition of each mine, and of each fatal accident. He also ascribes a large proportion of accidents as due to carelessness.

Mr. Roger Hampson of the Tenth Bituminous District, also, confines his report to statistics, descriptions of the condition of each mine, and a statement of how each accident occurred.

Taken as a whole the volume shows careful consistent work on the part of the Inspectors, and gross carelessness or ignorance on the part of the compilers, editors and proof-readers.

USE OF EXPLOSIVES IN MINES.

As a result of the great study and patient researches into the causes of accidents in mines, special rules and improvements in the mine laws have recently been made in many European mining districts. Among the more recent of these special rules are those promulgated for the Breslau (Prussia) Mine Inspection District. These regulations apply to the use of explosives, and they are very complete.

In the case of fiery mines the rules provide that blasting, when not entirely forbidden, must not be carried on at any points in the mine where the presence of fire-damp may be detected by the safety lamp. This prohibition also extends to all working places in the same division of the mine which are closely connected with working places in which fire-damp has been found, or which receive their air via working places in which fire-damp has been found. This prohibition remains in force until the underground manager, or foreman, has satisfied himself that the working places in question, and those connected with them in the manner above described, are entirely free from fire-damp.

Even if fire-damp be not present, blasting with black powder, or other explosive, is prohibited in working places in which coal dust, known by experience to be dangerous, may have accumulated. In all cases immediately before firing a shot, a careful examination must be made with a safety lamp to prove that there are no accumulations of fire-damp within a distance of 20 metres (66 ft.) from the shot.

In regard to the general use of explosives the rules provide that where sufficient protection from the effects of the blast is not afforded by the workings, special places of refuge must be provided. In the case of missed shots the men are prohibited from returning to the working face for a period of at least ten minutes, and then they may approach it only on permission of the most experienced man in the party. Shot holes charged at the same time must be fired simultaneously, and the *boring* out of shots that have missed fire is prohibited. Shots that have missed fire, and the tamping on them, may, however, be drawn, if copper or soft brass tools are used. At the changes of shifts, the most experienced man must either satisfy himself that missed shots have been rendered harmless, or point them out to the most experienced hand in the shift relieving his gang.

After shots have been fired in a working place, the men are prohibited from entering it until after the most experienced man in the party has satified h mself that a sufficient quantity of air is entering the place to remove the smoke and permit work to be carried on without danger.

In case blasting powder is used, it must invariably be put up in cartridges made with well sealed paper, or other substance that does not give off sparks, and, if it should be necessary to change a cartridge in any manner, such change must be effected at a safe distance from the stock of explosives and the other men. As an additional precaution, the mining lamp must be suspended at a distance from the cartridge so that all danger of fire from it is prevented. The use of iron blasting needles, and of oiled paper or straws filled with powder for squibs is strictly prohibited.

Special rules regarding the care and use of high explosives provide that cartridges containing nitro-glycerine must be thawed, with great care and precaution, before being given out, and afterwards they must be carefully protected from a degree of cold sufficient to refreeze them. Under no circumstances are such cartridges to be brought near a fire, a stove, a steam pipe or any place or substance hotter than a hand can bear. All changes in cartridges of high explosives must be made by the most experienced man in the party using them, who must also make up the cartridges, if they have not already been made up by a man specially appointed for this work. The charging of holes with high explosives must be performed by the "shot-master," or most experienced miner, and the tamping and firing must be done either by the latter or specially deputed miners. The insertion of the fuse, detonator or other igniter in a cartridge must only be done immediately before the cartridge is used. Shots, when high explosives are used, may be tamped with either sand or water.

TECHNICAL EDUCATION.

Technical education in its truest sense means a knowledge of proven principles combined with experience. Such a combination fits a man to direct and lead others in the industry in which he has educated himself. A man a may hold an official position through what is known as "practical experience" but in such a case his "practical experience" has made him familiar with more or less theory. He has learned from observation that certain causes produce certain effects, and this knowledge is "theory."

The practical man who adds to his own experience a knowledge of the experience of others broadens his usefulness and ability in direct proportion to the amount of knowledge of other men's experience he acquires.

A few years ago it was a difficult matter for a workingman to acquire a knowledge of his trade or avocation. While there are text-books, many of a high order of merit, they present technical subjects in a way that makes a fair knowledge of mathematics and physics necessary in the student who attempts to study them. As a rule, the ordinary working man, whose education is limited, either cannot understand the principles and formulæ at all, or he only partially understands them and misapplies them.

There have been a few men, who despite all obstacles, have educated themselves and risen to eminence in the engineering profession. Thousands of others have been successful in a lesser degree through following their examples. These men would have been leaders in every sense had they had such opportunities to secure a technical education, in their early manhood as are now open to American workingmen of all classes. The systematic plan of study, which starts at the beginning of each branch and provides personal assistance and help for each student of The International Correspondence Schools, affords every workingman in America a chance to rise above his present station. A better education than was obtained by the self-educated man by years of application and hard study can now be acquired in as many months by the correspondence system provided the student applies himself.

The International Correspondence Schools are specially designed to educate practical workingmen in mining, mechanics, electricity, architecture, sanitary engineering, civil engineering, etc. Every department is under the supervision of educated and experienced men in the trades or professions taught. They have now enrolled nearly 10,000 students in all parts of the world, and many of them have, through the education gained in these schools materially improved their financial conditions. Full particulars of the schools and an outline of the courses of study are sent free to any person writing for them, and stating what branch he wishes to be educated in. A postal card containing the request addressed The International Correspondence Schools, Scranton, Pa., is all that is necessary.

BOOK REVIEW.

Iowa Geological Survey, Vol. IV, Annual Report for 1894.—This is the Third Annual Report or Prof. Sam'l Calvin, State Geologist. It contains an exhaustive and finely illustrated report on the geology of Allamakee county, by Prof. Calvin, and similar reports on the geology of Linn county, by William Harmon Norton; on Van Buren county, by C. H. Gordon; on Keokuk county, by H. Foster Bain; on Mahaska county, also by Mr. Bain; and on Montgomery county, by Elston Holmes Lonsdale. The report makes a handsome octavo volume of 450 pages, well supplied with maps, cross sections, etc. The book as a whole is too voluminous interesting and instructive to be described in the space at our disposal. It should have a place in every reference library and in the library of every man interested in American geology.

Mining Notes and Formulae.—By William Williamson, Certificated Colliery Manager and Science Teacher; Teacher of Mining and Applied Mechanics in Hamilton, Fife and Midlothian Classes. Second Edition. Published at Hamilton, Scotland by W. Naismith, and sold in America by The Technical Supply Co., Scranton, Pa. This is a revision of Mr. Williamson's first edition, and numerous additions have been made to the original work. Examples illustrating the principal formulae are also given and worked out to show how the formulæ are applied. It is an excellent text-book on coal mining and is well worth the $1.25 charged for it.

Economic Mining, "A Practical Handbook for the Miner, the Metallurgist, and the Merchant," is the title of an octavo volume of 650 pages, by C. G. Warnford Lock and published by Messrs. E. and F. N. Spon, of London and Spon and Chamberlain of 12 Cortlandt St., New York. Bound in cloth, price $5.00. This work is the production of an educated mine manager whose previous reputation as a writer on mining subjects is in itself a guarantee of quality. It deals with the subject as comprehensively and practically as it is possible in a closely printed volume of its size. Matter having only an academic or historic interest is excluded from this book. This affords space in which to deal with just those points which, while not of a strictly scientific value, are of prime importance from an economic standpoint. In briefly describing the features of the work we cannot do better than adopt the author's own language. "Accepting the beds, and lodes, and veins as accomplished facts, this book endeavors to describe in plain language and a practical aim how these deposits may be best worked under the various conditions encountered, and how the valuable portion of their contents can most cheaply and effectively be separated and prepared as marketable commodities." It is profusely and well illustrated.

Hand-Book for Mining Students and Colliery Managers.—Part I., published by the "Science and Art of Mining," Wigan, England. The small pamphlet before us contains four sections. Section "A" treats of elementary geology on the question and answer principle; Section "B" treats on surveying; "C" on lighting of mines, and "D" on the Coal Mines Regulation Act, by the same method. Price six pence (13 cents) or by mail seven pence (14 cents). While the work is more especially designed for British readers, and a large portion of it is applicable only to British mines, it deserves great commendation for its clearness and completeness, when its size is considered. Those portions applicable to mines in general are of so much interest that the mining student in any part of the world will find them of interest and value.

The Production of Coal in 1894.—By Edward Wheeler Parker. A extract from the sixteenth annual report of the Director of the United States Geological Survey. Issued from the Government Printing Office, Washington. This is a pamphlet of 224 octavo pages and contains in great detail the statistics and trade reviews of the various States and Territories, together with a mass of other interesting matter descriptive of the coal fields.

Report of the Inspector of Mines of Kentucky, 1894.—By Messrs. C. J. Norwood, Chief Inspector, and W. U. Grider, Assistant. This is the eleventh annual inspectors' report for Kentucky, and is worthy of special notice as the best and most complete thus far issued by that State. Messrs. Norwood and Grider have taken great pains to make this report a model one. It is a large octavo volume of over 200 pages, divided into twelve chapters, as follows:

I, Preliminary; II, General Conditions of the Mines, etc.; III, Statistical Information; IV, Accidents; V, Strikes; VI, List of Commercial Mines; VII, New and Other Mines; VIII, Notes on the mines; IX, An excellent and timely article on Mine Maps, by Mr. B. W. Robinson of Earlington, Ky., Mining Engineer of the St. Bernard Coal Co.; X, Brief Account of Kentucky's Natural Wealth; XI, Correlation of Kentucky Coals with those of Big Stone Gap, by Mr. J. M Hodge of Big Stone Gap, Va.; XII, Laws Relating to Mining, etc.

Geology of Cripple Creek, Colorado.—By Arthur Lakes, late Professor of Geology, State School of Mines, Golden, Colo. Published by the Chain and Hardy Co., Denver, Colo. This is a pamphlet of 32 pages, descriptive of the famous Cripple Creek gold mining region and its ore deposits. It is illustrated by a geological map of the region and 8 smaller special illustrations. The only adverse criticism we can give the work is to say that it is too good to be issued in pamphlet form. It should have been bound substantially in cloth, so as to ensure its preservation. While interesting reading, it is more than an essay to be once read and then discarded. Every man who reads it will want to preserve it for future reference and use. To do this with a small paper covered pamphlet is not always practicable.

Chemical Technology, Vol. II, Lighting, edited by Charles Edward Groves, F. R. S., editor of *The Journal of The Chemical Society* and William Thorp, B. Sc. Cloth, octavo, 400 pages, illustrated. Price $4.00. Published by P. Blakiston, Son & Co., Phila. This is a work that embraces five distinct heads as follows:—I, Fats and Oils, by W. Y. Dent; II, Stearine Industry, by J. McArthur; III, Candle Manufacture, by L. Field and F. A. Field; IV, The Petroleum Industry and Lamps, by Boverton Redwood; V, Miners' Safety Lamps, by B. Redwood and D. A. Louis. The work is a very comprehensive one, and is of special value to every man interested in the production and sale of illuminants, of appliances for lighting, and to those who are large purchasers or consumers of illuminants and illuminating appliances of any description.

Vitrified Paving Brick. Prof. H. A. Wheeler who has made a specialty of the study of clays, has given the results of his investigations in a pamphlet entitled "Vitrified Paving Brick"; T. A. Randall & Co., Indianapolis, publishers.

The book commences with a brief history of the use of brick as a paving in Continental Europe, and its first introduction into the United States.

The defects of the paving brick first used in this country, largely due to a lack of knowledge of proper materials and processes, are clearly stated and the best up-to-date methods of its manufacture are described in full, making the book of decided value to persons interested in the use or manufacture of paving brick.

The physical properties of paving brick are fully described and chemical analyses, deduced from a large number of reliable tests, are given in detail.

THE PROGRESS IN MINING.

ABSTRACTS FROM THE PROCEEDINGS OF THE MINING SOCIETIES

And Journals of Europe and America, Illustrating the More Modern Developments in all Branches of the Mining Industry.

Fire Damp at High Pressure.—The following translation from the French is copied from the *Colliery Guardian*:

According to Gruner's classification, the 13th seam worked in the Saint-Etienne Colliery belongs to the lower group of the Saint-Etienne basin, its thickness varying in the Treuil district between 4 and 5 metres. This seam is cut at the level of 125 m. below sea level by the Puits du Treuil No. 2, which forms the downcast shaft in this field of working, while the Puits de la Pompe (supplied with a Rateau fan of 2·8 m., (9 ft.) diameter), which strikes it at the level of—95 m., at present forms the upcast shaft and will eventually serve for letting down gob material. The seam is overlain by a small stratum of schistose coal, called *crue*, 1·3 m. (4 ft. 4 in.) thick, and, as a rule, unworkable, from which it is separated by a rock band, called by the miners *carreau*, about 20 cm. (8 in.) thick.

The preparatory headings were driven in this thin seam, between the upcast and downcast shafts; and two inclines, connected every 20 m., constituted the first airways, in forming which nothing occurred worthy of notice. Owing to the necessity of protecting the two shafts against the thrust of the measures, due to taking out the coal, a *massif d'arretsion*, about 100 m. wide, was left round them, beyond which large forward stalls are driven right and left. Levels were put out from the inclines on either side simultaneously, following the roof of the group, while taking out the whole of the thin seam, but a portion only of the thick. It was proposed in this way to pass rapidly across the protecting mass and reconstitute beyond it, by forward and descending headings, the airways necessary for the working. In the eastern district two levels were being driven ventilated by a pure air current, of sufficient intensity to dilute the fire-damp, furnished in the ordinary way by this double advance, when on the 18th of July, 1893, at about 1 P. M. occured the first of the three outbursts of gas which followed in close succession.

Outburst A.—The "governor" of the pit who was behind two interlocked doors, all of a sudden heard a loud noise like the rolling of trams, and he immediately ran in its direction, but when he found his lamp extinguished, he rushed to the face. There he found that, without further preliminary warning than a cracking, caused by the fracture of the rock band which separates the thick from the thin seam, about 20 tons of very small coal had been shot forward into a heap in the level for a length of 3 m., in no way destroying the timber frames for supporting the roof, but giving rise to a considerable outburst of gas which lasted about twenty-five minutes. The lamps were extinguished of the nine men occupying various positions in the course of this vitiated air-current, but they were all able to reach fresh air in safety. The intensity of the current which effectually swept the faces of the working-place where the outburst occurred was 2½ cubic metres per second; and its gas content, found by analysis and daily observations with the Chesneau *grisoumetre* did not exceed three thousandths on the days preceding the outburst while on the day itself the maximum was 8 thousandths, and on the following day the content again fell to three thousandths.

The coal shot forward came entirely from the small upper seam, the compact roof of which had not yielded in any part; and no pocket was found, only a separation extending over a few centimeters between the coal and the overlying rock. When the heading was again pushed forward, it revealed, a few metres ahead of the point where the outburst occurred, the schistose and disturbed nature of the thin seam, which had evidently yielded to a strong internal thrust. After this incident, which no available means could have foretold, No. 2 working-place was stopped, the return preparatory ways were isolated and the intensity of the air-current was increased. Ultimately the heading was driven to its destined limit without further incident.

Outburst B.—Two months later, during the night between the 29th and 30th of September, a sudden, outburst occurred in forward heading No. 2, which was being put out towards the east. The same phenomena as in the last case were repeated—the throwing forward of coal greatly heated, also detached from the thin seam overlying the thirteenth, the absence of dislocation in the walls and roof, and a violent thrust which threw down 20 tons of small and friable coal. This working was ventilated by a current of fresh air coming directly from the shaft and only passing the men engaged in the advance. The useful volume of air at the face was 4½ cubic metres per second; and the duration of the outburst, as compared with an equal quantity of coal got, was only ten minutes instead of twenty-five. The lamps of only the three men in the working place went out, while in the former case the lamps of all the men passed by the current were extinguished. In consequence of this fresh manifestation, the speed of the fan was increased so as to augment the intensity of the current for ventilating the preparatory workings still to be driven, the useful volume of air, reaching the end of the tight partition that divided the level longitudinally, being thus increased from 4½ to nearly 7½ cubic metres.

Outburst C.—About half-past eight in the morning of the 18th of October a fresh outburst occurred in the same working place; and the enormous volume of air circulating through the level was insufficient to entirely purify the atmosphere contaminated by the gas. Three men were working at the face, two of them being in the fresh-air compartment, and the third, who alone had his lamp put out, in the return compartment. The thrust only brought down 2 or 3 tons of coal from the thin seam.

Seeing that the pressure of gas in the strata was the cause not only of the outbursts of gas but the thrusts of coal and rock, steps were taken to find the pressures of the confined gas.

Pressure Gauges.—For ascertaining the pressures, three types of gauges, a water, a mercury and an ordinary pressure-gauge were used, according to the amount of pressure to be measured. The two former were firmly fixed in light wood cases, provided with a movable shutter for protecting them from the shocks to which they would be exposed without this precaution. The ordinary pressure-gauge will measure a pressure up to 50 kilogs. per square centimetre (711 lb. per square inch), each division corresponding with 50 grammes per square centimetre.

Gauging of the volumes was effected by a gas-meter with five dials, registering from litres to tens of cubic metres, enclosed in a wood case provided with handles for permitting its being carried easily in the workings, and also for protecting it from shocks and dust.

Tamping.—The annular space between the iron pipe and the sides of the hole was tamped by a special tool, consisting of an annular metal disc 6 cm. (2⅜ in.) in outside diameter and half that dimension in inside diameter, to which are permanently fixed three iron rods connected at the other end and welded together so as to form a handle. The metal disc, guided by the pipe along which it slides, drives the tamping before it, the latter consisting of clay, slightly damped and rendered sufficiently plastic to adapt itself readily to the sides of the hole. The elaborate tamping used by Mr. Lindsay Wood was not adopted—first, because such high pressures were never encountered as in his case; and, second, because the numerous daily tests made did not permit of such minute precautions. The clay was, however, found quite satisfactory, and it was rare that leaks occurred.

Extent and Results of the Tests.—The distinction between ascertaining the pressure of fire-damp in the coal of the large working places, and in that of the compact coal in the levels or parts of the stalls near them, is equivalent to the consideration of two cases—viz., that in which the face is very large, and that in which it is limited. From the 1st of January, when borings in the face were made regularly, 135 holes were bored from 1 m. to 7 m. deep, the maximum pressures being taken every metre. The observations as to volume, however, were only made from the 25th of May.

In order to facilitate comparison of the results and permit deductions to be drawn from them, the author formed diagrams for each series of observations in the stalls and levels, representing, for the most characteristic types, the leading particulars, such as, (1), the increase of pressure and volume with the depth of hole; (2), the variation of these volumes with the lapse of time; and (3), the progress of the pressure, at a given depth, in a function of the lapse of time, etc., referred to under their separate heads:

Conclusions.—The following are the conclusions arrived at by the author from his observations:

1. The phenomenon of high tension occurs whenever the coal, owing to exceptional compactness, cleaves with difficulty when being taken out, and is especially to be feared in preparatory headings.

2. As a rule, in the large working places of the thirteenth seam, the tension of fire-damp enclosed in a prism of coal 3 m. deep is slight, and generally the mass cleaves sufficiently to this depth for the gas to escape by the numerous channels formed by the spaces caused by a partial *foisonnement* or swelling.

3. The pressure and the volume increase with the depth, according to a variable law depending upon the compactness of the coal.

4. The distribution of the tensions is highly irregular, and the permeability of the coal very variable.

5. For equal pressures observed, the ultimate tension is attained after a very variable duration, which is a function of the gaseous volume escaping from the sides of the hole and of the permeability.

6. The operation of boring pure and simple, regarded as means for taking off the gas, is but slightly efficacious; and, other things being equal, a hole left to itself will show a constant pressure of gas for a long period.

Detonators for Shot Firing.—The experiments of Abel and Trauzl have established the following conclusions:

1. Nitro-glycerine, which can bear exposure for a considerable time to a heat of 193 degs. Cent. without igniting, can be immediately exploded by a cap containing 0.2 gramme of fulminate of mercury.

2. Soft dynamite requires the same amount (0.2 gramme) of this detonator for its explosion.

3. Frozen dynamite cannot be exploded by a cap containing 1 gramme of fulminate.

4. Loose guncotton, in flakes or spun into yarn, which ignites at 150 degs. Cent., requires a much larger detonating cap to produce explosions than suffices for compressed gun-cotton.

5. The last-named can be fired by the aid of 1 gramme of detonator, but weaker caps only pulverize and destroy the cotton.

6. Web-guncotton—containing 100 per cent. of water—is the least dangerous of all ordinary explosives, requiring a powerful initial impulse to cause its explosion.

7. Gunpowder is exploded much more briskly by the aid of detonators than by ordinary means of ignition, other circumstances being equal.

8. The effective power of a cap is dependent on the strength of the case containing the detonator.

These experimental data show that each explosive requires, for the production of its maximum effect, a fixed initial impulse which must be produced in practice by regulating the strength of the detonating cap.

The small detonating charge found by Nobel to be reliably sufficient for the explosion of ordinary kieselguhr-dynamite was 0.3 grammes of fulminate of mercury. These caps were made of copper and were of such a length as to permit the detonator being completely inserted in the cartridge, without, however, allowing the safety fuse, by which the detonator was fired, to come into contact with the explosive. This was necessary in order to prevent ignition of the dynamite from the fuse, which would have only resulted in the imperfect combustion, without explosion, of the material, and in the subsequent production of irrespirable gas, a circumstance to be especially avoided in gassy mines and confined spaces.

Such caps were not sufficiently powerful for the ignition of frozen dynamite owing to the greater amount of heat required in this latter case, and attempts were made to employ mixtures of nitro glycerine, nitre, wood pulp, resin, soda and kieselguhr as igniting cartridges, but unsuccessfully, since these could not even be exploded themselves by 0.6 grammes of fulminate in caps, and for a long time miners had to content themselves with warming the frozen dynamite before use. The military authorities in Germany conducted numerous experiments during several years with the object of obtaining detonating cartridges strong enough to explode the (army) mining ammunition of frozen dynamite in all seasons, with the result that Trauzl's preparation, consisting of 75 per cent. nitroglycerine and 25 per cent. gun-cotton, was accounted the best of its kind. The 1-gramme detonator cap giving equal results was adapted for the German army, but the firms entrusted with its manufacture declined to continue the supply on account of the danger to life and plant incurred in the process of pressing the fulminate into the caps. However, in the following year the introduction of new compound dynamites containing cellulose and gelatine necessitated the manufacture of 3-gramme detonators, although the material employed for army purposes was explosible by detonators of lower strength (2 grammes).

In 1887, there being no longer any doubt that the strength of the initial impulse influenced in the highest degree the effective power of an explosive, the manufacture of powerful detonators became more general, and the following eight sizes were in current use:

1.	2.	3.	4.	5.	6.	7.	8.
0.300	0.440	0.540	0.650	0.800	1.	1.500	2.000

grammes fulminate, stronger ones being made if required, but the effects of the caps produced by different manufacturers were not the same, since each used the casing he considered best, notwithstanding that Abel's researches had revealed the important influence of the casing on the power of the cap. For instance, he found that whereas a 1.3 to 2 grammes detonator encased in a thin wooden box or paper wrapper was required to explode loose cotton wool, the same effect could be obtained by a 0.32 gramme cap in a thin metal sheath, and the German military committee ascertained that the electric fuse gave with brass tube caps, charged with 0.7 gramme of fulminate, an effect equal to that from 1-gramme detonators in simple copper caps.

In storing the caps for use it is advisable to dry them in a closed room for at least forty-eight hours at about 20 degs. Cent., taking all due precautions to prevent explosion, and to then enclose them in cases tightly closed by binding the edge of the cover round with an indiarubber band. Dry caps only should be used, and it is well to subject them to another drying with the cover off the box, so as to reduce to a minimum the chance of miss-fires.

In case blasting holes have to be left some time before firing, the detonators may be kept intact from moisture by surrounding the junction of the cap and fuse with a ring of wax or waterproof paste. It may be remarked that detonating caps may suffer considerable alteration of shape without exploding, and that danger of such a mishap is only to be dreaded when cutting-pliers are used to squeeze the caps, since in that event there is danger of the cap casing being cut through, whereby the fulminate may be compressed by the pliers sufficiently to cause explosion. It is therefore advisable to use only flat pliers for this purpose.

It is especially important in gassy mines to ensure that the detonators employed are able to impart to the blasting charge a sufficient initial impulse to produce explosion. Otherwise, as in cases mentioned by the author, the cap and charge only flare up, and may give rise to an explosion of the gas, doing an immense amount of damage which could have been avoided with a little precaution. The amount of initial impulse required by every new explosive, and the most suitable detonator to give the desired result, should be experimentally determined before blasting is commenced. Only such caps as have the fulminate protected from the influence of the weather, shocks, &c., should be employed, and these ought always to be maintained and used in a dry condition, protected by the application of some waterproofing material at the junction with the fuse whenever used in damp or wet situations.

By adopting these precautions as supplementary to the others practised when blasting in gassy mines, the danger of explosion may be minimized, but to disregard them is inexcusable, in view of the danger to the miners such neglect might produce.

New Regulations as to Mine Explosives in Germany.—The following is a summary of new regulations as to mine explosives, that came into operation on the 1st May, in the Dortmund district of Germany:

General Provisions.—By explosives in the present regulations must be understood all the substances mentioned in section 2 of the Ministerial Ordinance of 19th October 1893, especially blasting powder and saltpetre; dynamite guhr, explosive gelatine and dynamite gelatine; carbonite and other nitro-glycerine compounds; guncotton; securite, roburite, dahmenite, westphalite, and similar compounds; and also detonators. The explosives and igniters required for mine working, except firing tubes, can only be procured by the mine owner or on his account by his representative, and the explosives mentioned in the above named ordinance can only be obtained with the written permission of the competent authority, at the works of the manufacturer or at the places of sale authorized, and inspected by the police, and in the prescribed packing. Besides the underground manager, only the officials and overmen appointed by him, whose names must be entered in the mine journal and posted up permanently, are authorized to receive supplies of explosives, to distribute them to the men and receive back those not used, or to rearrange them if necessary. Only those persons appointed for the purpose by the underground manager may be employed in the transport, storage, distribution and handling of explosives inside the magazines, where flint and steel, naked lights and smoking are expressly forbidden. Only the men appointed to fire shots are permitted to have in their possession explosives other than blasting powder and saltpetre. No other explosives or igniters than those supplied by the mine manager, except firing tubes, may be charged into a shot-hole; and explosives so given out may not be taken away. If other explosives than blasting powder or saltpetre be used in a mine, a special journal must record the consignments received, the names of those appointed to distribute them and receive back those not used, the names of those to whom the explosives have been given out, the date of such distribution and taking back, the quantities of explosive cartridges given out or received back and the year and number of the cartridges distributed.

Storage.—Explosives delivered at a mine must be immediately transferred to a suitable magazine, which may be situated on the surface or underground.

Transport.—As regards transport to the mines, the supply of explosives must not be carried at the same time as other substances or tools; and the men in charge must warn those in the neighborhood by calling out "*Sprengstoffe kommen!*" The lighting must be effected by closed lamps not carried by those directly engaged in the transport. Explosives must not be carried in the shafts while the men are going down or coming up, and only after warning given to the men at the landings and also the engineman, who must not run his engine at a greater speed than when men are being wound, nor bring the cage down upon the stops with a shock. The men at the underground landing must carefully draw off from the cage the receptacles containing explosives, and only allow them to be taken by those authorized to receive them.

Giving out Explosives.—Explosives may only be given out underground, by the officials mentioned above, to the oldest hand of a working-place, or the man appointed to fire shots (*Schiessmeister*) when he assumes the responsibility imposed below on the oldest hand. Only those may be employed as firemen who are experienced in shot-firing, and whose names, notified to the inspector of mines, must be inscribed in the mine journal; and they must be provided with a written order signed by the underground manager and approved by the inspector of mines. Firemen and old hands receiving explosives other than powder must be personally known to the official giving them out. Iron tools must not be used for opening cases or casks containing explosives. Blasting powder and saltpetre must only be given out in the ante-chamber of the magazine; and the explosives must only be distributed in perfect condition and in the form of cartridges, while compounds with nitro-glycerine base must not be given out when frozen. No greater quantity than 13 lbs. of powder and explosive saltpetre, and half that of the other explosives, including the quantity given back by the preceding shift, may be entrusted at one time to the oldest hand of a working-place; but firemen placed over several working-places may receive as much as 22 lbs. of an explosive while for mechanical rock drilling, or in other exceptional cases, the inspector of mines may authorize the distribution of larger quantities. The explosives given out may only be taken away by the oldest hand, and in a closed receptacle which must be marked with a number and supplied by the mine manager; and blasting powder and saltpetre must only be taken away in metal boxes, and not in the same receptacle as the other explosives or igniters, which latter must not be taken away loose. The explosives and igniters not used, except powder, explosive saltpetre and firing tubes, must be brought back after each shift to the magazine, or to be a special storage place appointed for the purpose; and empty receptacles must also be brought back. The reception and storage of explosives so brought back is not regarded as constituting a fresh introduction into the magazine, so long as they remain in their receptacle; but, if three days elapse, they must be returned to the magazine and again entered in the journal. On changing a shift at the working-place, the oldest hand of one shift is authorized to remit the explosives and igniters not used to the oldest hand of the next shift; but in all other cases it is forbidden to hand explosives other than blasting powder and saltpetre to anyone else. Drawing the charges of shots which have missed fire is forbidden; and, with nitro-glycerine explosives, deeper boring is forbidden, while holes drilled near shots which have missed must have such a direction that they cannot come into contact with the latter.

Electric Motor Percussion Drill.—A percussion drill actuated by an electric motor, has long been a desideratum in every department of mining, and many forlorn hopes and practical failures may be found in the records of the patent offices of all the great engineering countries, and strange to say, the substantive basis of all these unsuccessful attempts has been a soft iron core for a piston, and two or three solenoids forming what we may call the shell of the electric cylinder.

The spirals of insulated wire that made the solenoids were the means through which direct and indirect electric currents were made to alternately attract and repel the soft iron core that was mounted on the shank of the drill. The solenoids and core however, made in every case a wasteful electric motor for communicating a reciprocating motion direct to the drill, and the result has been that compressed air has up till now been the most economical and efficient dispenser of transmitted energy for drilling in mines. No one can overestimate the value of a power drill, because drilling and blasting make the impossible possible in mining, and as the transmission of electric energy is more efficient, and more cheaply effected through cables than the energy of the compressed air that is conducted through pipes, we cannot do other than make a mistake if we under-estimate the welcome that will be given to the advent of a really successful percussive drill that is actuated by an electric motor. The failure of all these previous attempts with the solenoids and core, arose from resistance produced by induction with the consequent heating, waste of energy, destructive derangement of the motor and stoppage of work.

The prime cause of all the induction could, however, be traced to the interference of the solid core, where local or consequent polarity induced counter currents in the solenoids, and the core and the drill bar, for it was found to be impossible for the core and the drill bar to cut through the lines of force of the solenoids without setting up consequent polarity, and the resulting counter electric induction, from which a high percentage of the transmitted energy was dissipated as heat, for not only did the solenoids heat, but the core and the drill bar also, and so much was this the case that they were obliged to use two motors, that they might have one cool to relieve the other, and even then they had to use wet cloths to lay on the solenoids to keep them cool. It may be thought that something could have been done to correct these defects in the solenoid and core motor, but unfortunately the only correction possible must be found in the substitution of a new principle of action in the motor, for had the cores been built of lamina the local and consequent polarity would have been prevented, and, as a matter of course, the counter currents also, but no laminated cores could be used in these cases, because the great inert force generated at the starting and stopping, or at the beginnings and endings of the strokes, would shake the laminations loose at once, and, therefore, the structural core would have been a mechanical failure.

The first solenoid and core motors were actuated with an alternating and direct current, and to prevent sparking in the mine the direct current was commuted at the generator, but in some of the later solenoid motors a direct current only was used, and it was commuted at the drill, yet, notwithstanding these changes, no real improvement was made, and the solenoid and core motor remained as imperfect as before. We are happy to say now, however, that the electric drill has a chance of asserting its claims to that of a position of first rank as a mining tool, as a new motor, free from all the defects of the solenoid and core class, has, we learn from an article in *Kuhlow's German Trade Review*, been patented and put in practice by the firm of Siemens & Halske of Berlin, Germany. It appears that in 1891 this firm patented and put in use a rotary motor to work a percussive drill, and, of course, this means that a rotary motion had to be converted into a reciprocating one, and it does appear strange at first glance when we try to discover how a relatively slow and uniform motion could ever be made to act as a hammer that would deliver a blow of great inert force to the cutting edge of a drill, but on closer observation we discover that between the pin of the crank on the shaft of the rotary motor and the shank of the reciprocating drill springs are interposed in such a way that the energy of the recoil at the back stroke is collected potentially in the springs and is given out to fortify the momentum of the drill when advancing to strike. It is no doubt easy to see how the mass of the drill is made to accelerate during the advancing stroke, but there are other unseen matters that may escape our notice, while their effects are felt very strongly, and this is especially so in relation to the effects of heating and waste of energy, and the undue strains that affect the moving parts of the drill, arising from intermittent motion; and to remedy this defect the company have, in their latest patent, put on the crank shaft of the drill a fly-wheel that secures in the most successful manner the uniformity of motion required, while it prevents all consequent magnetic and electric induction arising from a jerky motion. To render the drill portable and easy of being removed from place to place in the mine, the drill proper is separate and distinct from the electric motor. The motor is in a chest that can be carried by men, and the rotation of the motor is communicated to the drill by a flexible shaft, so that no adjustments are required for the motor connection when fixing the drill for the performance of useful work. Altogether, this drill will be a mighty factor in the world's future of mining, for it has been a development by adaption to all the conditions of a cheap motive power, and an efficient rock drill.

The Copper Deposits of Chota-Nagpore, Bengal, India.—An excellent paper on the copper and tin deposits of Chota-Nagpore was recently read by Mr. R. Oates before the members of the Federated Institute of Mining Engineers, and the facts the paper furnishes have been made the basis of the following article: It is not difficult to see that the present time is one of transition in mechanical appliances, and in the collection and transmission of energy. When railways were first made they gave a great and unprecedented stimulus to the iron trade and iron manufacture, and this demand was succeeded by a second in the transition from wood to iron ships, and again, a third demand arose for the supply of armor plates for the protection of the sides of ships of war, and this great development was followed up by the substitution of steel for iron, and the manufacture of heavy artillery and millions of small arms for fighting men.

The present period, however, makes a great demand that is likely for a century to come to be an increasing one, and that is neither for iron nor steel, but for copper, for the manufacture of solenoids and cables for the transmission of electrical energy. The exchange, or market, for buying and selling stocks is extremely sensitive to a diminishing or increasing demand for any commodity, and, therefore, the increasing and diminishing pulse of the money market is a sure index of changes; and at the present time the rage for mining investments at London and Paris is phenomenal, and especially is this the case in the buying of shares in copper mining.

We used to reckon that when the yield of copper ore fell below 6 per cent. of metal the undertaking could not pay, but with improved appliances for dressing and smelting smaller percentages are made to pay better now than larger yields used to do. As the consumption of copper increases new deposits of the ore are sought for and developed, with the result that in every land and every clime mines are being opened, and qualified and efficient mine captains find good appointments among strange peoples and in the midst of strange scenes, such as Chota-Nagpore in the province of Bengal, and about 227 miles from Calcutta, on the eastern side of India.

The schistose formation, in which the copper ore occurs, is, as far as is known, about 80 miles in length and belongs to the sub-metamorphic period and consists of bedded schists and quartzites, and these, again, rest on a wide extent of gneiss.

As a rule the small hills that are spurs off the large ones all lie in the course of the copper belt, and what is remarkable about the matter is this, the ore is found like a stratified deposit, and is therefore remarkably persistent over a large area.

The belt has a lateral pitch of 40 degrees and everywhere gives proof of having been subject to repeated dislocations that have produced numerous joints and cracks in the ore body, and again the faces of these joints have been rubbed on each other with a grinding and polishing action caused by earth tremors, until the facets or "slickensides" have been rendered perfectly smooth, and shine and reflect images and light like mirrors.

The proof of these tremors is found in the numerous intrusions of trap rock that cut through the gneiss and the overlying schists. The most singular thing about the region, however, is its history. A thousand or more years before it appears, the more easily fused ores were mined for the manufacture of knives, hatchets and pans and other utensils for the purposes of peace and private use, and also for the manufacture of swords, daggers, arrow heads and other implements of warfare, for not only are the old excavations there to attest the fact, but the slag heaps the ancients have left doubly assert the conclusion.

The ancient miners removed the softer portion of the ore body and left the richer material as pillars to support the roof.

Coming to the practical portion of the subject that refers to the class of men that can be obtained on the spot as miners, for unless we know this, all mining experiments are but wild adventures, Mr. Oates says: "The laborers consist of *Santals*, that is aborigines, and Bengalis. They are quick to learn, and would become a very useful class of miners if they would only attend regularly at work. Native festivals, which are of almost weekly occurence, are the curse of the country. On these occasions the workmen leave without the slightest notice, regardless of the well-being of their employers. From this cause progress is slow, and the patience of the management often completely exhausted. It will be a fortunate day when the government steps in and affords the mine owners protection from such conduct."

The following, in the words of Mr. Oates, will supply a good gauge of the cost of labor: "The indurated character of the formation was a bar to speedy work, so that four men per shift of eight hours would only advance the face about 3 inches. The rate per week did not exceed 4 feet, and generally did not reach that. A pair of Cornish miners would probably drive 12 feet, or three times as much, but, on the other hand, a European would get twelve times the pay."

Fuel, timber and building materials are cheap and abundant. The ore yields from 10 to 15 per cent. of metallic copper.

The Narunga Tin Deposits.—These deposits are found in the gneiss underlying the schistose rocks of the copper belt of Chota-Nagpore in the province of Bengal as previously noticed and we base the conclusions at which we have arrived for the subject matter of this article on the observations of Mr. Oates as given in his paper on the Chota-Nagpore mining resources.

The gneiss is cut through by frequent veins of quartz, and eruptive and intrusive dykes and sills. The discovery of the tin stone was purely accidental and came about in the following manner. The natives are iron smelters in their primitive way, and one day they charged the furnace with what they thought was an iron ore, and on tapping it, much to their atonishment a white metal flowed out which they mistook for silver and they carried it off in hot haste to Raneegunge, the nearest town, when the true character of the metal was made known to the smelters. The tin bearing rocks are of considerable extent and have a general dip of 26° to the east, the strike running north and south, and as far as is now known, although the prospecting has only partially been done, tin crystals have been found scattered over a surface area of 21 square miles. What a field for mining adventure!!

Hear what Mr. Oates has to say: "Mining over an infinitesimal portion of this tin bearing area has thus proved the existence of tin beds extending to the deep, in most congenial ground, and under the most favorable conditions met with in mining in a virgin country. Not only in the Palgunj estate is in expected to be found, but also further north in Burkutta and Leda, where outcrops of tin-beds are known to exist. It is most probable, also, that further search in an easterly direction from Narungo may disclose a tin bearing formation along the south bank of the Barakur river, and across that river into the estate of Deopore, a total area, roughly speaking, of upwards of 200 square miles." Labor is plentiful and cheap. Timber is cheap, abundant, and well suited for mining appliances. The coal mines are situated at a distance of only 18 miles from the edge of the tin bearing rocks.

The stream tin deposits as may be expected in such a region are very rich, for one ton of ore was found to yield 215.2 pounds of tin, and samples of the vein were found by Mr. Samuel Gifford, of Bristol to yield the following results:

No. of Sample.	Vein Stuff.	Residue of Wash'ng.	Visible Gangue.	Tin Oxide.
	Lbs.	Lbs.	Lbs.	Lbs.
1	42	11.0	4.0	7.0
2	39	11.0	5.0	6.0
3	36	8.0	4.0	4.0
4	18	1.0	0.5	0.5
5	20	4.0	1.5	2.5
6	19	4.5	1.5	3.0
Totals...	174	39.5	16.5	21.0

Surely such a region can be made to amply repay the miner for a few years seclusion among the dark skins of Hindustan.

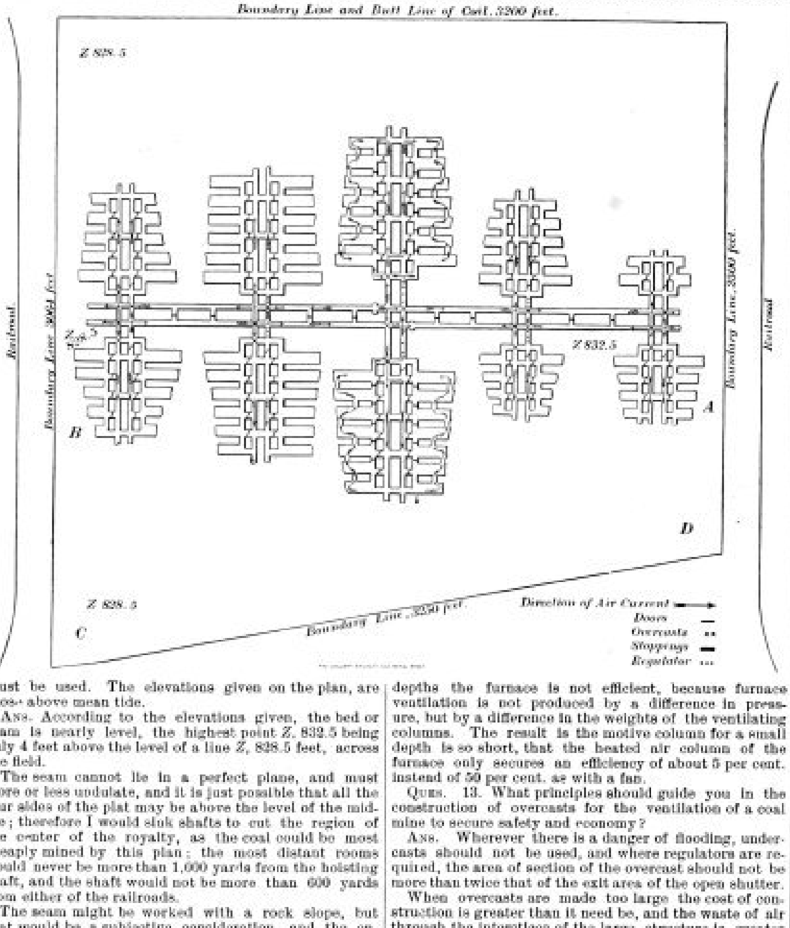
EXAMINATION QUESTIONS.

THE MINE FOREMEN'S EXAMINATION IN THE BITUMINOUS FIELDS OF PENNA. JAN. 22, 1895.

Correct Answers to the Questions, Prepared Especially for the Use of Mining Students. Practical Mining Points Explained.

9. Sketch and locate on the plan given to you, the positions of the openings, entries, airways, doors, overcasts, stoppings, and regulators; and show by arrows the directions of the air-currents:

Two accessible railroads are shown, but only one must be used. The elevations given on the plan, are those above mean tide.



ANS. According to the elevations given, the bed or seam is nearly level, the highest point Z. 832.5 being only 4 feet above the level of a line Z, 828.5 feet, across the field.

The seam cannot lie in a perfect plane, and must more or less undulate, and it is just possible that all the four sides of the plat may be above the level of the middle; therefore I would sink shafts to cut the region of the center of the royalty, as the coal could be most cheaply mined by this plan; the most distant rooms would never be more than 1,000 yards from the hoisting shaft, and the shaft would not be more than 600 yards from either of the railroads.

The seam might be worked with a rock slope, but that would be a subjective consideration, and the entrance to the slope might be at *C* or *D*, according to the railroad preferred, but it would certainly be bad mine engineering to cut the *level* bed by any other means than a shaft, unless a surface depression caused the seam to nearly outcrop, then a slope might enter the seam at such a point as would furnish the best approach to the railroad. The ventilation of the plan is arranged for the working of the coal by the system of double entry. It will be seen that the four double entry panels in the middle of the plat, are ventilated in detail, and to prevent the blurring effect of an overdone detail, the other panels are only ventilated to the doors of the bottom cross-cuts of the rooms.

10. The depth of a hoisting shaft is 200 feet; the diameter of the drum is 5 feet, how many revolutions then would a first motion engine make for each hoist, when the rope makes no overlaps on the drum?

ANS. 200 feet are equal to 2,400 inches, and as the mean diameter of the velocity ratio is 5 feet or 60 inches, plus the diameter of the hoisting rope; then let the diameter of the rope be 1 inch, when the diameter for the true velocity ratio will be 61 inches, and the number of revolutions will then be

$$\frac{2{,}400}{61 \times 3.1416} = 12.5236 \text{ revolutions.}$$

11. An airway is 10 feet wide across the floor, and 8 feet wide across the roof, and it is 6 feet high, and if the quantity passing is 60,000 cubic feet per minute, what is the velocity of the air-current in feet per second?

ANS. The transverse section of the airway is a trapezoid and its area is as follows:

$$6\left(\frac{10+8}{2}\right) = 54 \text{ square feet.}$$

The velocity per second of the air-current will then be

$$\frac{60{,}000}{60 \times 54} = 18.518 \text{ feet per second.}$$

QUES. 12. What are the principles of the ventilating fan, and is it more effective than a furnace in overcoming the friction of air in mines? If so give your reasons in full.

ANS. The principle of action in all mechanical ventilators is the same, that is they give motion to the ventilating current by a difference of pressure in the ingoing and returning ends of it, or it may be expressed as a difference in the pressures at the ports of entry and discharge or a difference of pressure in the ventilating columns. With the exhausting fan the pressure of the air is reduced at the return end, and with the blowing fan, the pressure is increased at the ingoing end.

For all mines with depths not greater than 1,500 feet, the fan is decidedly the most efficient, and even at greater depths the efficiency of the furnace does not exceed that of the fan, excepting when the furnace shaft is free from water feeders and is very dry. For mines of moderate depth the fan is very much more efficient than the furnace, because its power to exhaust the air is independent of the depth of the mine. At moderate depths the furnace is not efficient, because furnace ventilation is not produced by a difference in pressure, but by a difference in the weights of the ventilating columns. The result is the motive column for a small depth is so short, that the heated air column of the furnace only secures an efficiency of about 5 per cent. instead of 50 per cent. as with a fan.

QUES. 13. What principles should guide you in the construction of overcasts for the ventilation of a coal mine to secure safety and economy?

ANS. Wherever there is a danger of flooding, undercasts should not be used, and where regulators are required, the area of section of the overcast should not be more than twice that of the exit area of the open shutter.

When overcasts are made too large the cost of construction is greater than it need be, and the waste of air through the interstices of the large structure is greater than the waste due to a smaller one. Wherever the overcast can be cut through solid rock, certain important advantages are secured; first, freedom from leakage and waste; second, this class of overcast is not damaged and rendered inoperative by a mine explosion; third, Section 3, Article IV of The Act Relating to The Bituminous Coal Mines of Pennsylvania provides that, "In mines generating fire-damp in sufficient quantities to be detected by ordinary safety lamps, all main air bridges or overcasts made after the passage of this act shall be built of masonry or other incombustible material of ample strength, or be driven through the solid strata."

[TO BE CONTINUED.]

Electric Machinery.

The Link-Belt Machinery Co., Chicago, are still running their works day and night using the largest force ever employed by them.

Recent contracts for electrical coal mining machinery have been closed with the following companies.

Norfolk Coal & Coke Co., Norfolk, Va., consisting of two 66″ x 18 ft. boilers, one 14 x 16 McEwen engine, one 7 ft. chain breast machine, one enclosed electric grinder, circuits, etc.

Reed City Coal & Mining Co., Reed City, Ill., one 15 x 16 McEwen engine, one emery grinder, one 100 K. W. dynamo, switch board, circuits, and four 6 ft. chain breast machines.

Osage Coal & Mining Co., Krebs, Ind. Ty., one 6 ft. chain breast machine.

A Great Concentrating Plant.

The largest concentrating plant in the world is at the De Beers Diamond Mines, South Africa. The principal machinery for the immense plant was furnished by Messrs. Frazer and Chalmers of Chicago, Ill. A description of this plant will be of interest to every man engaged in any class of mining in which the production of concentrates is desirable. Messrs. Frazer & Chalmers have recently issued a fine illustrated pamphlet descriptive of the De Beers concentrating plant, which will be sent free on application. We advise all our readers interested in the subject to send for a copy.

LEGAL DECISIONS ON MINING QUESTIONS.

Reported for THE COLLIERY ENGINEER AND METAL MINER.

Breach of Contract for Purchase of Ore.—A party agreed to purchase dry ore of usual quality at a certain price per ton, guaranteed to contain a yield of 50% of iron "with a sliding scale at the rate of three pence per unit additional for every unit over 50%, and with a deduction of four pence for every unit under 50%. The ore was to be mined at C. in Spain and delivered in this country. The buyer refused to perform the contract because the ore only analyzed 48% or 49%. The seller offered to prove the custom at C. was to fix a standard of 50%, with a sliding scale, and that the purchaser was obliged to receive the mineral, provided it did not go below 45% or 46%. The Supreme Court of Pennsylvania held that evidence of such custom was admissible, and that the measure of damages is the difference between the contract price and the market price at the place of delivery when the seller discovered definitely that the buyer would not complete the contract by acceptance of the ore.

Guillon v. Earnshaw, 32 Atlantic Reporter, 545

Mining Lease.—A license for the possession of a mining claim, which by the terms of the instrument creating it is made exclusive and irrevocable, and which by reason of the expenditures of the licensees in development of the mines under the agreement, has become a license coupled with an interest, under which possession may be maintained against the world, is a lease within the law, securing a lien for work and materials furnished for the working of a mine, which shall attach to the mine.

A lease grants an estate in the land, while a license passes no estate; and when the license is mine upon the land of another, the right of property in the minerals, when they are severed from the soil, vest in the licensee. There is a clear distinction between the two, and they are further distinguished, in that the one is a corporeal and the other an incorporeal hereditament. Licenses, however, are frequently granted with terms and conditions and upon considerations which ally them closely to leases, so that it is frequently difficult to determine when the border line has been transcended, and whether or not they are in reality leases instead of licenses. A mere license while it remains executory is revocable at the pleasure of the licensor, is indivisible and nonassignable. But a license may confer either a sole or exclusive right, or simply a right in common. If it simply confers a right to take ore or work a mine it is not exclusive, and the licensor may himself take ore from the same land or mine, or license others to do so. So a license to dig and carry away all the ore in certain land does not confers an exclusive right. Such a grant shows the extent of the license, but not its exclusiveness. It is a license without stint as to quantity. Another test is, whether the grantee has acquired any interest in the land in respect to which he may maintain ejectment. But a license may amount to a lease if conferred in such manner as to give it validity; such is the case where an interest in the land is given, or where the license is for a definite period.

Stinson v. Hardy (Supreme Court Oregon) 41 Pacific Reporter, 117.

Innocent Purchaser Protected.—A judgment in an action between the heirs of a party, and persons claiming under another, as to the title to certain coal, does not affect the title to the coal of a prior purchaser from the deceased party.

Moreland v. Frick Coke Co. (Supreme Ct. Penn.) 32 Atlantic Rep. 634.

What is Essential to Conveyance of Fee to Coal.—The tests which determine a particular instrument to be a conveyance in fee of the coal as a parcel of land: (*a*) It must relate to all the coal. (*b*) The right to mine and take the coal must be exclusive of the grantor. (*c*) The grantee must agree either to mine all the coal or pay for it if mined. If the instrument contains these characteristics, it is, in legal effect a grant in fee of the coal as land. For the purposes of these rules, the word "lease" is deemed an apt word of conveyance.

Genet v. Del. & H. Canal Co. 35 N. Y. S. Rep. 147.

Catalogues, Etc.

The Jeffrey M'f'g. Co., of Columbus, Ohio, has just issued a new and handsome catalogue of elevating, conveying and power transmission machinery, which is a model of convenience and completeness. It is sent free on application.

All mine owners and mine managers will be interested in the catalogue of hoisting and haulage machinery just issued by the Robinson Machine Co. of Monongahela, Pa. It is a very neat and convenient exposition of their efficient and economizing products.

A unique publication has just been issued by the Jos. Dixon Crucible Co. of Jersey City, N. J., entitled "The Boys have Something to Say about Dixon's Pure Flake Graphite." The little publication contains the expressions of opinion of numerous locomotive engineers as to the efficiency of pure flake Ticonderoga graphite as a lubricant. "The Boys" are the men who use it and there are no better judges of the quality of a lubricant.

Pumps.

We have received from the Henry R. Worthington Hydraulic Works a copy of their General Catalogue, special edition for distribution at the Atlanta Exposition, where Worthington steam pumps are used to furnish the water supply for the grounds and for the electric fountains. The Worthington exhibit, as usual, is a very complete and practical one. The catalogue is neatly bound in a flexible board cover and is remarkably convenient in shape and arrangement. It is a publication that should be in the hands of every pump user, and should be referred to whenever the question of purchasing a steam pump, for any purpose, arises. The merits of the Worthington type of pumps are known all over the world, and the construction of "Worthington" pumps by the Worthington Works, is fully of as high a grade as the efficiency of the type.

EASY LESSONS ON MINING.

This Department contains articles to assist ambitious Miners to educate themselves, and obtain Certificates of Competency as Mine Foremen, or to become Mine Superintendents.

The articles are written to be understood by the unlearned and the learned alike. Plain language is used, no obscure terms are employed, and each subject treated, is made as clear and easy to understand as possible.

Further: The Questions asked at the different Examinations for Mine Foremen and Mine Inspectors, are printed and answered.

☞ The Series of Articles "Geology of Coal," "Chemistry of Mining," "Mining Methods" and "Mining Machinery" was commenced in the issue of March 1894. Back numbers can be obtained at twenty-five cents per single copy, $1.00 for six copies, and $2.00 for twelve copies.

MINING MACHINERY.

The Paths of Current Motion.—Diffusion of Air-Currents.—The Form of Fan Blades.—Re-entering Air.—The Drag and Trail of Currents.—Improvement in Fan Construction.—Back Pressure Due to Involute Cases.—Throbbing Produced by Ventilating Machines.—Ventilating Pumps.—Recapitulation.

88. The Paths of Current Motion.—We are simply stating a law of nature as satisfying as an axiom, when we say, that fluids when uncontrolled always move along the paths of the least resistance, but in an attempt to particularize these paths we are obliged to proceed with trepidation because they are directly opposite in character. For example, it would be correct to say that sometimes, the path of the least resistance is where the velocity is lowest, and the area of the section of the channel is greatest, as when air currents are split or diffused from one into two or more airways in mines. Again it would be equally correct to say, that sometimes the path of the least resistance of a current is where the velocity is *highest* and the area of a section of the channel is *least*, as when a stream is deflected by a curve, and the water striving to run in a straight line gathers on the outside of the curve, and as the curvilinear deflection continues the water moves at an increased velocity, and correspondingly decreased area of section. Now this must be the path of the least resistance because the water is nearly motionless along the inside of the curve, while it cuts into the outside of the bend and carries away with it tons of earth in a few hours, and if the bank consists of hard rock, then the stream is viciously active with energy due to centrifugal force, and pelts the rock with pebbles, and thus batters it away.

89. Diffusion of Air Currents.—Observe there is not in the bed of a stream any tendency to diffusion but there is a marked constriction, and this brings us to the point that requires our strictest attention, namely, that the air entering a fan does not diffuse within the blades, because it cannot do so, but runs up the advancing faces of the blades as a stream, being subject to centrifugal force, and therefore to explain this matter Fig. 125 is introduced, and to realize that the air can only move in a constricted stream, let us set a particle in motion through a fan and closely watch it. Suppose then it begins its journey at the bottom of the blade A_1, and that we are following the a_1 until it becomes a_2 when the blade A_1 has taken the position of A_2, and at last, watch a_1 become a_3, when the blade A_1 has taken the position of A_3, and we will find that the particle has been accelerating every moment during its jounrey outward, and we ask what force is there present in the movements of a fan that could still further accelerate the particle until its velocity both linear and angular was greater than that of a particle at the periphery of the fan. Let us see what would occur if diffusion took place between the blades of the fan, that is if all the air within the blades moved outward in mass then a portion of the air entering would have to move at a higher velocity both linear and angular than that of the fan blades. For example, while the blade B_1 moved through an angle of 45° to take the position B_2, the particle b_1 would have to move through an an angle of 67° 30′ to take up the position b_2 and while the blade B_1 moved through an angle of 90° to take up the position B_3 the particle b_1 would have to move through an angle an angle of 135° to take the position of b_3. It is clear then that the line of least resistance through a fan is subject to the direction of centrifugal force and as the particle is ever subject to deflection, the stream of air must run along the advancing faces of the fan blades.

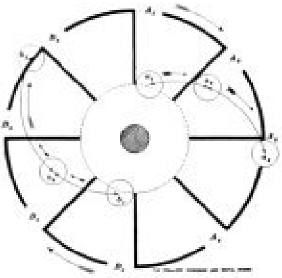


Fig. 125.

90. The Form of Fan Blades.—We cannot leave this phase of the lesson without noticing another matter correlated to the principles just treated on, and that is illustrated by Fig. 126. It was supposed that by giving the fan blades a backward or receding curvature, the air leaving the tips of the blades would by some mysterious means loss a portion of its angular velocity, and recede to be wiped gently out by the curved tips of the blades, but we see by the figure that this cannot happen, for the particle a has a tangential velocity that will carry it outward and forward, say from a to b outward, and it can never, therefore, be touched by a point in the blade, as c; or take the particle l and we can see that it will retain its tangential velocity, and can not, therefore, be touched by the particle n. Fig. 127 furnishes a still clearer light on subject, and here the particle a is seen to advance outward as a, b, c, d, and e, and the last letter is seen to be e just leaving the shoulder of the blade. At r the particle is shown as having arrived tangentially at the periphery of the blade circle, without having retreated, according to the assumption of the use of the receding curvature of the tips of the blades. At g the particle appears to have acquired a velocity, greater than either the linear or angular velocities of the shoulders of the blades, but this is impossible, and therefore sustains the conclusion we have previously arrived at, that the stream of air through a fan runs up the advancing faces of the blades, because every particle in the stream is subject to an accelerating velocity, and under precisely the same conditions of inertia as a current of water running round the bend in a river, and as we might foreknow, the air within a fan behaves in other respects like the water of a stream, subject to the action of centrifugal force. Perhaps no better mode can be given of explaining the drag and the trail of fast running water by the side of still water, or of fast moving air beside relatively still air, than by proceeding with the aid of Fig 128.

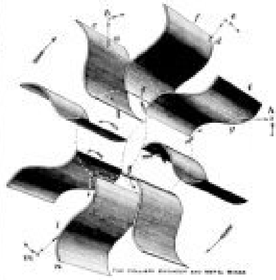

Fig. 126.

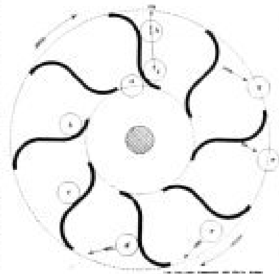

Fig. 127.

91. Re-entering Air.—The streams of air running up the advancing faces of the fan blades are shown by different diagrams of efficiency on each blade, and the object of this arrangement is to show the volumes of air due to the different angular velocities of the fan; for example, at f the fan is supposed to be running slowly, and at the blade e, the velocity has been increased, and consequently the depth of the stream is shown to be greater, but let us be careful to notice that this supposed increase in the depth of the stream is given, not as a diagram of volume, but of velocity; because, if the velocity of the stream is doubled, the volume of discharge will be doubled without any increase in the depth of the flow. At d, c and b the velocities are quick, very quick and quicker, and at a the velocity is seen to be quickest, and it really appears that we might have stated all this without hazard and without a diagram, but let us proceed to notice that the different velocities of the air streams in a fan generate a serious interference by causing a re-entry of air and thereby entailing a considerable loss of useful effect.

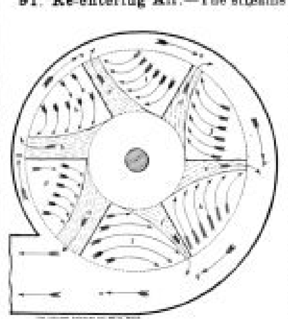

Fig. 128.

92. The Drag and Trail of Currents.—It is impossible for a rapid stream of water round a curve to have its inside limit so sharply defined that the moving particles of water can glide past the particles at rest along its inside boundary plane without moving them; and indeed they are moved, and sometimes large eddies or whirls are set in motion, beside innumerable small ones, and what takes place in the water stream takes place under the excitement of the same cause in a ventilating fan of open construction.

There is, however, in a fan with a clear open discharge either into an evolute case or into the open air, a cause of interference with the incumbent air between the blades, and that is the depression in the rear of the blades, whereby the outside discharged air is made to re-enter, and the re-entered air is next ejected by the drag and trail of the air streams, as their surfaces swiftly wipe up and carry with them the particles of re-entered air. The principal directions in which the re-entry streamlets flow into a fan are shown in the figure, and also the modifications of these movements due to the different velocities of the fan, as at g, h, i, j, k and l.

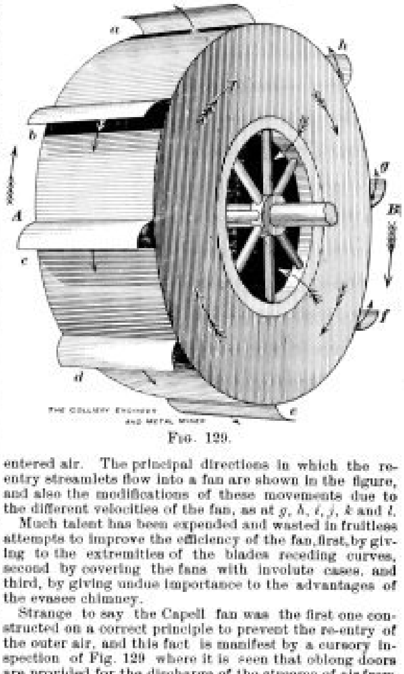

Fig. 129.

Much talent has been expended and wasted in fruitless attempts to improve the efficiency of the fan, first, by giving to the extremities of the blades receding curves, second by covering the fans with involute cases, and third, by giving undue importance to the advantages of the evasee chimney.

Strange to say the Capell fan was the first one constructed on a correct principle to prevent the re-entry of the outer air, and this fact is manifest by a cursory inspection of Fig. 129 where it is seen that oblong doors are provided for the discharge of the streams of air from the blades, while the rest of the cylindrical space is covered with a close shell to prevent the re-entry of air, and experience has proved most conclusively that this was a step in the right direction, as we shall just now show most clearly. Every opening or port of discharge was in the first Capell fans covered with a reaction cap with the intention of recovering the otherwise lost energy of discharge by first deflecting the outflowing air in such a way, that its tangential velocity would be neutralized and second, it was expected that the inertia due to the

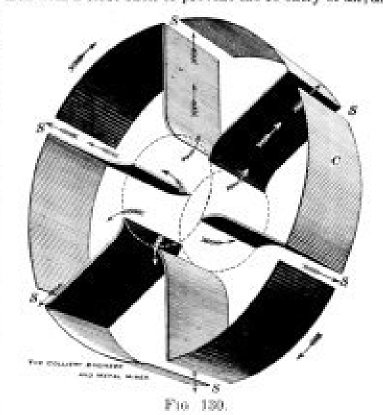

Fig. 130.

arresting of the motion, would react on the caps, and thereby restore the otherwise "great" loss of energy; but the resistance due to the excessive friction of the air pressing unduly on the under surfaces of the caps and the wasted energy lost by the caps beating against the external air, was found to be greater than the gain. The caps are seen *a*, *b*, *c*, *d*, etc., the direction of the motion of the fan is shown by the arrows *A* and *B*, and the supposed directions of the ejected currents are shown also by arrows.

93. Improvement in Fan Construction.—The caps are now dispensed with in the Capell fan, and as far as the cylindrical shell and the ports of discharge are concerned it is now like Fig. 130, and the ports of discharge are seen at *S*, *S*, *S*, etc., and the closed shell is marked *C*.

The closed shell and ports did not however altogether prevent the rotary motion of the air between the rears of the blades and the surfaces of the outflowing air streams, for it now only changed in character and became truly cyclonic as shown at *d* and *e* Fig 131. We might conclude that these innocent eddies could not seriously interfere by setting up a high resistance within the fan, but this is a mistake because the air of these whirls turning at a very high velocity would meet with considerable resistance, first from friction, but second, and most of all from the arresting of the motion of the air when thrown off tangentially from the whirl, for then it is constantly in course of being arrested and of being set in motion, and the energy thus wasted directly reduces the efficiency of the fan. To prevent this waste, Capell has come to the rescue again as shown by Fig. 132.

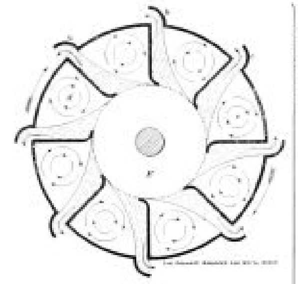

Fig. 131.

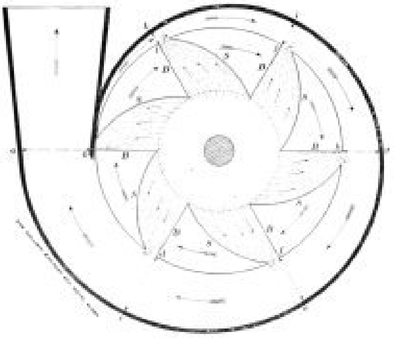

Fig. 132.

This cut was actually made by the direction of the writer, before he had seen a drawing of Capell's latest patent, and by the figure it will be seen that the writer introduces covering constricter blades that confine the air streams within a proper depth on the advancing faces of the propeller blades. The covering blades are marked *S*, *S*, *S*, etc., and the propeller blades are lettered *B*, *B*, *B*, etc., and the spaces between *B* and *S* are chambers that contain confined air, cut off or isolated from the air streams on the propeller blades. Capell claims that he has by this means increased his efficiency, others that have tried his fans support his conclusions, and the evidence that has been produced from deductions out of the operations of mechanical law, appears at any rate, to be irrefutable.

94. Back Pressure Due To Involute Cases.—The back pressure due to the resistance or friction in the path of the swiftly moving air, discharged through the involute case of a fan, is at any rate as great as the gain of reduced resistance, in the evasee chimney. In short, the involute case and the evasee chimney do not, except in the case of the blowing fan, increase the efficiency when the joint areas of the ports of discharge are sufficiently reduced to prevent current oscillation. The Waddle fan is without an involute case, and, therefore, without an evasee chimney, and we cannot conceive how the addition of these costly appurtenances would improve the efficiency of that fan. It is true that where there is no enclosure over the spaces between the propeller blades, an involute case and an evasee chimney are essential, but where the blade ports of discharge are reduced to a correct area, and especially by constricter covering blades, the involute case and the evasee chimney cannot increase, but rather reduce the efficiency of a fan. Back pressure is necessary at the discharge of a fan, but at most it is only a small fraction of the mine resistance, and yet the proportionate value of this fraction varies with fans of the same make, exhausting from different mines that are like as many organ pipes, of different wave pitch. It would appear at first glance that the involute case supplied the required back pressure without any further reduction of the ports of discharge from the propeller blades, but we have learnt that by so doing we introduce other causes of waste, such as the re-entry of air between the blades, and, therefore, we see that to improve a fan, due attention must be given to the ports of entry, to see that they are large enough to prevent needless waste of energy, and for the same reason we must so adjust the areas of the ports of discharge, that the back pressure is just sufficient to prevent the re-entry of air, or we must provide covering constriction blades, to prevent the formation of revolving cycles, that consume energy by the constantly arrested tangential motion of these air streams.

95. Throbbing Produced By Ventilating Machines.—The wave motion that is so detrimental to the efficiency of mechanical ventilators, is strongly pronounced, where the engine is on the same shaft as the fan, or on the first motion, and the steam is used at a high pressure with an early cut off.

Here the throbbing due to the intermittent action of the fan can be felt as a strong pulse in the furthest nook of the mine and so strong is your perception, that you can count the strokes of the engine. Careless observation in these matters, has made many costly experiences where rotary and reciprocating pumps have been tried to secure a greater efficiency than that of the fan. The inventors of the ventilating pumps did not foresee the loss of energy that would occur by setting air in motion with a varying velocity, and consequently these machines have all rapidly fallen out of use, and we only introduce them here to interpret the mechanical laws that operate in all other machines used for ventilating mines.

96. Ventilating Pumps.—First then let us notice Nixon's ventilating pumps as illustrated by Fig. 133.

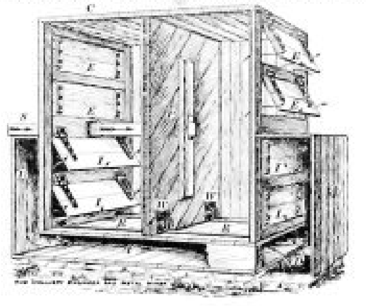

Fig. 133.

They made the air move in distinct gusts and it was expected that they would directly force the air, without any recoil whatever, and would replace the machines that depended for their action on the operation of the "mystical" centrifugal force. None of these expectations, however, were realized, because the loss of energy due to intermittent action, and the resistance at the door valves was so great, that these machines were very far behind the worst examples of the centrifugal fan in efficiency. The figure furnishes an example of a reciprocating piston pump, that is oblong in its transverse section, the piston being 20 feet high and 12 feet wide as shown at *P*. This heavy moving partition was made to run with very little friction on wheels rolling on rails fixed on the floor of the pump chamber, as *W*, *W*, and *R*, *R*; the wooden piston rod or spear *S*, was connected directly with the piston rod of a steam cylinder of very long stroke and the piston *P* is now according to the indication of the arrow and the positions of the valves, moving from left to right. It will be seen that two valves at the "top left" and other two at the "top right" and marked *E E* and *E E* are delivery or ejection valves and open outward, and that two at the "bottom left," and other two at the "bottom right" open inward, and are intake or injection valves, as *I I* and *I I*. The injection valves are connected with an air drift, as *T* and *F*, and these flues are in open connection with the shaft or slope at *D*. When the piston is moving from the left, the "left bottom" injection, and "right top" ejection valves are open, and consequently when the piston is moving from the right, the "right bottom" injection and the "left top" ejection valves are open. Fig. 134 illustrates in vertical section, Cook's rotary ventilating pump. The wind wave pulse due to this pump was painfully manifest, and it was difficult indeed to obtain a correct reading of the mine resistance in consequence of the unsteadiness of the water levels in the gauge as they oscillated rapidly.

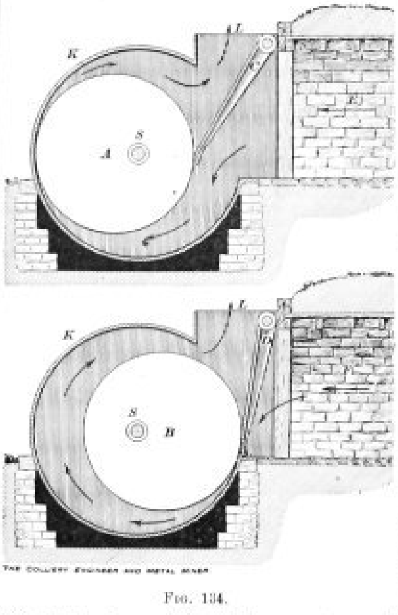

Fig. 134.

Several of these rotary pumps were set to work at the iron mines in Cleveland, Yorkshire, and at the coal mines in Durham, England, and the writer recently noticed in the *Colliery Guardian*, that the last of these machines in Durham was lately replaced with a fan at Hutton Henry Colliery, Wingate, Durham. This pump first consisted of two cylindrical drums *A* and *B*, set in separate cases *K*, *K*, side by side and mounted on the same shaft *S*. The drums were from 10 to 16 feet in diameter and from 8 to 10 feet in length. The main shaft passed through the centers of the cases, and the drums were mounted eccentric to the shaft, so that when the oscillating shutter *D*, closed the mouth of the drift the center of the drum *B*, was right of *S*, and when the mouth of the drift was wide open at the shutter *C*, the center of the other drum was left of *S*. Now as a drum revolved one side was always nearly touching the inside surface of the circular case, while the shutter was oscillated by a crank on the hinge ends of *C* and *D*. The shutters were the same in breadth as the drums were in length, consequently it is easy to see that, as the eccentric drums revolved and the shutters so oscillated that they always nearly touched them with their tips, the pair of drums constituted a double acting pump having their intake at the drifts *E* and *F*, and their discharge into the open air at *L*, *L*. In looking into this pump, from the standpoint of *L*, when it was in motion, you felt as though you were at sea and as the huge gas tank-like drum came swelling up it seemed very like the roll of a huge wave. There were three serious shortcomings in this machine.

First, the re-entry of air was very great, as the drums could not closely touch the case either on the face or at their ends, and the tips of the shutters were always about an inch and a half from touching the drums.

Second, the machine could not be run at a speed of more than 20 revolutions per minute, because the centrifugal force, due to the rotation of the eccentric drums, would otherwise break the shaft or tear it out of its bearings.

Third, the drums made such a variable depression in the drifts that the loss due to intermittent action made it an exceedingly wasteful motor for mine ventilation.

97. Recapitulation.—1st. There are two paths of the least resistance in current motion, and true to one of these paths the stream of air through a fan is confined or constricted on the blades.

2nd. We have noticed the reasons why diffusion does not occur between the blades of a fan.

3rd. The retreating curvature of the outward extremities of the fan blades is wrong in principle and wasteful of energy.

4th. The waste resulting from the eddy movements produced by the re-entry of air between the blades ought to be prevented.

5th. There should be a separate port of discharge for every blade in a fan, and therefore the open space between the blades should be partially covered to prevent re-entry.

6th. The waste within the fan blades, even when covered, as the result of cycloidal eddies casting off the rotating air tangentially, when the energy of the moving particles is wasted by their motion being arrested.

7th. The importance of the Capell constricter covering blades.

8th. The loss due to the intermittent action of reciprocating and rotary air pumps.

CHEMISTRY OF MINING.

Oils Used for Illumination.—The Behavior of Burning Oils.—Smoking and Non-Smoking Oils.—The Three Stages of Combustion.—The Causes of Smoking.—How to Test Oils for Safety Lamps.—Photometric Measurements.—The Two Modes of Measuring Light.—Shadow Measurement.—Measuring Light by Equalization.

69. Oils Used for Illumination.—It is now our business to become acquainted with the various illuminants that are in use in mines, and as many of them are only different in kind and not in character, the investigation of the whole matter will not therefore require the expenditure of much of our time.

In so far, however, as the physical properties of these luminants are concerned, they are recognizable under four heads, as, electricity, coal-gas, the fixed oils and the volatile oils, and it will be chiefly with the fixed and the volatile oils that we shall be engaged, as they are the chief illuminants in use in mines.

The fixed oils are vegetable and animal productions that can be separated from their containing tissue without the application of heat, and are such as olive-oil, palm-oil and cocoanut-oil, etc. Nearly all the oils obtained by great heat and distillation are volatile, that is, they evaporate at ordinary temperatures as gas, and such are often called "spirits," as "methylated spirit," spirit of turpentine, spirit of sugar or alcohol, etc. Many of the mineral oils are very volatile when heated above 90° F., as petroleum, benzine, etc.

70. The Behavior of Burning Oils.—The burning of these oils is full of interest to the miner, and not only from the standpoint of their use as illuminants, but from what we learn in the burning of these different oils.

All the oils are hydro-carbons, and, strange to say, the individuality of the oils in every case, results from the greater or lesser proportion of carbon contained in each compound; and more remarkable still, the fixed oils contain more carbon than the volatile ones, and beginning with CH_4 or marsh gas, and continuing through a series of gaseous hydro-carbons, we at last reach a compound of carbon and hydrogen, in which, if the temperature of the gas is reduced, it becomes a spirit, and after this, with a little more increase of the carbon element, we get a volatile oil, and with a still greater increase of carbon we get a fixed oil, and with a further increase of carbon we get a solid fat, or wax, and with a still greater increase of the carbon element we get resin, pitch or bitumen.

71. Smoking and Non-Smoking Oils.—The reader must have noticed that in burning alcohol, methylated spirit, or spirit of wine, all three being nearly the same compound, we obtain a very hot flame with very little illuminating power and no smoke. Now the illuminating power of a flame is the result of a vast number of unburnt solid particles having had their temperature raised to a white heat, and in this state they emit light; if however, these particles are burnt as in the case of the carbon in a Bunsen flame, then the flame of olefiant gas gives no more light than that of the flame of alcohol. This brings us to the sought-for point, namely, good light is the result of the imperfect combustion of a portion of the carbon in the flame under notice, and there are three stages in the combustion of the carbon that are of first-class importance, and especially so when we notice, that we are always trying to obtain the best possible light with the smallest consumption of oil.

72. The Three of Stages Combustion.—The first stage occurs when all the carbon is completely burnt as in the Bunsen flame.

The second stage occurs when much of the carbon is burnt, and just sufficient remains unburnt to give a good light, without a smoky flame.

The third state occurs when very little of the carbon is burnt, and it is therefore nearly all set free as a dense black cloud of soot and smoke, making the air thick and suffocating.

There are four causes of the production of smoke by the flames of lamps.

73. The Causes of Smoking.—The first cause is, carbon will not burn in oxygen until it reaches the temperature of incandescence; the result is, if cold air chills the flame it prevents the ignition of the carbon.

The second cause is an insufficient supply of air to carry on the combustion of the gas evaporated by the burning oil.

The third cause is the high proportion of carbon in a thick oil, burning with a thick wick.

The fourth cause is the too rapid volatilization of the oil when more gas is evaporated than the limited supply of air to the surface of the flame can burn; for example, the proportion of carbon in turpentine is very much less than in resin and yet so rapid is the volatilization of the gas from turpentine when heated, that the flame gives off more black smoke than that of burning resin. From all this we see that different oils contain different proportions of carbon, and are quicker and slower in their volatilization, hence some are better adapted for one use and some for another, and this brings us to the point where we should be able to determine the adaptability of an oil for producing light in a miner's safety lamp.

74. How To Test Oils For Safety Lamps.—After a little investigation we discover that the destructive analysis of the oil is not the best mode of testing, and an easy and correct gauge can be applied by finding the length of the funnel required to produce a clear light without smoke. First, then let us refer to Fig. 114, and it will be seen that the flame is capped with a lazy cloud of smoke, as the result of the too rapid volatilization of the oil at the wick W, or the too rapid conversion of the liquid oil into gas; and a further cause is found in the small supply of oxygen, as it can only enter into active combination with the combustible gas at the surface of the flame F, as shown by the arrows a, b, c, d. In these days of "kerosene lamps," the smoking of the flame before the funnel is fixed is a familiar experience, and the change produced by the addition of the chimney is very pronounced, and we can, therefore, imagine that there will be degrees in the completeness of the change from imperfect to perfect illumination; for example, the case before us is the worst so far as light is concerned, and if we add a very short chimney we would slightly improve it, and a longer one more so, and as this is the case, we may also see that a length of chimney that would produce a good light with one sample of oil would not be long enough to do the same with another.

Fig. 114.

It is evident then we have at our disposal one of the most simple and decisive tests of the fitness of an oil for use in a miner's lamp. Smoke is generally prevented by applying a draught to the flame, but the motive column to produce a draught in a miner's lamp is very small, and when we consider how a small increase of carbon in the composition of the oil, or a small increase in the rapidity of the volatilization of the oil, or further, when we consider the resistance the air has to overcome in forcing its passage into and out of the lamp through the meshes of the gauze, we cease to wonder at the much repeated cry of "bad oil." For to explain then, how the oil is tested for its fitness to be used in miners' lamps Fig. 115 is introduced, and as we may expect, the process is dependent on the use of standard values such as cotton wick of a fixed size, and a glass chimney 3 inches long. Tin-plate vessels for oil wells are provided, and these are filled with the oils to be tested as shown in the figure at D and E. Now to make the explanation easy to comprehend, let us make a test "in fancy," and first try the short chimney on E, and here the flame is found to smoke freely; next try the long chimney B, and now the flame is found to be clear and smokeless, but we could not provide to have a draught equal to this in a miner's lamp, therefore, however good the oil may be as a lubricant and even as a luminant in a good draught, it is nevertheless unsuited for burning in a safety lamp. Again, try the short chimney on the sample D and here it is found to burn brightly and without smoke, and now we conclude this oil is as good as any we can buy for safety lamps, and therefore the sample D is accepted.

Fig. 115.

75. Photometric Measurements.—Oils have not only to be tested for smokeless flames, but also for their illuminating power, and lamps also require to be tested to determine their efficiency of diffusion. For improperly constructed lamps set up an interference or obstruction to the free passage of light.

We therefore require a simple test for measuring the illuminating power of oils, and the efficient dispersion of the light by lamps. For these tests we also require a guage based on standard and accepted values, and the gauge for safety lamps is one candle power.

76. The Two Modes of Measuring Light.—There are two modes of measuring the illuminating powers of flames and the first is based on an adjustment for the equalization of shadows, and the second is based on an adjustment by which one light is made to equalize the light of another, when both illumine one point.

The intensity of light varies inversely as the squares of the distances of points from the luminous centres, as, for example, let some distances from the luminous points be 1, 2, 3, 4, 5, 6, 7, 8 and 9, then the intensities of the light at the distances will be 1, $\frac{1}{4}$, $\frac{1}{9}$, $\frac{1}{16}$, $\frac{1}{25}$, $\frac{1}{36}$, $\frac{1}{49}$, $\frac{1}{64}$ and $\frac{1}{81}$.

This means to say that if the intensity of the light at a distance of 1 is 1, then at a distance of 9 it will be $\frac{1}{81}$. Perhaps there is not to be found a better teacher tha that furnished by an example, and for this purpose. therefore, let us introduce Fig. 116. This is the most easy method known for measuring the illuminating

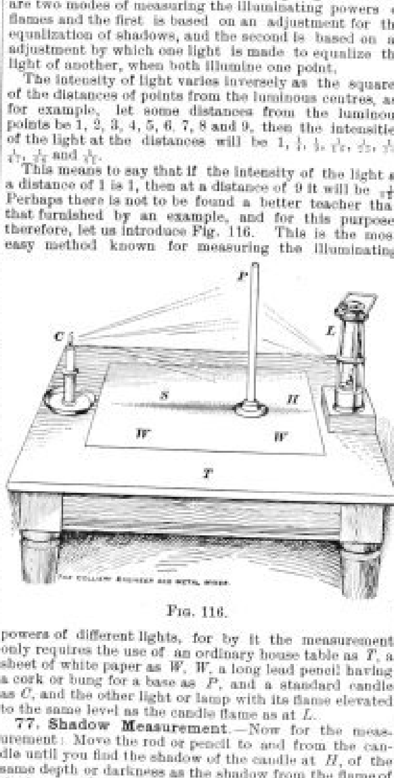

Fig. 116.

powers of different lights, for by it the measurement only requires the use of an ordinary house table as T, a sheet of white paper as W, W, a long lead pencil having a cork or bung for a base as P, and a standard candle as C, and the other light or lamp with its flame elevated to the same level as the candle flame as at L.

77. Shadow Measurement.—Now for the measurement: Move the rod or pencil to and from the candle until you find the shadow of the candle at H, of the same depth or darkness as the shadow from the flame of the lamp at S, and when the shadows are thus equal in darkness, then the lights are proportionate in illuminating power to the squares of their distances from the pencil, and suppose the lamp L is distant 10 inches from P, and the candle C, is distant 20 inches from P, then if the candle be taken as the unit of measure, the illuminating power of the lamp is $\frac{10^2}{20^2} = .25$, or the lamp is .25 candle power. Again, if the lamp be taken as the unit of measure, then the candle is $\frac{20^2}{10^2} = 4$ lamp power. Lamps are, however, always reckoned in candle power.

Fig. 117 is another illustration of a photometer or light measurer, and in this case also the means employed are of a simple character. Two boards are joined

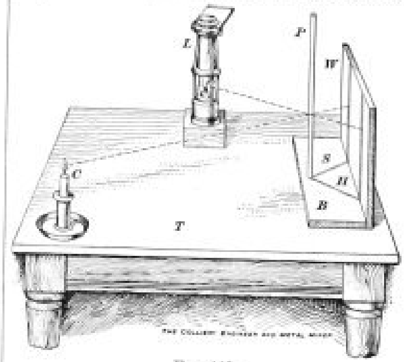

Fig. 117.

together in such a way, that one is perpendicular to the other, as B and W, and they are covered with white paper and a pencil rod is fixed in the base board as at P. By this means the candle C is made to cast a shadow as shown at S, and the lamp is made to cast a shadow on the base and the upright board as at H, and if the lamp is moved alternately nearer and further from the pencil until the shadows are equal in depth, then the powers of the lights, are as before directly proportionate to the squares of their distances from the pencil. Suppose in this case the lamp is distant 11 inches and the candle is distant 17 inches, then the candle power of the lamp is $\frac{11^2}{17^2} = .418 +$.

78. Measuring Light by Equalization.—Fig. 118 is an illustration of the photometer often met with at gas works, and in this case a disc D is moved to and fro

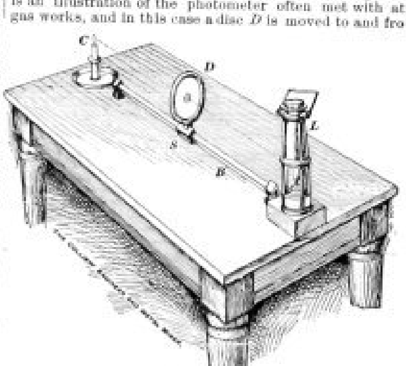

Fig. 118.

on a bar B, until a spot of oil on the centre of the paper diaphragm, fixed in the sliding sleeve at S, appears quite black. Now if S is too near to C and you look at the diaphragm from the L side, a light is seen from C, or if it is too near to L and you look at the diaphragm from the C side you can see light from the lamp, but if S is set at a point where the two lights are of equal intensity then no light is seen by looking at either side and the spot appears black, and if the distances are now measured, and are found to be L 20 inches and C 30 inches, then the candle power of the lamp is $\frac{20^2}{30^2} = .44 +$.

[TO BE CONTINUED.]

MINING METHODS.

High Pressure Ventilation—Terms Used in Ventilating—Potential, Velocity and Pressure—The Situation of Mine Shafts—Directions of Currents Along the Faces of Workings—Favorable Conditions for Ventilation—Recapitulation of Facts.

72. High Pressure Ventilation.—Erratum: In our last chapter, in the November number, the last formula, $P - \left(P\frac{Q^2}{q^2}\right) = p$, should have been $P - \left(P\frac{q^2}{Q^2}\right) = p$.

The difference of current potential, or the power that sets the ventilating air currents of a mine in motion, is greatest when the workings are situated upgrade from the shafts, or where the shafts are situated at the bottom of the pitch. The reason for the high pressure required to ventilate a mine with the ingoing air ascending and the return air descending, is soon found and as easily explained, but there are other matters of great importance involved in this investigation that claim our attention; for example, a high pressure implies great resistance and a reduced current velocity, or a great expenditure of cost to produce the energy required for the high resistance to be overcome.

It is a mistake to act on the supposition that a large volume of air is all that is required for the complete and satisfactory ventilation of a mine, because a large volume of air is often found to be circulating, while some of the upgrade districts in a mine are standing, not only charged with gas, but with a stagnant ventilation. Here, then, we are confronted with two facts that require explanation; first, much gas and an inefficient ventilation, while all the other districts in the mine have a more than sufficient quantity of air circulating; second, the upgrade workings are not ventilated, while the downgrade workings contain no gas and are ventilated with a "strong breeze of wind." What, then, is the cause of this opposite condition of the upgrade and downgrade workings? The answer is, the current pressure is too low to overbalance the descending return current, that has been rendered specifically lighter by being heated and mixed with marsh-gas. We see, then, that a high current pressure is as necessary for the complete ventilation of a mine as a large volume of air.

The first proposition is a satisfactory introduction to to the solution of the problem that a mine always requires a high current pressure when the shafts enter the seam at the bottom of the pitch of the upgrade workings.

73. Terms Used in Ventilating.—To make all this clear it is necessary in the first place to define our terms and the most important ones are those of "potential," and "difference of potential." Potential means the disposable power that sets the ventilating currents in motion and speaking of the entire mine it may mean 1,000,000 units of work. The "difference of potential" can be best explained with an example. Suppose an airway to be 6,000 feet long, and that a quantity of 60,000 cubic feet of air per minute passes through it with a pressure of 10 pounds per square foot, then the potential of the ventilation of that airway is $60,000 \times 10 = 600,000$ disposable units of work, and the difference of potential will be seen and understood if we divide the airway into two equal halves as 3,000 feet from A to B, and from B to C other 3,000 feet, or if the potential or disposable power at A is 600,000 units of work, at B it will only be 300,000 units of work disposable, or the difference of potential between A and B is $600,000 - 300,000 = 300,000$, and the difference between A and C is 600,000. The difference of potential for every foot of the airway is $\frac{600,000}{6,000} = 100$.

74. Potential, Velocity and Pressure.—Another matter requires close attention and it is this: The potential that would set up a high velocity against a low resistance, would only set up a low velocity against a high resistance, because the pressure required to remove gas downgrade is obtained at the expense of the velocity of the current. For example, suppose that by some unknown cause the airway, we have just noticed as 6,000 feet long, has been nearly closed at the end C, then in that case nearly all the ten pounds pressure per square foot setting the air in motion at A, would be found as static pressure at C. Or this means, as before, you cannot obtain pressure to remove gas without doing so at the expense of the velocity of the current; and independent of all the differences in velocity that arise from splitting, greater differences are produced by the resistances set up by return air-currents that are descending from upgrade workings and have been rendered light

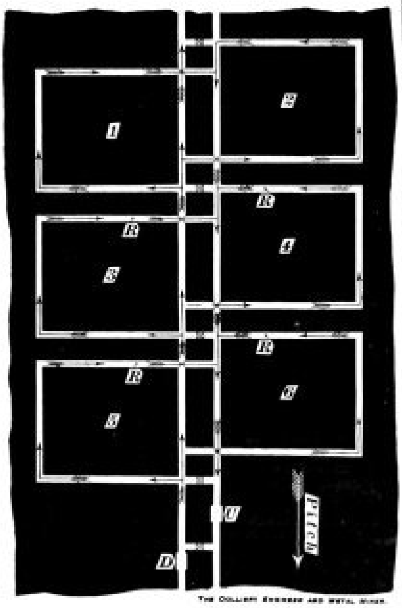

Fig. 118.

by being heated and charged with marsh gas. Where the air-current is moving at a low velocity, it is not easy to mix the air and the gas so that the latter may be removed, but under these circumstances it is wise to ventilate by ascension along the working face, and make the rapid main currents descend, as shown in Fig. 118.

75. The Situation of Mine Shafts.—Here the shafts are below the upgrade workings, the result is the ingoing fresh air has to ascend, while the return light air has to descend. The directions of the currents may be traced by the arrows, and the movements of the local currents in the panels are seen to be all ascensional, and, indeed, if this provision was not made, the resistance would be very great. A little explanation of the figure will assist in making the previous remarks still more evident. The direction of the pitch is shown by the arrow. The districts most distant from the shaft as 1 and 2, are seen to require no regulators, but they are provided for the districts 3, 4, 5, and 6. It is commonly said that the regulators in the districts near the shafts, are to prevent too much air circulating in those panels, but the real use of these regulators is to throw forward a greater difference of potential, for the ventilation of districts 1 and 2.

76. Directions of Currents Along the Faces of Workings—Fig. 119 shows the air currents moving downgrade along the working face, and the disadvantages of this mode of current motion are two in

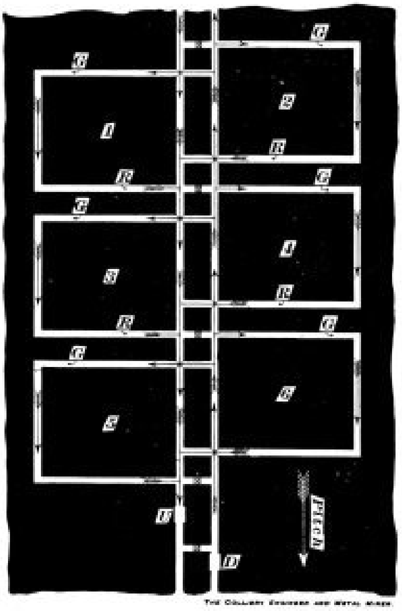

Fig. 119.

number, for it may be said, the system is bad *altogether*.

First, when the main airways and the working face are all downgrade to the shaft, a very high potential is required for the ventilation of the mine.

Second, when the regulators as shown at 1 and 2 are used, they are entirely out of place, as they introduce a resistance that is already too great, and any gas collecting behind them would stratify, and the little air that did pass along the working face would blow through the

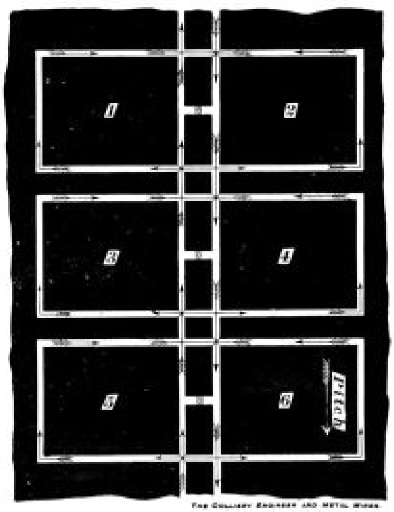

Fig. 120.

regulators and leave the gas behind. The same conditions would prevail in panels 3 and 4, only a little modified, and even in panels 5 and 6 it would require the full force of the wind blowing without regulators, to remove gas.

77. Favorable Conditions for Ventilation.—Fig. 120 illustrates the most favorable conditions for ventilating a mine with a small potential. Here the seam is entered at the top, or the beginning of the pitch with slopes, and the ingoing air descends, while the light gas-charged return air ascends, and even the currents along the working faces in the panels are moving upgrade. The regulators are not shown, but if used they should be fixed at the ends of the return airways of the panels 3, 4, 5 and 6. Strange to say regulators can often be dispensed with in a mine of this kind when worked and ventilated as shown by the figure, because the panels low down the pitch have their ventilation aided by the ascending current, that is heated and charged with light gas. Contrast this figure with the former one, and we will find the reasons for the high potential required for the preceding example, and those for the low potential of the present one. For example, suppose the potential required to ventilate the workings of a level seam was taken at 4, and the potential required to ventilate an inclined seam with the shafts at the bottom of the pitch was 6, then if the inclined seam was entered at the top of the pitch with slopes, the potential would be infernally 2, and therefore, we see that the potential required to ventilate with shafts at the bottom of the pitch, is 6, or $\frac{6}{2} = 3$ times greater than that required for ventilating the workings by slopes entering at the top of the pitch.

78. Recapitulation of Facts.—Let us now recapitulate the facts of prime importance in the lesson; First then, with a given potential, this disposable energy overcomes a great resistance by reducing the square of the velocity of the air current and correspondingly increasing the pressure. Second, to remove gas in upgrade workings, the velocity may be so reduced, as to raise the pressure almost up to its static value, or to that required for the ventilation of an entire mine. Third, the air current along the working face should move upgrade, when the line of the face pitches. Fourth, the slopes or shafts secure the least expensive ventilation, when they enter the seam at the top of the pitch. Fifth, regulators are often dispensed with when all the return air-currents of the mine have an ascending motion.

[TO BE CONTINUED.]

A Good System for Your Store.

A question that has bothered the different mining companies for a good many years is "What is the correct and best system to use in our store?" Stores which are run in connection with mines are generally in an isolated locality, and the store must have some system to prevent employes over-running their account at the store. A great many have adopted a round metal check, but it does not give the satisfaction the storekeeper or managers might desire. In the first place they are transferable and are good for merchanise at the store to whoever brings them in. Again, being transferable employes can sell, or otherwise dispose of them, and frequently a man's family is deprived of his earnings because he is too weak to resist the fascination of a poker game or a game of craps. Sometimes a rival store gets hold of a number of these checks and presents them for payment at inopportune times and causes a great deal of worry to the mine.

Another sysytem that has been tried with a greater or less degree of success is the old script or punch out ticket. These while they are not generally transferable have faults nevertheless. The employe says: "Hold on, you have punched out too much." The customer holding such ticket is usually looking for the worst of it, and after he thinks that the little punch has cut too wide a swath in his ticket, there is no way of convincing him that he has not been swindled. The punch out ticket is usually printed on a simple card which could easily be counterfeited, is easily destroyed or disfigured, and is the cause of many misunderstandings between the customer and proprietors.

The best system that has been brought to our attention is the Coupon Book. This system is calculated to take much trouble and worry off the mind of the man whose mine has a commissary annex. They are put up in book form, each book containing different amounts. These books generally represent \$1, \$2, \$3, \$5, \$10 or \$20 and have coupons in the books running from one cent or five cents up to 25 cents or a dollar as the store manager may deem best. It seems to us that the coupon scheme is vastly superior over any system of punch outs or metal checks. The book itself is not transferable and is good for merchandise only at the company store and only to the man to whom the book is issued or some member of his family. In the book the coupons are perforated so as to be easily detached, and after these are once torn out by the clerk at the store, they are worthless, as they are not good if detached. A man cannot claim that you punched out too much, or rather tore out too much, as the amount detached from the book is laying on the counter before the clerk and the customer. As they are not transferable, they cannot be sold. In fact the superiorty of the coupon book over any other system can readily be seen. The paper check wears out, is difficult to handle, bulky and unwieldy after short use. The coupon being not good if detached does not become a circulating medium and therefore offends no law, the Coupon Book being in substance simply an order to the employe on the store for a certain number of dollars worth of goods to be delivered in partial deliveries, and upon each delivery coupons to the value of such delivery are detached until the book is exhausted. We know that a large number of concerns have adopted this system within the last few years, and it seems to us that it will be used by a still greater number as soon as its merits are discovered, as the system wherever given a practical test becomes popular both with the employer and employe. Next to cash drawn by employes on account, it is the best system that can be devised for the convenience of employes, and it is therefore popular with them.

MISCELLANEOUS.

WHAT CAUSES THE LIGHT OF THE SUN.

The light of the great orb of day emanates solely from a closely fitting robe of surpassing brightness. The great bulk of the sun which lies within that brilliant mantle is comparatively obscure, and might at first seem to play but an unimportant part so far as the dispensing of light and heat is concerned. It may indeed be likened to the coal cellar, whence are drawn the supplies that produce the warmth and brightness of the domestic hearth, while the brilliant robe where the sun develops its heat corresponds to the grate in which the coal is consumed. With regard to the thickness of the robe, we might liken this brilliant exterior to the rind of an orange, where the gloomy interior regions would correspond to the edible portion of the fruit. Generally speaking, the rind of the orange is rather too coarse for the purpose of this illustration. It might be nearer the truth to affirm that the luminous part of the sun may be compared to the delicate filmy skin of the peach. There can be no doubt that if this glorious veil were unhappily stripped from the sun, the great luminary would forthwith lose its powers of shedding forth light and heat. The spots which we see so frequently flecking the dazzling surface are merely rents in the brilliant mantle, through which we are permitted to obtain glimpses of the comparatively non-luminous interior.

As the ability of the sun to warm and light this earth arises from the peculiar properties of the thin glowing shell which surrounds it, a problem of the greatest interest is presented in an inquiry as to the material composition of this particular layer of solar substance.

It is perfectly plain that it is not composed of any continuous solid material. It has a granular character which is sometimes perceptible when viewed through a powerful telescope, but which can be seen more frequently and studied more satisfactorily on a photographic plate. These granules have an obvious resemblance to clouds, and clouds, indeed, we may call them. There is, however, a wide difference between the solar clouds and those clouds which float in our own atmosphere. The clouds which we know so well are, of course, merely vast collections of globules of water suspended in the air. No doubt the mighty solar clouds do also consist of incalculable myraids of globules of some particular substance floating in the solar atmosphere. The material of which these solar clouds are composed is, however, I need hardly say, not water, nor is it anything in the remotest degree resembling water. Some years ago any attempt to ascertain the particular substance out of which the solar clouds were formed would at once have been regarded as futile, inasmuch as such a problem would then have been thought to lie outside the possibilities of human knowledge. The advance of discovery has, however, shed a flood of light on the subject, and has revealed the nature of that material to whose presence we are indebted for the solar beneficence. The detection of the particular element to which all living creatures are so much indebted is due to that distinguished physicist, Dr. G. Johnstone Stoney.

In the whole range of science, one of the most remarkable discoveries ever made is that which has taught us that the elementary bodies of which the sun and the stars are constructed are essentially the same as those of which the earth has been built. This discovery was, indeed, as unexpected as it is interesting. Could we ever have anticipated that a body ninety-three millions of miles away, as the sun is, or a hundred million of millions of miles distant, as a star may be, should actually prove to have been formed from the same materials as those which compose this earth of ours and all which it contains, whether animate or inanimate? Yet such is, indeed, the fact. We are thus, in a measure, prepared to find that the material which forms the great solar clouds may turn out to be a substance not quite unknown to the terrestrial chemist; nay, further, its very abundance in the sun might seem to suggest that this particular materal might perhaps prove to be one which was very abundant on the earth.

Carbon is one of the commonest as well as one of the most remarkable substances in nature. A lump of coke only differs from a piece of carbon by the ash which the coke leaves behind when burned. As charcoal is almost entirely carbon, so wood is largely composed of this same element. Carbon is indeed present everywhere. In various forms carbon is in the earth beneath our feet and in the air which we breathe. This substance courses with the blood through our veins; it is by carbon that the heat of the body is sustained, and the same element is intimately associated with life in every phase. Nor is the presence of carbon merely confined to this earth. We know it abounds on other bodies in space. It has been shown to be eminently characteristic of the composition of comets. But the greatest of all the functions of carbon in the universe has yet to be mentioned. This same wonderful element has been shown to be in all probability the material which constitutes those glowing solar clouds, to whose kindly radiation our very life owes its origin.

In the ordinary incandescent electric lamp the brilliant light is produced by a glowing filament of carbon. The powerful current of electricity experiences so much resistance as it flows through this badly conducting substance that it raises the temperature of the carbon wire so as to make it dazzlingly white hot. Indeed, the carbon is thus elevated to a temperature far in excess of that which could be obtained in any other way.

There is no known metal, and perhaps no substance whatever, which demands so high a temperature to fuse as does the element carbon. A filament of carbon, and a filament of carbon alone, will remain unfused and unbroken when heated by the electric current to the dazzling brilliance necessary for effective illumination. This is the reason why this particular element is so indispensable for our incandescent electric lamps. Modern research has now taught us that just as the electrician has to employ carbon as the immediate agent in producing the brightest of artificial lights down here, so the sun in heaven uses precisely the same element as the immediate agent in the production of its transcendent light and heat. Owing to the extraordinary fervor which prevails in the interior parts of the sun, all substances there present, no matter how difficult we may find their fusion, would have to submit to be melted, nay, even to be driven off into vapor. If submitted to the heat of this appalling solar furnace, an iron poker, for instance, would vanish into invisible vapor. In the presence of the intense heat of the inner parts of the sun, even carbon itself is unable to remain solid. It would seem that it must assume a gaseous form under such circumstances, just as the copper and the iron and all the other substances do which yield more readily than it to the fierce heat of their surroundings.

The buoyancy of carbon vapor is one of its most remarkable characteristics, accordingly immense volumes of the carbon steam in the sun soar at a higher level than do the vapors of the other elements. Thus carbon becomes a very large and important constituent of the more elevated regions of the solar atmosphere. We can understand what happens to these carbon vapors by the analogous case of the familiar clouds in our own skies. It is true, no doubt, that our terrestial clouds are composed of a material totally different from that which constitutes the solar clouds. The sun evaporates the water from the great oceans which cover so large a proportion of our earth. The vapor thus produced ascends in the form of invisible gas through our atmosphere until it reaches an altitude thousands of feet above the surface of the earth. The chill that the watery vapor experiences up there is so great that the vapor collects into little liquid beads, and it is, of course, these liquid beads, in countless myraids, which form the clouds we know so well.

We can now understand what happens as the buoyant carbon vapor soars upwards through the sun's atmosphere. They attain at last to an elevation where the fearful intensity of the solar heat has so far abated that, though nearly all other elements may still remain entirely gaseous, yet the exceptionally refractory carbon begins to return to the liquid state. At the first stage in this return the carbon vapor conducts itself just as does the ascending watery vapor from the earth when about to be transformed into a visible cloud. Under the influence of a chill the carbon vapor collects into a myraid host of little beads of liquid. Each of these drops of liquid carbon in the glorious solar clouds has a temperature and a corresponding radiance, vastly exceeding that with which the filament glows in the incandescent electric lamp. When we remember further that the entire surface of our luminary is coated with these clouds, every particle of which is thus intensely luminous, we need no longer wonder at that dazzling brilliance which, even across the awful gulf of ninety-three million of miles, produces for us the indescribable glory of daylight.—*Condensed from a Lecture by Sir. Robert Ball in the N. Y. Sun.*

THE BRIDGE OF AN OCEAN LINER.

Let us spend an hour with Captain Randle of the American liner, *St. Louis*, on the bridge in mid-ocean. He first takes us into the wheel house. It is a room about ten feet long and ten feet wide, with a curved front. A wheel about three feet in diameter is placed in the center of the room, and you are surprised to see that the quartermaster keeps turning it almost constantly. You have always thought that he had simply to keep his eye on the floating compass in the box directly in front of him and hold the ship steady in her course. As you look at the compass you see the ship veering now this way and now that as she rolls and plunges, or as one screw turns faster than the other, and thus pulls the ship around. It is hard to make two independent screws go at exactly the same speed, and so this man at the wheel is busy all the time turning the ship straight. He has to fight the waves and the screws and the winds at the same time, and he is a busy man.

This steering-wheel controls the ship by means of a small column of oil in a little tube. By turning the wheel this way or that the oil in the tube is forced up or down, and that opens or closes certain valves in the steam steering-gear four hundred feet away, and the rudder is turned as easily as if a child had done it. In most steamships the steam steering gear is controlled by hydraulic power—that is, by water—but the use of a column of oil is an improvement.

As you look about, you see fastened to the cornice directly in front of the wheel man, a little scale in black with white lines marked off on it. There is a dial on it, and as the ship rolls you see that this is a device to mark the degree of a roll. You may notice that it takes about a second for every degree of a roll. On each side of the room is another long, black gauge, and the dials point to certain figures, generally between ninety and ninety-five. These dials are little electrical devices, showing exactly how many revolutions the screws are making. The Captain, at a glance, knows what is going on in the engine rooms.

Over in the corner of the room is another curious electrical device. It is a little box with a clock in it. The Captain tells you it is the machine that controls the whistle in time of fog. The law requires a long blast of the whistle at such times every two minutes. By pressing in a button on this little clock apparatus, and by setting the clock in a certain manner, the whistle is blown automatically for seven seconds every minute. There can be no error of man in that work. Just as sure as every minute comes around that whistle will blow seven seconds. Under the old way, when a man pulled the whistle cord, there was no exactness in the work. When the fog is over the button is released, and the whistle stops. —*From Harper's Round Table.*

THE PAY OF MEMBERS OF CONGRESS.

The question of whether or not members of Congress should be paid and the amount and manner of payment, has been one which has provoked much argument and warm debate since the Union was formed. In his work, *The American Government*, Dr. B. A. Hinsdale treats this subject in an interesting manner:

The clause of the Constitution relating to this subject runs: "The Senators and Representatives shall receive a compensation for their services to be ascertained by law and paid out of the Treasury of the United States." At the time of the adoption of the Constitution, as now, members of Parliament received no compensation whatever, but, as Dr. Hinsdale points out, the objections to such a practice are, first, that the State has no more right to demand the services of citizens than to demand their property, without a just compensation, and, secondly, that it tends to exclude poor men from the lawmaking function. These objections ultimately caused the Federal Convention to agree that members of Congress should be paid, though it was urged by Dr. Franklin and Gen. Pinckney that Senators, at all events, since they would represent the wealth of the country, should receive no compensation, and a proposal to that end received the votes of five States. A question more earnestly contested was who should be the paymaster. Some delegates to the Convention contended that the members of the new Congress, like the members of the old one (under the Articles of Confederation), and especially that Senators, should be paid by the States. Those, on the other hand, who advocated payment by the nation, argued that it was unjust to ask the State to pay for services rendered to the nation; that the several States would compensate their members at different rates, thus begetting jealousy and heart-burning; and that some of the States might make the pay so low as to substitute for the question, "Who is most fit to be chosen?" "Who is most willing to serve?" Mr. Madison, moreover, pointed out that State payment would impair the very elements of coherence and stability in the Federal Government which they were seeking to infuse; Senators would become the mere agents of State interests and views, instead of being impartial guardians of the public good. Mr. Hamilton presented the same view in the tersest form: "Those who pay are the masters of those who are paid." These arguments were decisive of the source of payment. Another question arose, however, namely, whether the amount of the compensation should be fixed in the Constitution or be left to Congress. On the one hand, it was urged that the pay would need to be changed from time to time, and that it would be difficult or impossible to amend the Constitution; on the other hand, it was predicted that Congress would be likely to abuse the power. It was also proposed that Congress should fix the compensation only once in twelve years. The following amendment to the Constitution was submitted to the States in 1789, but failed to secure the requisite number of ratifications;

"No law varying the compensation for the services of the Senators and Representatives shall take effect before the election of Representatives shall have intervened." The matter was finally left unreservedly to the law-making power; that is to say, each Congress has absolute power over its own pay, subject to the Presidential veto. In every case of change no matter when made, it has had effect from the beginning of the Congress making it. In other words, every law on the subject has been retroactive. The law for instance, of March 16, 1816, reached back to March 4, 1815, the law of Aug. 16, 1856, to March 4, 1855; the law of March 3, 1873, to March 4, 1871, or two full years. It will be remembered that the law of 1873, known as the "Back Pay Grab." provoked severe criticism throughout the country, and the law of 1816 had a similar reception. In both cases it was the popular opinion that the increased compensation was excessive, and that the retroactive feature, although constitutional, was improper and incompatible with the character of Congress. In both cases, the Congress hastened to repeal the obnoxious legislation.

The compensation of members of Congress from the adoption of the Constitution to the present time is given as follows: From 1789 to 1815 they received \$6 a day; from 1815 to 1817 the pay was \$1,500 a year; from 1817 to 1855 it was \$8 a day; for the two years 1855, 1856, it was \$3,000 a year; from 1856 to 1871 it was \$5,000 a year; from March 4, 1871, to March 3, 1873, the pay was raised to \$7,500 a year, but since 1873 it has been \$5,000. Except in the period 1815-1817 members have always received mileage. Down to 1815 this was \$6 for every twenty miles of necessary travel going to and returning from the capital. From 1817 to 1865 it was \$8 for every twenty miles of such travel; that is to say, in 1860 a Senator from Oregon going to Washington and returning to his home by way of Panama would receive some \$3,000 mileage each way. From 1865 to 1871 the mileage was only twenty cents a mile. In 1871–1873 it was the actual expense of travel. Since 1873 it has been the same as it was from 1865 to 1871. The curious circumstance is noted that for the single year 1795 Senators received one dollar a day more than Representatives. We add that the Speaker of the house and the President *pro tempore* of the Senate receive each \$8,000 a year.

FOOLISH SUPERSTITIONS.

So serious a person as an undertaker laughed not long ago when some one told him the story of an old lawyer who had counted the number of carriages in a funeral procession, and had died three months afterward.

"That superstition does not influence men in my trade," he remarked briskly. "For years I have made a practice of counting the number of vehicles in every funeral line falling under my eyes, and I still live and am reasonably happy. When I am employed professionally, I have to learn by actual count whether the livery order has been filled; and whenever I see a line of carriages following a hearse, I run over the number from curiosity to find out how my rivals are getting on. All undertakers do it, and you know they are proverbially long-lived."

A similar comment was made by a clerk in a Western furnishing-store, when he was cautioned by a superstitious customer against opening an umbrella indoors.

"I have raised at least ten thousand umbrellas in this shop," he remarked contemptuously, "and I have stood under eight thousand of them at least, and if it has brought me bad luck, I have never known of it."

A hospital surgeon in a large city heard an old practitioner assert that accidents and diseases always occur in groups of three; and that he knew, as a matter of experience and observation, that if one boy broke an arm, and he was called to set it, two other similar cases would be certain to come up in the course of a few weeks; or that if he had one case of smallpox, he would be certain to have three.

"Join my staff at the hospital, doctor," replied the surgeon, "and you will soon be convinced that accidents and diseases are repeated in an unending series, and that your triple effect is a figment of the imagination. You would very soon abandon your rule of three, if you were to see, as I do, a hundred patients brought into the wards in the course of a week.

"Why, man," exclaimed the surgeon, "you are as foolish as the old women in New England who carried horse chestnuts in their pockets to keep off rheumatism, and would faint from fright when they had broken a looking-glass or spilled salt on the table; and as unreasonable as their husbands, who felt almost sure they ought to make their wills because they had seen the moon over the left shoulder, or had been numbered in a company of thirteen people. The world would be governed by a whimsical god of fantastic freaks and caprices if such trifles as these could determine human fortune or shorten human life."

That was a common-sense way of dealing with popular superstition. All such foolish notions tend to impair faith in an orderly and all-wise Providence.—*Youths' Companion.*

PHOTOGRAPHS BY THE MILE.

One hundred thousand photographs of actors, actresses, and celebrities every day is the record forced by the tobacco manufacturers who give away such things to purchasers. For a limited time one company alone had a demand for four hundred thousand pictures daily. At another time recently the representative of a large tobacco concern went to a photographer of New York and desired to place an order for one million cabinets, to be delivered in six months. The man who says "Now look pleasant" simply threw up his hands helplessly and said that he could not possibly print so many photographs in that time were the sun to shine every day and for twenty-four hours at a stretch. He confessed that he found his limit from one negative to be from ten to twelve prints a day; also that, increase his negatives as he might and spread his printing frames on every roof in his neighborhood as he might, he would still be simply paralyzed when it came to fixing, toning, washing, and mounting. And the picture-hungry man went to a place near by, where they could fill his order in ten days, where they print, develop, fix, wash, dry, and mount pictures by the mile—where in fact, they run them out by machinery at the rate of 100,000 a day on a pinch, and produce between 60,000 and 70,000 daily, all packed, regularly.

It is a marvel of modern photography. It is, as compared with the hand process, what the great latter-day inset printing presses, are to the old Washington hand presses, and it works not so very differently, for a great roll of sensitized paper more than 3,000 feet in length and three feet wide goes into one end of the apparatus untouched and comes out at the other end in the form of large, dry sheets of finished photographs. All this is managed with the utmost mechanical precision, and every picture is perfect when it emerges.

The process is a new one. Of course it acquires its value from the constantly increasing demand for immense numbers of photographs. Six or seven negatives of the regulation sort are placed in a frame, side by side, and the string of them thus formed is placed in the printing machine. A roll of bromide paper, prepared with a quick-acting emulsion, is suspended or pivoted at one end of the machine, and the end of the paper is started through. In the half-cylindrical exposure box, containing the negatives, an intense light is produced by means of eight incandescent electric lamps. When all is in readiness a platen below presses the paper up against the negatives, the light is turned on, and an exposure of one or two seconds is made. Instantly the lamps go out, the paper is pulled along by a winding-up device and the operation is repeated. When one or more of the negatives are less intense than their fellows and the ordinary exposure is found to be too long, thin sheets of waxed or tissue paper are pasted over, to filter the light rays and render them less active.

The roll of paper, upon which nothing appears, the impressions being all latent, is now carried to the developing, fixing, and washing tank, where it is again suspended and unwound as the process goes forward. The first compartment of the tank is provided with a developing solution, the next with water; then come hyposulphide of soda (fixative), water, alum, and more washing, until finally the broad ribbon goes into the drying box, hot air heated, up which it travels to the top floor, to be cut into sheets for easy handling. All the tanks are provided with sets of rollers, both at the top and bottom, and, as the tanks are three or four feet deep, the strip remains in each solution for several minutes, although it travels at a rate of about ten feet a minute. The process, so easily watched, is most remarkable. The lamps over the roll and developer tank are red or non-actinic, and under their glow the white paper enters the fluid over the first roller. When next it appears, to dive again, the half developed faces show dimly, and at the next emerging are strong, clear, and wonderfully uniform. Down, after a washing, goes the band into the "hypo," to come up cleared, and when at last the washed and alumed pictures go up the drying chute they are things of beauty and perpetual joys.

The possibilities of this automatic process are almost incalculable. It would be comparatively easy to take a flash-light photograph of the largest audience that ever assembled in any theatre at 9 o'clock, and then to hand every one a finished picture as he or she went out at the door when the play was done. In the case of the Defender-Valkyrie races a company could have placed at least 100,000 mounted photographs of the finish on the streets next day. It would easily be possible to produce 250,000 pictures every day. Of the large panel pictures the apparatus would then turn out 25,000 as a fair daily average. From any one single negative 20,000 finished cabinet photographs could be furnished each day—as against the twelve produced by the ordinary method.—*N. Y. Sun.*

RAISINS.

A Raisin Vineyard is in full bearing in three years, but the grape has not reached its perfection until the vine from which it springs is six or seven years old.

The Muscat and Thompson seedless are the best variety of raisin grape cultivated, the latter having only been introduced within the last few years, but the Zinfandell and Sultana have also large claims upon popularity.

Standing before one of these vines, upon which inverted cones of countless perfect spheres are hanging—each cluster weighing several pounds—a vision of the Hebrew spies, with their magnificent grapes of Eshcol, borne "on a staff between the two," rises before us, and involuntarily we exclaim, "Is not this also the Promised Land?"

About the 1st of September the long sunny days, the dewless nights, and the percolated soil have perfected their marvellous work, and the first crop is ready to be gathered. By this time the laterals have run riot, and the vineyardist can scarcely see over the top of his vines.

The process of grape-gathering for raisins requires the most delicate handling and cleanliness. Hundreds of shallow wooden trays, about five feet square, are distributed among dozens of trained pickers. The bunches are carefully cut from the vine and as carefully laid upon the base of the tray to avoid bruising them. There they remain untouched for ten days and nights. One-half of the grape is by this time cured: but instead of turning them by hand, an empty tray is placed over them, the lower one is inverted, and the turning and the transfer have been made. In twelve more days the curing is completed. The trays and contents are then stacked about twenty trays high, where they remain for five days sweating, when they are ready to be graded and packed in boxes of five, ten, twenty and fifty pounds for the Eastern market.

Vines six years old yield one and a half tons of raisins per acre, giving a net income of two hundred dollars per acre. While the supply of raisins is as unfailing as the growing demand, there is an æsthetic as well as an economic side. A few women have not only found raisin-vineyards a source of comfortable revenue, but their cultivation a most elegant and healthful pastime.

The approach to some of their homes, with the vineyard in the rear of the dwelling house, is through avenues of palm and magnolia trees, and if they lie, as many do, against the foothills of the Sierras, a ride through the columnar glories of giant red woods is a fitting introduction to the beauty and utility which is sure to be beyond.—*From Harper's Weekly.*

SOME QUEER BOATS.

Of all the uncommon forms that boats take, the newest, instead of being strange and complicated like most nineteenth-century inventions, are almost as simple as anything that floats. Only rafts of logs are more simple than what we call our "car-floats." They are the newest type of boats we know, and have come into being because New York City is on an island, with only a few railroads crossing to it from the mainland. The other great and little railways, which bring and take goods and people to and from New York, all stop on the opposite shores of our harbor, in New Jersey, Staten Island, and Long Island. Since the cars of one railroad often have to go past the city upon the other roads, these "floats" are used to transport them around our island, so that goods from Boston or Sag Harbor, for instance, can be sent around New York to the tracks of the roads that will carry them to San Francisco without unloading or reloading. The floats that carry these cars are merely boxes, the shape of great dominoes, with railroad tracks laid upon them. Some carry six freight-cars, some carry eight, and some carry ten cars. Tiny little propellers that we call "tug-boats" are warped or hitched alongside of these clumsy floating boxes, where they look as a little kitten would appear beside a big St. Bernard dog, or as a locomotive would look beside a house. But our queer, snorting, fussy little tug-boats march away with every floating thing to which they are hitched—even dragging hugh Atlantic steamships at their sides—because they reach down deep into the water, where their big screws, driven by very powerful engines, obtain a mighty hold. Because our tug-boats are so small, and yet so strong, they are able to move swiftly when they have no burdens to carry.

The "floats" that carry passengers around New York, so that they can go to Boston from Philadelphia or Chicago without changing cars (and even without getting out of bed on the sleeping cars), are not floats at all. They are very powerful and large steamboats, with decks covered with iron plates, with car tracks on these decks, and with arrangements for locking the car wheels fast to the tracks, so that no matter how boisterous the water may be on stormy days, the cars cannot break loose and roll overboard. We have several queer sorts of boats and other floating objects that look like floating houses. Among them are what we call our floating baths, and our floating docks, and our cattle and ice barges. But there is one kind of floating building that looks like a tower or a steeple riding the waters and steering itself around. That strange thing—and we employ many such—is a floating grain elevator. It is a tall four-sided tower built upon a square snub-nosed boat. It has a great proboscis, that it sticks down into canal-boats full of grain, which it sucks or dips out so that it can load the grain into the holds of ships that are to carry it to Europe.—*From Harper's Round Table.*

ENGINEERING TOOLS AT POMPEII.

Under the title of "Things of Engineering Interest Found at Pompeii," Professor Goodman lately gave his inaugural lecture in the engineering department of the Yorkshire College, Leeds. The lecturer remarked that he had recently visited Pompeii, and was not only charmed by the great beauty of the works of the ancient Romans, but also by their extreme ingenuity as mechanics—in fact, it was a marvel how some of the instruments and tools they were in the habit of using could possibly have been made without such machinery as we now possess.

After explaining the situation and destruction of Pompeii by showers of ashes and mud, not lava, as is usually supposed, in the year 79 A. D., Professor Goodman showed a series of about fifty lantern slides, prepared from photographs taken by himself in Pompeii last Easter. The streets, he explained, were used as waterways to carry off the surface water, and probably sewage, from the houses. The pavements were raised about a foot above the streets, and stepping stones were provided at intervals for foot passengers.

The horses and chariot wheels had to pass between, and in many places deep ruts have been worn by the chariot wheels in the stone paved streets. The water supply of Pompeii was distributed by means of lead pipes laid under the streets. There were many public drinking fountains, and most of the large houses were provided with fountains, many of most beautiful design. The amphitheater, although a fine structure, capable of seating 15,500 people, was small compared with many in Italy. The bronzes found at Pompeii reveal great skill and artistic talent. The bronze brazier and kitchener were provided with boilers at the side and taps for running off the hot water. Ewers and urns have been discovered with internal tubes and furnaces precisely similar to the arrangement now used in modern steam boilers. Several very strong metal safes, provided with substantial locks, have been found. The locks and keys were most ingenious, and some very complex. On looking at the iron tools found in Pompeii, one could almost imagine he was gazing into a modern tool shop, except for the fact that the ancient representatives have suffered severely from rust.

Sickles, billhooks, rakes, forks, axes, spades, blacksmith's tongs, hammers, soldering irons, planes, shovels, etc., are remarkably like those used to-day; but certainly the most marvelous instruments found are the surgical instruments, beautifully executed, and of design exactly similar to some recently patented and re-invented. Incredible as it may appear, yet it is a fact, that the Pompeiians had wire ropes of perfect construction.—*Scientific American.*

THE RIGHT PHILOSOPHY.

It is worth while for us all, even when suffering pain, to refrain from frowning and wrinkling up our faces, and saying impatient words. Every passing thought and feeling write themselves upon the countenance, and the young girl is making day by day not only the woman she will be in character later on, but the woman she will be in looks. Handsome or plain, agreeable or the opposite, the woman of forty is dependent for her looks on the girl of fourteen. You owe an amount of thought and consideration to the woman you are going to be, and the friends who will love her, and so you must not let needless lines and furrows come to your pretty brows, but keep your foreheads smooth, and do not draw your lips down at the corners nor go about looking unhappy. It is possible, even when bearing much pain, to wear a tranquil expression if one will, but remember that the tranquil mind in the end can conquer pain.

Crossing town the other day in haste to catch a train, the horse-car was three times blocked by great vans which stood upon the track. I looked about on my fellow-passengers. Some had flushed and angry faces, some could not sit still, but tapped the floor with their feet, and uttered exclamations, and looked at their watches. One or two stepped out with their bags and walked hastily onward. But a dear old lady in the corner of the car was a pattern of sweetness and amiability, and I heard her observe to her neighbor: "We will probably lose our train, but at this time of day there are trains every half hour, and it's never well to be put out by little accidents of this sort." She had the right philosophy. —*From Harper's Round Table.*

WHAT SHALL WE EAT?

A pamphlet issued under the auspices of the United States Department of Agriculture, prepared by W. O. Atwater, Ph. D., professor of chemistry in Wesleyan University, on the nutritive value of food products, says:

"A quart of milk, three-quarters of a pound of moderately fat beef—sirloin steak, for instance—and five ounces of wheat flour all contain about the same amount of nutritive material; but we pay different prices for them, and they have different values for nutriment. The milk comes nearest to being a perfect food. It contains all the different kinds of nutritive materials that the body needs. Bread made from the wheat flour will support life. It contains all of the necessary ingredients for nourishment, but not in the proportions best adapted for ordinary use. A man might live on beef alone, but it would be a very one-sided and imperfect diet. But meat and bread together make the essentials of a healthful diet. Such are the facts of experience. The advancing science of later years explains them. This explanation takes into account, not simple quantities of meat and bread and milk and other materials which we eat, but also the nutritive ingredients or 'nutrients' which they contain."

The chief uses of food are two: To form the material of the body and repair its wastes; to yield heat to keep the body warm and to provide muscular and other power for the work it has to do. Dr. Atwater has prepared two tables showing, first, the composition of food materials, the most important of which are the nutritive ingredients and their fuel value; second the pecuniary economy of food, in which the amount of nutrients is stated in pounds. In the first table we find that butter has the greatest fuel value, fat pork coming second, and the balance of the foods mentioned being valued as fuel in the following order: Cheese, oatmeal, sugar, rice, beans, cornmeal, wheat flour, wheat bread, leg of mutton and beef sirloin, round of beef, mackerel, salmon. Codfish, oysters, cow's milk, and potatoes stand very low as fuel foods.

From the second table we learn that the greatest nutritive value in any kind of food of a specified value (Dr. Atwater takes 25 cents' worth of every kind of food considered) is found in cornmeal. In 10 pounds of cornmeal there are a trifle more than 8 pounds of actual nutriment. In 8½ pounds of wheat flour there are over 6¼ pounds of nutriment; in 5 pounds of white sugar there are 4¼ pounds of nutriment; in 5 pounds of beans there are 4 pounds of nutriment; in 20 pounds of potatoes there are 3¾ pounds of nutriment; in 25 cents' worth of fat salt pork there are 3½ pounds of nutriment; in the same value of wheat bread there are 2¼ pounds, in the neck of beef, 1½ pounds, in skim milk cheese, 1½ pounds; in whole milk cheese, a trifle more than 1½ pounds; in butter, 1½ pounds; and in smoked ham and leg of mutton about the same; in milk, a trifle over 1 pound; in mackerel, about 1 pound; in round of beef, ¾ of a pound; in salt codfish and beef sirloin, about ½ a pound; in eggs at 25 cents a dozen, about 7 ounces; in fresh codfish, about 6 ounces; and in oysters at 35 cents a quart, about 3 ounces.

PEDICULOSIS.

Every child who attends a public school, or is thrown into similarly miscellaneous company, is liable to the distressing affection known as lice, or in medical parlance as "pediculosis," which is perhaps a more euphonious term.

Cleanliness is the greatest safeguard against contagion of every kind, and lice will not breed generally except in conditions of more or less neglect. Yet the familiarity with which children meet in the school-room and on the playground is sufficient excuse for the transmission of pediculosis from one child to another.

Pediculosis is usually easy of recognition during its earlier stages, but it is so unlooked for and insidious in its establishment that often it is only after a sufficient time has elapsed for the aggravated symptoms to appear that treatment is begun. These later signs are by no means so unimportant as might at first be imagined.

The insect which distinguishes this disease from all others is poisonous in its nature, and it is possible by the simple act of scratching to bring on a general irritation of the skin in any part of the body. This irritation may appear to the inexperienced person to be an entirely distinct and unexplained affection.

The treatment of pediculosis is simple enough at any stage. The first thing, of course, is to get rid of both the insects and the spores, or nits. To do this about four ounces of crude petroleum are required. This can be purchased of any druggist. Pour one-quarter of the liquid carefully into the hair for four successive days, allowing it to remain for four or five hours. The hair must be carefully washed out with warm soapsuds and thoroughly dried after each treatment.

Probably every sign of insects and nits will have disappeared by the fourth day. If any nits should remain entangled in the hair, they may be washed out with a little vinegar.

This method is much better than the fine-tooth comb of our grandparents, since there is no danger of irritating the scalp. In aggravated stages of pediculosis the same treatment is necessary. The swollen glands and the eruptions on the skin will disappear as soon as the source of contagion is removed. A little simple ointment, say what is known as "boracic," rubbed on the skin over the swellings and raw surfaces, will hasten recovery.—*Youth's Companion.*

SHORTSIGHTEDNESS.

Myopia or shortsightedness being essentially a condition due to abuse of the eye, one is constantly obliged to say "don't" to patients. It occurs to me that it might be useful to put these prohibitory rules in aphoristic form:

1. Don't read in railway trains or vehicles in motion.
2. Don't read lying down or in a constrained position.
3. Don't read by firelight, moonlight, or twilight.
4. Don't read by a flickering gaslight or candlelight.
5. Don't read books printed on thin paper.
6. Don't read books which have no space between the lines.
7. Don't read for more than fifty minutes without stopping, whether the eyes are tired or not.
8. Don't hold the reading close to the eyes.
9. Don't study at night, but in the morning when you are fresh.
10. Don't select your own glasses at the outset.

It would almost seem as though some of these rules were too obvious to require mention, but practical experience shows that myopes abuse their eyes just in the way stated. Reading by firelight or by moonlight are favorite sins. Readin lying down tends to increase the strain on the accomodation, and while traveling tires the ciliary muscle because of the too frequent adjustmet of focus. In short, anything which tends to increase the quantity of blood in the organ favors the increase of the defect, leading in extreme cases to detachment of the retina and blindness.—*Dr. G. Sterling Ryerson of Trinity Med. College in The Canada Lancet.*

ACTION OF THE RAIN.

The rain falling on the rocks sinks into every crack and crevice, carrying with it into these fissures surface material which has been degraded by the weather, and thus affording a matrix sufficient to start the growth of vegetation, and afterward to maintain the plants. The fibers and roots of these plants, bushes, and trees thus brought into life, growing and expanding, act as wedges to split up the surface of the rock and to commence the process of wearing away. From this quality of destruction a large class of plants derive the name of Saxifrages, or rock breakers, from their roots penetrating into the minute fissures in search of water, and so assisting in the process of disintegration. In winter the water collected in the hollows and crevices becomes frozen, and expanding as it changes into ice, acts like a charge of blasting material in breaking up the rocks. The pieces thus detached become further disintegrated by frost and weather, and, being rolled over and over and rubbed against each other as they are carried away down the mountain currents, are ground gradually smaller and smaller, till from fragments of rocks they become bowlders, then pebbles, and finally sand. As the mountain stream merges into the river the pebbles and coarse sand continue to be rolled along the bottom of the channel, while the argillaceous particles and salts become mingled with the water, and flow on with it either in suspension or solution.—*Longman's.*

MINING MACHINE.

No. 547,896. Henry H. Bliss, Washington, D. C. *Patented Oct. 15th*, 1895. Fig. 1 is a side view partly in section; Fig. 2 is a top view with the motor removed; and Fig. 3 is an end view. This machine is to be driven by an electric motor, and the object of this improvement is to automatically graduate the feed, so that the strain upon the motor will be constant. In using electric motors it is necessary to run the armature at a constant speed. If the speed falls below the normal, the efficiency of the machine falls off greatly, and there is also great danger of burning out some part of the machine. In undercutting coal, the cutters are very liable to encounter hard streaks, sulphur balls, etc., which impose heavy work on the motor and reduce its speed. In this machine the pressure upon the cutters is varied to suit the hardness of the material which the cutters are working in. The cutter bar *D* is rotated by means of a chain 2, and a sprocket wheel on the rear shaft *K*, which is connected by suitable gears to the armature shaft *H'*. The working parts are all mounted on a frame *B* which slides within the stationary frame *A*. The sliding frame is fed forward by means of a

piston, that is to the pressure existing at that moment in the engine cylinder. The wheel will partly slide and partly roll, on the surface of the drum as it revolves back and forth, the amount of the rolling motion depending upon the angle to which the wheel is turned. A pair of counting wheels *m* are provided to register the revolutions of the wheel *D*. When in operation, the piston rises and swivels the wheel, and the drum *A* turns back and forth, at each stroke. During the forward stroke, the wheel measures the power exerted by the steam pressure, and during the return stroke it runs backward and deducts the resistance due to the back pressure. It thus records on the registering wheels, the net power exerted upon the piston of the engine, and adds the successive strokes together, showing at all times the net sum of the power exerted, during the time it was in operation.

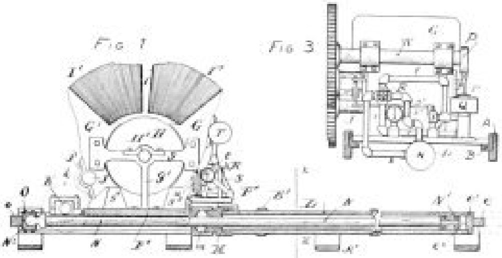
PUMP FOR GRITTY WATER.

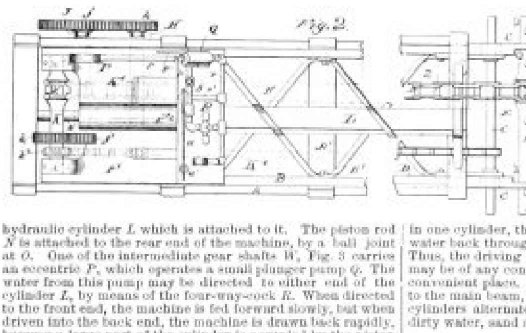
No. 547,576. Albert G. Fuller and Barton H. Coffey, New York, N. Y. *Patented Oct. 8th*, 1895. Fig. 4 is a section through one half of the pump; and Fig. 3 is a section along the line *X* of Fig. 4, and on a smaller scale. Two pumps are employed, one on each side of the centre line *X*, and the piston rods are coupled to a beam *Z*, which is supported upon the A frame *J*. The beam serves only to couple the pistons, not to drive them. The pistons move loosely in a brass cylinder or liner *E*, which can be easily removed. The pistons are driven downward by means of clean water, which is forced in through the pipe *H*, and valve *G'*, by a common direct steam pump of any kind. When the piston descends

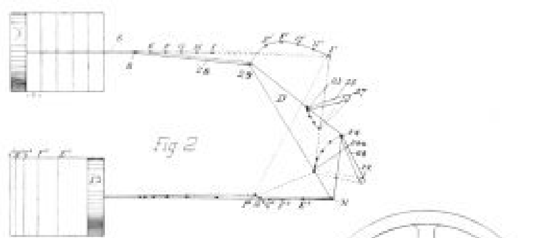
The dirty, sandy water is expelled through the pipe *L*, into the air chamber 3, and out through the discharge pipe *M'*. The clack valves *N*, are hung loosely on their centers, so that they can tilt over any rubbish that may lodge on their seats, and they are hung upon crank arms *N'*, by which they may be slid across their seats at any time, to free them from obstructions, as shown at 5.

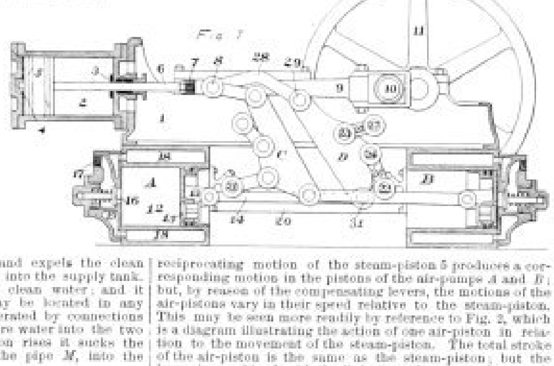
COMPENSATING PUMPING ENGINE.

No. 547,558. Albert P. Massey, Watertown, N. Y. *Patented Oct. 8th*, 1895. Fig. 1 is a vertical section of the engine cylinder and pumps; Fig. 2 is a diagram showing the modification of the power of the steam piston, by the compensating mechanism. The object of the improvement is to permit the steam to be cut off at three eighths stroke, or earlier, and to so apply the power that the air may be properly compressed in the pumps, without depending upon the fly wheel. The fly wheel serves only to enable the crank to pass the centre properly. The steam-piston is operatively connected to the air-pistons by the compensating levers *C* and *D*. The lever *D* is suspended at two points 23 and 24 by the links 25 and 26. Link 25 is attached to the frame by pin 27, about which it is free to revolve. Link 26 is attached to the frame by the pin 22, about which 26 is free to revolve. The upper end of lever *D* is connected to the cross-head pin 8 by the connecting-rod 28 and pin 29. It is connected to the air-piston 13 by the connecting-rod 14 and pin 31. Lever *C* is connected in a similar manner to transmit power from cross-head pin 8 to the piston of air-pump *E*. In operation the





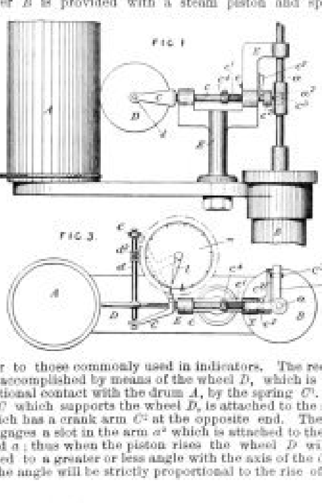




hydraulic cylinder *L* which is attached to it. The piston rod *N* is attached to the rear end of the machine, by a ball joint at *O*. One of the intermediate gear shafts *W*, Fig. 3 carries an eccentric *P*, which operates a small plunger pump *Q*. The water from this pump may be directed to either end of the cylinder *L*, by means of the four-way-cock *R*. When directed to the front end, the machine is fed forward slowly, but when driven into the back end, the machine is drawn back rapidly, because a large part of the cylinder is occupied by the piston rod, and the area of the piston is therefore much smaller. All of the water which is delivered by the pump is forced through a by-pass valve *S*, which is closed by an adjustable spring. If the cutters strike hard stuff, so that th pressure in the feed cylinder rises above the proper amount, the water lifts the valve and escapes into the suction pipe. Thus the pressure upon the cutters is never allowed to become so great as to reduce their speed and check the motor. If they encounter soft stuff, they are fed forward correspondingly faster, so that the load upon the motor is made practically uniform.

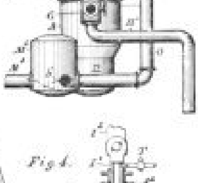
POWER METER.

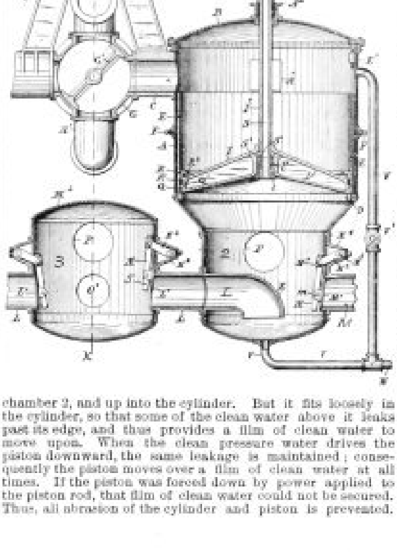
No. 546,897. William G. and Charles W. Little, Heckington, England. *Patented Sept. 24th*, 1895. Fig. 1 is a side view; and Fig. 3 is a top view of the instrument. This meter is designed to record the power which is exerted in the cylinder of a steam engine, and to register the amount, continuously. It resembles a common "indicator" in many particulars. The drum *A* is rotated by a cord which is attached to some reciprocating part of the engine; and the cylinder *B* is provided with a steam piston and spring,



similar to those commonly used in indicators. The recording is accomplished by means of the wheel *D*, which is held in frictional contact with the drum *A*, by the spring *C'*. The fork *C* which supports the wheel *D*, is attached to the shaft *C*, which has a crank arm *C²* at the opposite end. The pin *C³* engages a slot in the arm *a²* which is attached to the piston rod *a*; thus when the piston rises the wheel *D* will be swiveled to a greater or less angle with the axis of the drum *A*. The angle will be strictly proportional to the rise of the

in one cylinder, the other piston rises and expels the clean water back through the lower pipe *H'*, into the supply tank. Thus, the driving pump handles only clean water; and it may be of any convenient size, and may be located in any convenient place. The valve *G'*, is operated by connections to the main beam, and turns the pressure water into the two cylinders alternately. When the piston rises it sucks the dirty water, sand and stones through the pipe *M*, into the



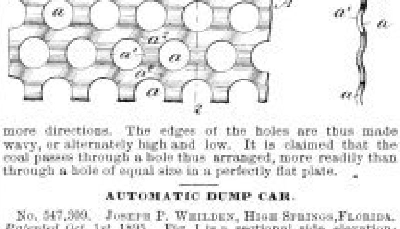


chamber 2, and up into the cylinder. But it fits loosely in the cylinder, so that some of the clean water above it leaks past its edge, and thus provides a film of clean water to move upon. When the clean pressure water drives the piston downward, the same leakage is maintained; consequently the piston moves over a film of clean water at all times. If the piston was forced down by power applied to the piston rod, that film of clean water could not be secured. Thus, all abrasion of the cylinder and piston is prevented.

reciprocating motion of the steam-piston 5 produces a corresponding motion in the pistons of the air-pumps *A* and *B*; but, by reason of the compensating levers, the motions of the air-pistons vary in their speed relative to the steam-piston. This may be seen more readily by reference to Fig. 2, which is a diagram illustrating the action of one air-piston in relation to the movement of the steam-piston. The total stroke of the air-piston is the same as the steam-piston; but the lever is combined with the links in such manner that a uniform horizontal motion of the upper end of the lever to right will give a constantly-decreasing motion to the lower end of the lever to the left. In the beginning of the stroke the virtual fulcrum of the lever is at 23, and link 26 serves merely as a guide. In the latter portion of the stroke the pin 24 is the fulcrum and link 25 is a guide. In intermediate positions the virtual fulcrum is a point somewhere between the pins 23 and 24. The paths described by the two ends of the lever are indicated on the drawings; also, the position of the centers for each fifth of the stroke of the steam-piston. The spaces into which the cylinders are divided, show the volumes swept by the air-piston compared with the volumes swept by the steam-piston during each one-fifth of its stroke. If steam were admitted to the steam-cylinder full stroke, the pressure per square inch would be uniform, and the pressure per square inch of the air-piston would be inversely as the volumes swept by the air-piston at any part of the stroke. This would give a pressure of air, much higher than that of the steam which was used to drive the machine.

SCREEN SEGMENT.

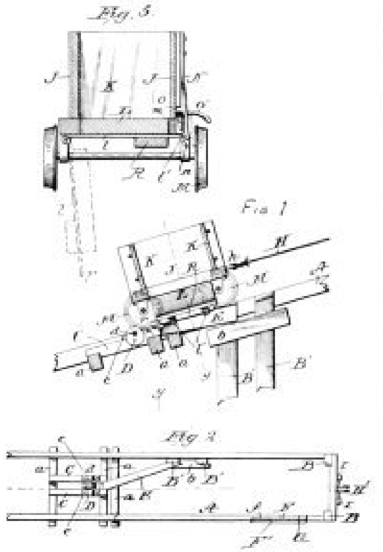
No. 547,140. George W. Cross, Pittston, Penna. *Patented Oct. 1st*, 1895. Fig. 1 shows the top surface of this improved screen plate, and Fig. 2 shows a cross-section of the same. The plate is corrugated between the holes, in two or



more directions. The edges of the holes are thus made wavy, or alternately high and low. It is claimed that the coal passes through a hole thus arranged, more readily than through a hole of equal size in a perfectly flat plate.

AUTOMATIC DUMP CAR.

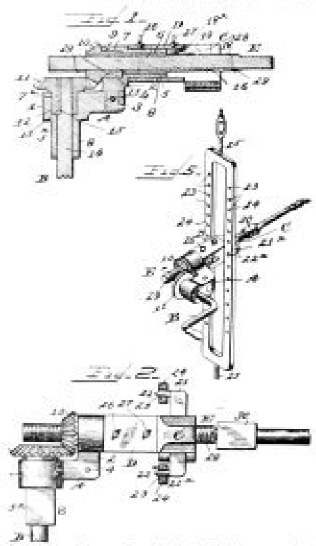
No. 547,360. Joseph P. Weilden, High Springs, Florida. *Patented Oct. 1st*, 1895. Fig. 1 is a sectional side elevation; Fig. 2 is a top view of the track; and Fig. 5 is a cross section of the car. The car bottom is hinged to the side sills as shown in Fig. 5, and when it is closed, is held in place by a spring catch *N*, which is attached to the side of the car. The catch is opened, to dump, by means of a rock shaft *O*, having a finger *M*, and an arm *O'*. As the car reaches the place to dump, the arm *O'* encounters an inclined block which forces it upward, and thus releases the bottom door. The door then hangs downward as shown by dotted lines in Fig. 5. When the car starts back, the door encounters the diagonal bar E, between the rails, and as it moves along the door is partially closed. As the car proceeds, the door glides off the bar E



onto the eccentric roller D, shown in Fig. 1. The roller turns over by friction with the door, and the part having the greatest radius crowds the door upward until the latch secures it. As soon as the car passes, the heavy side of the roller drops down again, so that it is out of the way of the next advancing car. Thus the car door is automatically closed and latched.

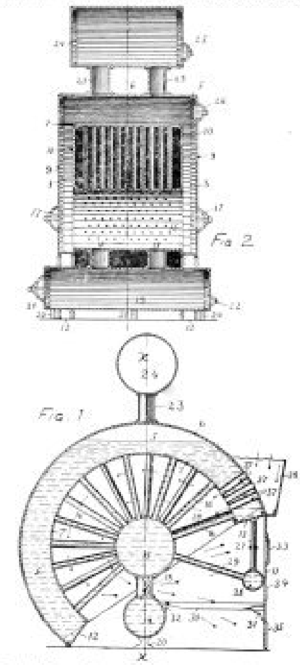
MINING DRILL.

No. 546,008. Joseph E. Hart, Briceville, Tenn. *Patented Sept. 10th, 1895.* Fig. 1 is a section through the bracket and gears; Fig. 2 is a top view; and Fig. 5 shows the machine in position for work. The object of this device is to change the speed of the drill readily, without extra gears. Each arm of the bracket 8 is made square to fit into the square coupling box D. Each gear 10 and 11 is provided with a feather, and has a central hole which exactly fits the drill spindle E. The crank shaft B fits in either gear equally well. When it is desired to change the speed of the drill, the crank shaft is pulled out of its gear, the set screw 26 is slacked off, and the entire bracket with the gears, is slipped off over the end of the spindle. The spindle is then entered into the hole in the other arm of the bracket, the bracket is shoved up into the box D and made fast. The proportions of the gearing are thus reversed. The crank is then inserted and the machine is ready to go ahead. The feed nut is made in halves in the usual manner, and is coupled to the box D by a set-screw 27. The lower half of the nut has two arms 21 provided with prongs 22, which enter holes in the drilling post, and thus support the machine in working position, as shown in Fig. 5.



STEAM BOILER.

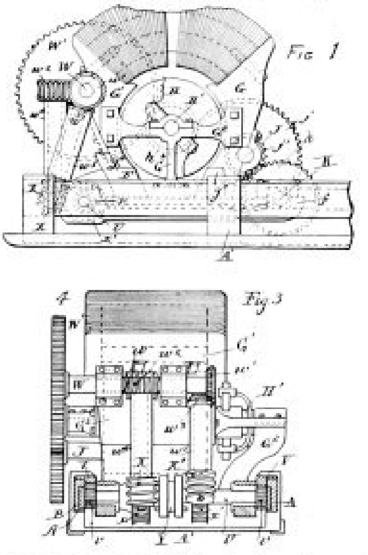
No. 546,786. James J. Rohan, St. Louis, Mo. *Patented Sept. 24th, 1895.* Fig. 1 is a vertical section from front to back of the boiler; and Fig. 2 is a vertical section along the line x of Fig. 1. The body of the boiler consists mainly of two cylindrical shells 6 and 7, which comprise a little more than half a circle. The inner shell 7 is closed by end plates 10, and the outer shell is similarly closed by the heads 9. The water spaces thus enclosed between the heads 9 and 10 are connected, not only by the space 5, but by the central drum 15. Water tubes 16 connect this drum with the inner shell 7. A small water drum 28 is suspended at the front, by the pipes 27. A series of water tubes 29 connect the drums 28 and 15, and constitute a "water grate." The fire which is maintained on this grate burns downward, the hot gases passing through the grate in the direction of the arrows. The combustion chamber is closed at the top by tiles 36 which rest on the last row of tubes 16. The whole surface of the inner shell, and the end heads 10, are good heating surfaces, and the water tubes are very effective, because they



extend at right angles with the current of hot gases. The smoke and spent gas escape through short fire tubes 37 into the smoke box 38. An ordinary grate 30, resting at one end on the mud drum 19, is provided, when it is desired to fire in the ordinary manner.

FEED FOR MINING MACHINES.

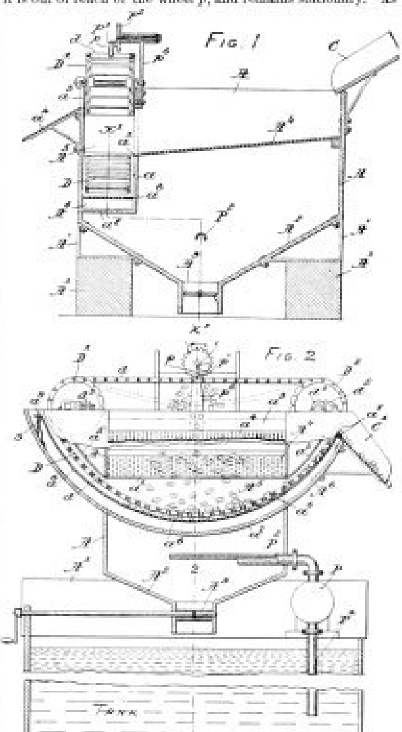
No. 547,837. Henry H. Bliss, Washington, D. C. *Patented Oct. 15th, 1895.* Fig. 1 is a side elevation; and Fig. 3 is a rear end view. The feed mechanism here shown is adapted to any variety of machine which carries a rotating cutter bar at the front end of the sliding frame. The motor and all of the working parts are attached to the sliding frame which is moved forward upon the stationary frame, by means



of racks V, pinions v, and shaft U. The forward movement is obtained by means of the shaft W (which is geared to the motor) and the worms and wheels w, w, and X, x. The backward motion is made by means of the gears w', w', and the worm and wheel X', x'. Both wheels x, x' run loose on the shaft U, and either may be coupled to the shaft by means of the clutch Y.

COAL JIG.

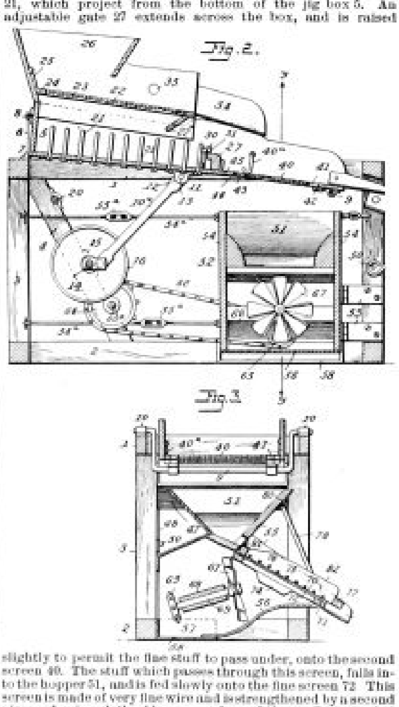
No. 547,129. David E. Phillips, Mahanoy City, Penna. *Patented Oct. 1st, 1895.* Fig. 1 is a vertical section on the line 2 of Fig. 2, and Fig. 2 is a cross-section on the line x' of Fig. 1. The coal which is to be cleaned is fed from the spout C, onto the perforated plate A^4. The water is pumped in by jerks by the pump P, and passes upward through the plate and lifts the mass of coal and slate at each stroke. The coal rapidly works to the top and passes off through the notch a^2, with the water. The delivery chute a^4, is perforated and the water drains back into the tank to be used over again. The slate and rubbish accumulates in the bottom of the circular pocket A^5, and is removed therefrom by the conveyor D. This conveyor is driven intermittently by means of a finger attached to the rotating wheel p. The circular pocket is provided with a false bottom a^6, of bronze, which is hinged at the edge of the slate chute c^1, and is supported by springs s, at a^7. So long as there is not enough weight of slate, etc., on the plate a^6, to depress the springs, the upper run of the conveyor d, sags as shown by the dotted lines, consequently it is out of reach of the wheel p, and remains stationary. As



soon as a^6 sinks downward, the upper run straightens out and engages the driving wheel, and the conveyor is thus driven until the slate is removed from the pockets. The conveyor is thus made automatic in operation.

CONCENTRATOR.

No. 544,828. George M. Reed, Waltham, Mass. *Patented Aug. 20th, 1895.* Fig. 2 is a vertical section taken lengthways of the machine; and Fig. 3 is a cross section on the line y y of Fig. 2. The crushed ore is fed into the hopper 26, and and falls on the coarse screen 22. The coarsest lumps which fail to pass through, work off the end of the screen and into the chute 34. The material which passes through is broken up and divided by means of a series of upright pins 21, which project from the bottom of the jig box 5. An adjustable gate 27 extends across the box, and is raised



slightly to permit the fine stuff to pass under, onto the second screen 40. The stuff which passes through this screen, falls into the hopper 51, and is fed slowly onto the fine screen 72. This screen is made of very fine wire and is strengthened by a second piece of wire cloth of larger mesh, and the stuff is retarded upon the screen by the riffles 76. This screen, and the jig box 5 are hung on swing links and, are vibrated by means of pitmen which connect to cranks on the shaft 14. The final separation is performed by an air blast, which is generated by the fan wheel 67. The fine concentrates pass down the incline 56 into the pan 58.

The Colliery Engineer

AND

METAL MINER.

VOL. XVI.—NO. 6. SCRANTON, PA., JANUARY, 1896. WITH WHICH IS COMBINED THE MINING HERALD

Written for THE COLLIERY ENGINEER AND METAL MINER.

PROSPECTING FOR PLACER GOLD.

A NOVEL AND GIGANTIC SCHEME IN CLEAR CREEK CANYON, COLORADO.

Showing how Gold is Obtained on a Large Scale from Gold Bearing Gravels under Favorable Conditions.

(By Prof. Arthur Lakes, Golden, Colo.)

[CONCLUDED FROM NOVEMBER, 1895.]

In the November issue we gave a full description of the plant of the Roscoe placer up to date. Fig. 1, which we herewith present, shows a view of the last and biggest undercurrent which was omitted from that article for want of space. On a recent visit we find yet some more improvements. A derrick planted on the bank worked a small steam engine to hoist the enormous boulders out of the pit by placing them on a truck, on an inclined plane, which is also hoisted up to a level by a wire rope from the engine passing over a wheel at the head of the inclined plane. The miners had just reached bed rock and imbedded in it the box to catch the debris blown down by the great nozzles (See Fig. 2.) This box is sunk into bed rock forming a receiving trough, as shown in the sketch. There the water is forced up through the Ludlum water elevator; and the sand, rocks and gold are driven up through the Ludlum gravel elevator with its funnel like pipe by a small giant imbedded in bed rock a few feet below the end of the elevator. The elevators as seen in the sketch are supplied with water power force by pipes let down at a steep angle from the main pipe on the bank.

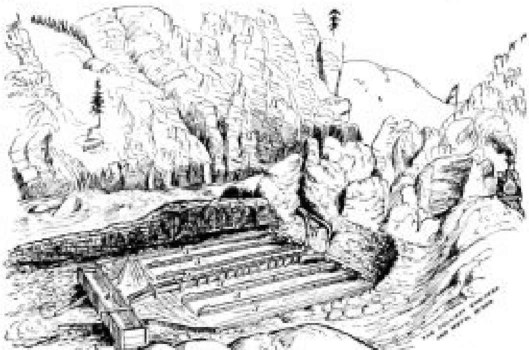


FIG. 1. LAST AND BIGGEST UNDERCURRENT SLUICE.

1, FLUME FROM UPPER UNDERCURRENT; 2, FLUME CARRYING COARSE MATTER; 3, BOXES LINED WITH BURLAP.

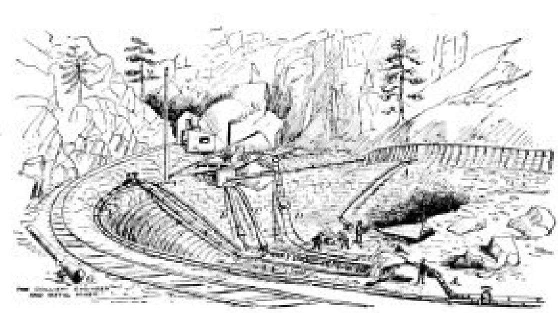

FIG. 2. LATEST VIEW OF ROSCOE PLACER.

A, A, GIANTS; *B*, LUDLUM'S GRAVEL ELEVATOR; *C*, WATER ELEVATOR; *D*, STONES HOISTED UP TRAMWAY BY STEAM ENGINE *E*; *F*, BOX OR TROUGH TO GUIDE MATERIAL TO ELEVATORS; *G*, AN ELEVATOR PIPE.

The Roscoe placer and other placers in Colorado will soon have to go into winter quarters and cease work for the winter till next spring, owing to ice forming on the streams.

Passing up the stream from the Roscoe placer we see numerous small parties engaged in placer mining on a small scale, some with the rocker or cradle and long-tom and small sluices as shown in Figs. 3 and 4.

The "rocker" is a box forty inches long, sixteen inches on the bottom, one foot high, with sides sloped like a cradle, and rockers at middle and back end. The upper end is a hopper twenty inches square with half-inch diameter holes. The top hopper is removable. Under the perforated plate is a light frame, placed on an incline, upon which a canvas apron is stretched, forming a riffle. In washing with a rocker, the material is thrown into the hopper, water poured on with a dipper held in one hand while with the other the cradle is kept rocking. The water washes the sand and dirt through the bottom of the hopper, and gold or amalgam is either caught in an apron or picked up in the bottom of the rocker, while the sand and lighter material are discharged at the end, and the coarse material in the hopper is thrown aside. In California, rockers were used before ditches came into use; now they are used in cleaning up placer claims and quartz mills, for collecting finely-subdivided particles of amalgam and quicksilver.

The "log tom," or "tom," was imported from Georgia. It was first used in Nevada County in 1849. It is a rough trough twelve feet long, fifteen inches to twenty inches wide at top, thirty inches at the lower end, and eight inches deep. It is supported on timbers or stones and set on an incline of twelve inches, or one inch per foot. A sheet-iron plate, perforated with holes half an inch in diameter, forms the bottom of the lower end of the trough, which is beveled on the lower side so as to have the plate on a level. Material, when fed in from sluices, on striking the riddle or perforated plate, is at once sorted, fine dirt, with water, passing through it, while coarser stuff is shoveled off. Under the perforated plate is a flat box, set on an incline, into which finer gravel passes. By continual discharge of water through the plate, and occasional aid the of shovel, the sand is kept loose, allowing gold to settle. The "tom" disappeared with the arrival of sluices.

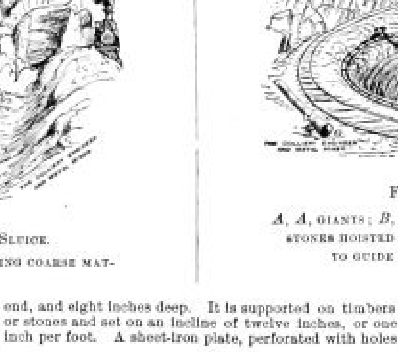

FIG. 3.—ROCKING GOLD.

1, BOX LINED WITH PERFORATED COPPER SHEET; 2, BOX LINED WITH WOODEN SLAT RIFFLES; 3, ROCKERS.

The "puddling box" is a box six feet square, eighteen inches deep, arranged with plugs for discharging contents. The box is filled with water and clayey dirt containing gold. By stirring with a rake the clay is dissolved in water and run off. Concentrated material collected in the bottom is washed later in a pan or rocker. In Australia it was much used and worked by horse power in 1860.

The "pan" is pressed from a single piece of Russia sheet iron twelve inches diameter at bottom, fifteen inches at top, with sides inclining outward at an angle of 30°, turned over a wire around the edge to strengthen it. It is used in prospecting, cleaning gold-bearings and collecting amalgam in sluices. Washing requires practiced skill. The pan is filled with dirt and submerged in a tub or pool of water. Gravel is worked with the hands till all cement is disintegrated. Coarse stones are cleaned and thrown out. In washing the residue, the pan is held in a tilted position. By a circular motion and careful use of water, into which the pan is continually dipped, all lighter dirt is worked to the top and over the edge. Pebbles are picked out by hand till only fine gold and black iron sand reman.

The "batea" is a shallow wooden bowl, commonly used in Brazil and Spanish American States for separating, on a limited scale, grains of gold from sand, pyrites and magnetic iron or black sand. A disc of seventeen inches diameter being turned conical 12° will have a depth of one and seven-eighth inches from center to surface; thickness five-eighth inch. Outer edge, perpendicular to axis, requires wood two and a half inches thick for construction; mahogany is used.

Derricks with a mast 100 feet high and boom ninety-two feet, set in cast-iron box placed on sills are used to remove large boulders. The mast is held in position by six guys of one inch galvanized iron wire rope; it has a whip block with three-quarter inch steel rope for hoisting tackle. A twelve-foot diameter hurdy-gurdy wheel is attached, using thirty inches of water under 275 feet head. This derrick will lift stones eleven tons weight. The guys are held by double capstans. Instead of the hurdy-gurdy, at the Alma placer, South Park, a Pelton wheel ten feet in diameter, is used for working the derrick.

Just above Roscoe we found a party of four prospectors sluicing in the decomposed outcrop of a gold bearing quartz vein they had discovered about 100 feet above the river bed. This vein consisted of soft greenish schist, traversed both longitudinally and crossways by small veins of quartz and feldspar. (See Fig. 5.) They had constructed a small wooden sluice, or flume,

FIG. 4.—SLUICE ON A SMALL SCALE, NEAR ROSCOE.

F, VEIN.

about 30 feet long and a foot wide lined at the bottom for the first 10 feet with little wooden riffles or strips of wood an inch apart. The rest of the bottom of the flume lined with tin was full of holes like a colander and the last foot or two was lined with carpet or woollen stuff. They had found a spring about a quarter of a mile up in the mountain and had procured an old used up fireman's hose which they had patched up with rags and canvas to bring the water down to their excavation; at the end of this hose was a tin nozzle about 1 inch diameter. Through this the water was squirted onto the rotten vein and the material washed down into the sluice, the gold as the water and gravel passed over the sluice dropping into the riffles. The greatest amount of gold was usually caught in the first few riffles, what escaped them was caught in the perforated tin bottom and what escaped that in the burlap or carpet. In this way they cleaned up quite a fair amount of gold daily, averaging from 10 to 15 dollars per man. In their clean up they would come across black sand, garnets, and flakes of galena together with the gold. The gold was usually in little flat, somewhat oval flakes. This small scale of mining looked like a diminutive caricature of the huge undertaking going on at Roscoe in the stream below. Doubtless it was from such veins as this that the Roscoe placer derived some of its gold.

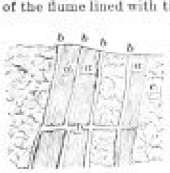

FIG. 5.—GOLD VEIN. a, a, a, DECOMPOSED GREENISH HORNBLENDE SCHIST; b, b, b, b, THIN VEINS OF QUARTZ; c, c, COARSE FELDSPAR AND QUARTZ.

Electricity in Powder Mills.

"The appetite comes while eating" say the French, and that the same principle may be truly applied to the use of the electric motor is emphasized by certain experience which the General Electric Company has recently had with the Aetna Powder Company, of Aetna, Ind.

In November, 1894, this powder company decided to install two small slow speed generators for operating incandescent lamps on the Edison three wire system. As these could not be delivered immediately, two second hand machines were installed temporarily, and before the first two new ones ordered could be delivered, the order was changed to two larger moderate speed generators, with the privilege of changing them for two still larger ones. In June, 1895, the last two were ordered together with two motors, one of one horse power, the other of five horse power. On August 2nd, the Aetna Company ordered another motor of 5 H. P. and on August 14th, still another of the same capacity. The company having enlarged its plant during the summer found its electrical installation insufficient and on October 12th, ordered two 45 Kilowatt moderate speed generators, and two moderate speed motors, one of 20 H. P. the other of 30 H. P. Thus within one year electricity had given the powder company such satisfaction that it now has 66 H. P. in motors and 93 incandescent lamps taking current from the two 45 Kilowatt generators. The one H. P. and the five H. P. motors are used to drive small mixing machines in the manufacture of dynamite. The 30 H. P. motor operates a large machine used for pulverizing nitrate of soda and the 20 H. P. runs a number of machines such as the dry pan and mixing machines. The Powder Company found that the first 5 H. P. motor, which they substituted for a steam engine, readily performed a duty with which the engine found difficulty in doing.

The recent gradual increase in the use of electric power in powder mills is especially noteworthy. During the past year the General Electric Company has equipped several with electric motors and present indications point to the speedy complete elimination of the steam engine from the operation of machinery in and about powder manufacturing establishments.

Written for THE COLLIERY ENGINEER AND METAL MINER.

THE LOOP CREEK, WEST VIRGINIA, COAL FIELD.

Its History, Nature of the Coal, How Mined, Its Analyses, Physical Features.

By Daniel W. Langdon, Ph. D., F. G. S. A.

In 1871, immediately following the labor troubles in Pennsylvania, and upon the completion of the Chesapeake & Ohio Railroad to the Ohio River, Jos. L. Beury, an old anthracite miner, opened the Quinnimont Mine on New River. With the commencement of this operation was marked a new era in steam making, and while these coals are now well-known throughout this country and even in Europe, there may be some hitherto uncollected details of interest to the readers of THE COLLIERY ENGINEER AND METAL MINER.

The coal thus first opened, was in general physical appearance the same as the well-known George's Creek or Cumberland Coal, and not unlike it in chemical composition. It is soft, much broken in mining, so that 80% will pass through a 4″ bar screen and 50% through a 1″ bar screen. This physical character has given rise to much prejudice wherever the coal has been taken into new markets and frequently causes its rejection.

At present this coal is mined in only three districts, two of which, the Pocahontas tapped by the Norfolk and Western Railroad, and the New River tributary to the Chesapeake & Ohio Railroad are already well known, while the Loop Creek, an intermediate district, is of such recent development that it has only within the past few months become a factor.

Upper Loop Creek, known locally as Loop or Dun Loup Creek, is an affluent of New River into which it debouches opposite Thurmond Station some sixteen miles from its sources, having flowed approximately along the strike of the rocks or *N N E*. The drainage is in Fayette and Raleigh Counties, West Virginia. Early in 1893, the Chesapeake & Ohio Railway began the construction of a branch line to develop this region, and in February the following year completed the roadway to Macdonald, the present terminus, ten miles from Thurmond.

The Loop Creek mines are all located in the uppermost or Sewell seam of I. C. White's Quinnimont series, which according to Mr. David White of U. S. Geological Survey (*Bull. Geol. Soc. of America Vol. 6, pp. 305-310.*) is the probable southern extension of the measures under the Pottsville Conglomerate. C. R. Boyd (*Trans. Am. Inst. M. E., Vol. XXIV, p. 255.*) states this series and that at Pocahontas to be identical though in this more northern region the big Pocahontas seam has thinned down below workable size.

A detailed section of the seam shows:

SECTION OF SEWELL SEAM, LOOP CREEK DISTRICT.

1. Sandstone.	
2. Gray slate, very brittle	0-20 ft.
a. Hard coal	12″–33″
b. Soft bright coal	10″–12″
c. Hard coal having columnar structure	24″–39″
d. Soft bright coal	12″–15″
Hard slate floor.	

Wherever the slate (1) becomes less than 12″ thick and the roof is of sandstone, a is very pyritous and unmarketable the vitiating mineral occurring in thin laminae parellel with the plane of stratification. At all times this division of the seam is the most impure of the series, being more or less slatey, though when not too high in sulphur content, it is marketable.

The coal is remarkably pure as the analysis made by Dr. Frœhling of Richmond, Virginia shows:

Hygroscopic moisture	0.52
Fixed carbon	75.80
Volatile matter	21.80
Ash	1.80
Total	100.00
Sulphur	0.37

Coke made from this coal is as yet new to the market and may be said to be in the experimental stage. An average sample of 48 hour coke shows:

Volatile matter	1.10
Fixed carbon	94.78
Ash	4.12
Total	100.00
Sulphur	0.58

This coke was made from 1,000 tons of screenings through a 1½″ "straight away" screen by a prospective contractor and is a reliable sample, not selected, and therefore misleading, as is too frequently the case with published analyses.

The conditions for mining are almost ideal. The average dip of the seam is 4% in the direction of the railway, so that loaded cars come out of the headings by gravity, and the empties are hauled back and distributed by mules. The height of the seam, seldom less than five feet and usually six feet, gives good room for working, permitting the use of good heavy mules. The pillar and stall system of mining is used in connection with a modification of double entry development. The main entries are sixteen feet wide, to permit double tracking, and cross entries on alternate 300 feet centers, ten feet wide, neither requiring timbering as a general practice. The rooms are 24 feet wide and pillars are 29 feet through except next to the main entry where they are 50 feet. The coal is all undercut, there being a soft streak about fifteen inches thick at the bottom while a similar streak near the top permits the use of an ordinary breast auger in preparing for the shots. FFF black powder is used, a keg lasting a careful miner a month. As the mines are all above water level there are no serious problems of ventilation to be solved. In general practice an occasional cross heading is run through the outcrop to the surface and currents resulting from natural draught furnish sufficient air for the men. In some cases a modified Brazil fan is used with satifactory results. The mines are not as yet at all "fiery" and are damp enough to obviate any danger of explosions from accumulations of coal dust.

The miners are paid for a standard car of 72 cubic feet 55 cents in rooms and 70 cents in entries with no allowance for yardage, being required to clean up all slate within fifteen yards of the face and to set all props, the companies laying and maintaining track and hauling props into the rooms on request of the miners.

The track has a guage of 44″, custom differing considerably as to the weight of the rail, though experience seems to show that 40 lb. steel rail in the main entry and 20 lb. rail in the cross headings are necessary to carry the loaded bank cars having a dead weight of nearly 4 tons. In the rooms the track is usually of 3″x4″ oak rail in 14-feet lengths, laid flat on the hard slate floors, the floor being notched to receive the cross-ties spaced about six feet apart.

Each of the six companies maintains a store for the sale of general merchandise in which the prices are somewhat less than those charged by neighboring country merchants. The men are paid off once a month.

The mining population of the district is about 75% whites and 25% negroes the latter being employed mainly as drivers and outside laborers. Of the whites fully 80% are native Americans the remainder being Englishmen with a small admixture of Hungarians.

Men of fair skill and average experience can load six cars a day in rooms and five cars in entries, though instances of seven cars a day per man in entries are not unusual, twenty days being counted a months run because of "car famines" and unwillingness of the miners to do much work after pay day.

The coal finds its market in New England and in the West, taking the place formerly held by anthracite and coming within the "smokeless" provisions of municipal ordinance. It is valued for steam making where continued high pressure is demanded as in electric railways, large manufacturing plants and steam heating. From this district it is shipped almost exclusively without being screened though, through mistaken prejudice, demands are being made for lump while the so-called "slack" is the purest, *i. e.*, freest from ash and sulphur, part of the seam. The following table shows the value compared with anthracite as determined by the Bureau of Steam Engineering, U. S. Navy:

		Rate of Combustion.	New River.	Anthracite.
Rate of Combustion per hour per square foot of grate surface.	Pounds of Crude Coal	Slow,	7.9896	7.7935
		Medium,	13.0534	10.5798
		Maximum.	14.3664	12.9531
	Pounds of Gasifiable Portion of Coal	Slow,	7.4859	6.611
		Medium,	12.2496	8.978
		Maximum.	13.4517	10.992
	Pounds of Water Vaporized per Pound Crude Coal.	Slow,	10.9795	9.9933
		Medium,	10.2023	9.1943
		Maximum.	10.1286	9.9923
	Pounds of Steam Produced per Hour.	Slow,	2636.96	2335.36
		Medium,	3984.14	3171.50
		Maximum.	4369.67	2882.96
	Per cent. of Refuse Ash, Clinker, and Soot.	Slow,	6.367	15.1492
		Medium,	6.367	15.1492
		Maximum.	6.367	15.1492

At the present time there are six companies in active operation and several developing leases. None of the companies owns its own property, all operating under leases at a uniform royalty of ten cents a ton. The following is a list of the companies operating, with their capacities:

	Daily Capacity.	Coke Ovens.	P. O. Adress.
Harvey Coal & Coke Co.	750 tons.	100	Bisset, W. Va.
Collins Colliery Co.	1000 tons.	125	Glenaeau, W. Va.
Star Coal & Coke Co.	250 tons.	....	Glenaeau, W. Va.
Dunn Loup Coal & Coke Co.	600 tons.	....	Dunn Loup, W. Va.
Turkey Knob Coal Co.	600 tons.	....	Macdonald, W. Va.
Macdonald Colliery Co.	500 tons.	....	Macdonald, W. Va.

Worth Having.

Messrs. Frazer & Chalmers of Chicago and London, have recently issued a new catalogue entitled "Gold and Silver Mills." It is a handsomely illustrated volume of 180 pages descriptive of gold and silver milling machinery built in their shops, (they rank as the leading builders in the world), and also contains a few pages of "Useful Information" which ensures that the catalogue will be saved for future reference by every practical gold or silver mining man receiving one. It is sent free, on application, to any owner or official of a gold or silver mine, or to any person contemplating engaging in mining and treating gold or silver ores. A request on a postal card directed to Messrs. Frazer & Chalmers, Chicago, Ill., will secure a copy.

Fatal Accident to a Fire-boss.

Mr. Alex. Howieson, of Delancey, Pa., was instantly killed on the morning of the 10th ult., whilst in discharge of his duties as fire-boss, by a fall of rock in the mines. Mr. Howieson was an exemplary man and stood high in the estimation of his associates and neighbors. He was a member of the Knights of Pythias, and Knights of the Golden Eagle, both of which societies adopted appropriate resolutions on his death.

Written for THE COLLIERY ENGINEER AND METAL MINER.

GOLD AND SILVER MINING.

TIMBERING FOR PRECIOUS METAL MINES IN COLORADO.

The Methods of Working and Conditions Which Influence the Methods of Timbering.

By Francis T. Freeland, B. S., C. S. S., A. S. M. E., A. I. M. E.; Gen'l Mgr. Aspen Contact Mg. Co., Lenado; Durant Mg. Co., Aspen; Isabella Gold Mg. Co., Cripple Creek, Colo., etc., etc.

(CONCLUDED.)

Plate IV, Fig. 8 shows a simple set designed by the writer for the Stevens shaft, Leadville, without side posts. Plate V, Fig. 11 shows the framing of the Penrose shaft, Leadville, through which some 1,800 gallons were pumped a minute. There is a full set of side posts, the dividers are not keyed, but can readily be so designed. The lagging is placed flush by means of 2 by 4 inch strips spiked to the set. In sinking, the new set is swung from the last one by the hangers shown, the posts set up, all drawn snug by the nuts, and then spreading by a chain, or better by having long guide shoes on the cage.

A convenient way of opening a station was used by the writer in the 16th station of the three compartment New Con. shaft of the Durant mine, Aspen. See Plate VIII, Figs. 17, 18. The shaft is 5 by 16 feet and this station was not intended for pumping. On arriving at the floor of a new station, four hitch timbers are wedged under the last set, crosswise of the shaft and clear of the compartments. The shaft is then continued a short distance for a sump as before. The width of the station is such as to cover two hoisting compartments with the jamb chamfered off to afford access to the pumpway.

A three post cap and sill set is placed against the shaft timbers and secured by long bolts and treenails into the dividers. The portions of the wall plate lying between the shaft and the station, opposite the hoisting compartments and breast high in the station, are then sawed out. This method of starting the station is better than having special shaft timbers opposite the station, as they delay the sinking and open too much ground. The station may be continued as far as required and then tapered down to a drift of the usual size.

The station may be covered with ¼ inch steel plates provided with irons to guide the cars on the rails. But I in reaching the rock. However the open caisson, or the pneumatic method to 80 or 100 feet may be used in quicksand without large boulders requiring blasting. The Poetsch freezing system for several hundred feet may be used in quicksand or quicksand with boulders. The Kind-Chaudron method of drilling the full size of the shaft in rock leaving the water in the shaft and following with a metal tubbing is applicable to rock giving a large flow of water. These methods are usually prohibited by their cost and have not been used in Colorado.

The open caisson method of sinking has been used in California drift mining, see Mills; and the shield method in Illinois coal mining, see Rice, with a moderate cost. I believe it possible to use the shield method or perhaps the open caisson method of sinking from a shaft started in the ordinary way in depth on going from hard ground into a quicksand. For instance in such ground as the dolomite sand or contact matter of Leadville where there is a heavy flow of water. But the ground must be drained sooner or later and then the difficulty vanishes. The great danger consists in removing the material running from behind the timbers, when rushes occur destroying the alignment of the shaft timbers and crushing them.

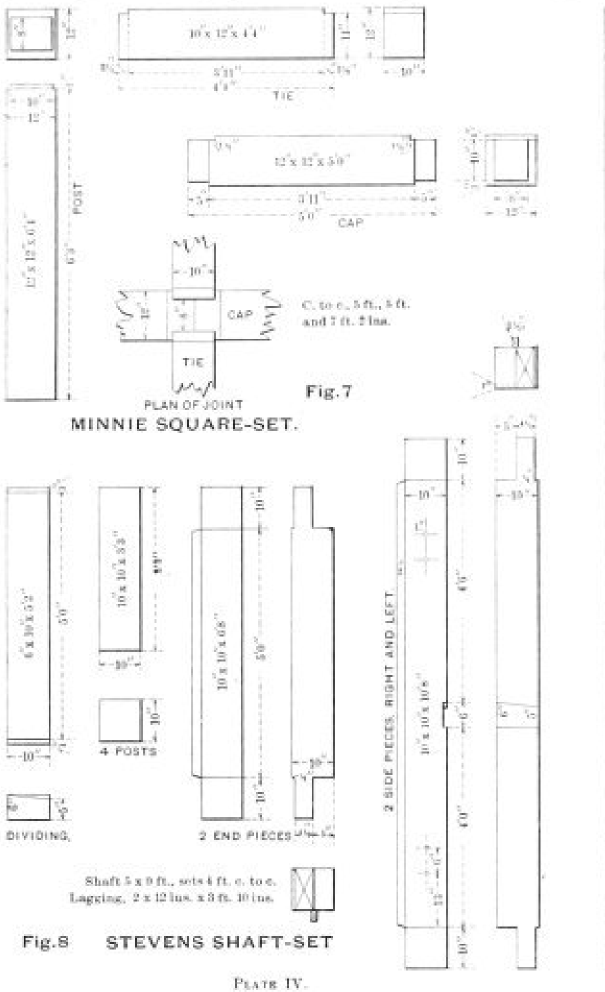

PLATE IV.
Scale [illegible]

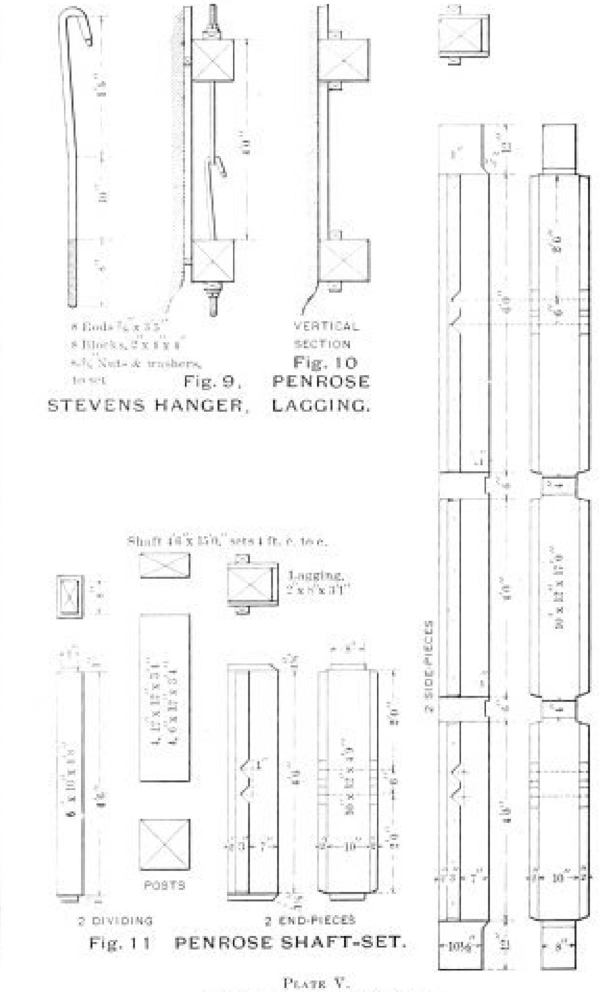

PLATE V.
Scale [illegible], except hook bolt, which is [illegible]

plumbed, blocked and wedged. With this design the dividers can be temporarily left out of the bottom set for convenience in handling the long side pieces and inserted from below. With the former design no hangers are needed on the end pieces. The lagging is set close.

The shaft is plumbed by three or four lines hung in the corners a few inches from the timbers and covering several sets. It is checked from time to time by lines or annealed brass wires with heavy weights steadied in water or oil, extending from the surface or for several levels. The wire may be kept on reels with cranks for winding up. The guides must be accurately set or reset by a template in case the timbers vary much or are crushing.

The Smuggler mine, Aspen, uses for a reserve a water-box running in the guides holding 1,000 gallons, as a relief to the pumps. Four disk valves in the bottom afford ingress to the water. Two of them are covered by a spout and these two are opened wide at the top by a bell-crank lever and rods rubbing on a slide. The spout directs the water clear of the shaft. With such an arrangement water may be hoisted very rapidly and economically.

The shaft may be sunk with a bucket or a bucket hanging under the cage, or with a car on the cage, the cage being run to the bottom on short guides held from prefer the track to be continued to the shaft and a complete siding laid down for standing cars. For a large tonnage it will be convenient to have a tracked bye-pass around the shaft. Then keeping the full cars on one side will permit a quick change. This should be done at the surface at any rate. A fork will then lead to either cage. Spring switches can be arranged to move automatically directing the cars in the proper course. Such a plan is used at the El Paso shaft, Leadville, and also a switch that can be set ahead of the car when running, by the foot to run into the ore-house or to the dump.

In bad ground spiling and perhaps bottom boards may be used with sets. Where little ground can be opened at once, 2 by 12 inch plank may be used cribbed solid, laid flat and breaking joints at the corners. They are inserted one at a time and spiked up from below. The partitions are made of timbers skin to skin, in this case.

A way of starting a shaft I have used with success at the Stevens shaft is to bed a double cross of heavy flatted timber into the original surface of the ground, just outside of the shaft. Then four or more heavy rough posts are erected to a suitable height on this foundation and lagged to carry the collar and gallows frame. The sinking will then proceed without interruption from the surface work.

There is usually little difficulty in this sort of mining

In continually swelling ground sets may be eased by cutting out the lagging or by prying off the strips shown and the removing sufficient ground to relieve the pressure. This work seriously delays the hoisting. On the Comstock a false set has been placed outside the shaft leaving 19 inches clear space. By having chutes down to the next lower level, the easing can proceed without delaying the regular work of the shaft.

A few vertical automatic skip roads have been used in Colorado, but they were not satisfactory and have been abandoned. The handling of timbers and men have a greater relative importance in precious metal mining, especially of the high grade ores, than in other kinds of mining.

INCLINES.

Many shafts in Gilpin, Co., and Cripple Creek are sunk on the vein, and where steep are worked with a bucket on a slide. The California shaft near Nevadaville is 2,300 feet. It is the deepest shaft in the state and is an irregularly inclined bucket shaft. Where the walls are good the shaft may be stulled but if scaly it must be provided with wall-plates or sets and lagging.

The Silver Cord incline, Leadville, 1,400 feet long at 25 degrees pitch was worked by hoisting 6 ordinary mine cars in a train on their own wheels. The main incline, Iron Silver mine, Leadville, 1,100 feet long at 14 degrees hoisted 4 mine cars on 2 gigs running on a 3 feet gauge. These inclines had no separate manway on account of their flatness and were about 6 by 7 feet in the clear.

The McKeon incline, Iron Silver mine, Leadville, sunk by the writer is 750 feet deep at 50 degrees pitch. It was worked with an automatic skip holding about 2 tons of rock running on a 3 feet gauge. The crosscuts and stations came away over the incline and each contained two bins in the acute angle for ore and waste. The skip was loaded from chutes in the incline. At the top there were two bins also provided with a flip-flap door for directing the discharge from the skip. Ordinary cars ran from these bins to the ore-house and dump. The incline was setted with round posts and heavy cap and a flat sill. The hoistway was about 5 by 5 feet and the manway 2½ by 5 feet. The divider was 6″ by 8″ and four braces were used. The manway was partitioned off and fitted with steps. Partitions are necessary in inclines of more than 25 degrees.

The Isabella Incline, Cripple Creek, sunk by the writer, 400 feet at 50 degrees is worked with an automatic skip holding 20 cu. ft. on a 3 feet gauge. The incline and levels are on the vein. The stations are formed by bowing the level out over the incline. The cars to be taken off at each level without interfering with the manway. The Johnson incline above the tunnel has a skip which dumps automatically on reaching the bottom, as the rock is lowered in this case.

There are several important inclines at Creede, the one on the United Mines having three compartments. The incline on the Gregory-Bobtail, Central City, owing to peculiar conditions was on a curve and hoisted 64 cu. ft. cars. These cars where divided in two transversely, being hinged at the top edge and secured at the bottom edge by latches. When dumping they had the appearance of being back-broken. The dirt went between the rails.

The alignment of a gentle incline is similar to a drift, but steep inclines require great care. Four adjustments are necessary and they are best made on the sill. For line a sawcut is made across each sill say 6 inches from one end, before being sent underground. Two hubs are set in the sills on this line by an instrument within 50 feet of the face, and this line is produced by a cord. The new sill is then set by the sawcut and a grade stick, one mud brace being in place. In addition it must be made square with the line and level lengthwise on the corner edge.

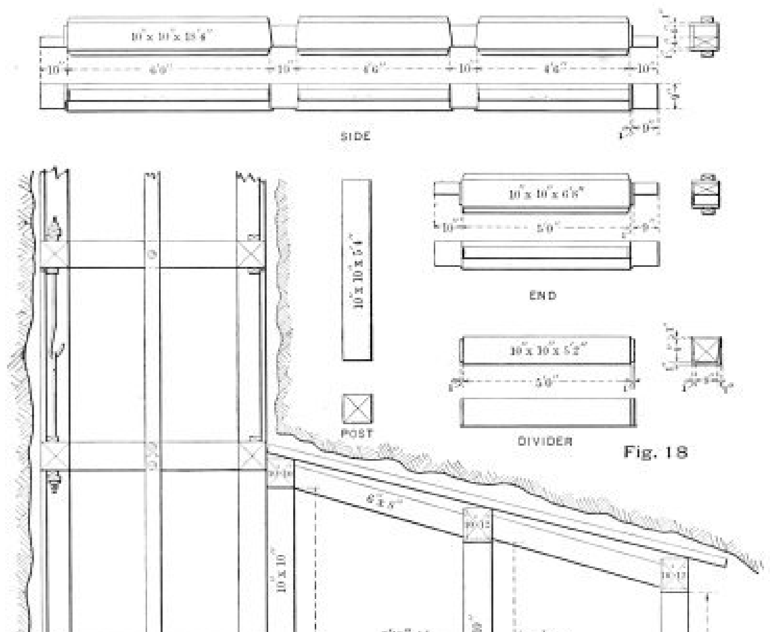

PLATE VIII.
Scale ⅝″ = 1 foot.

mine cars dump directly into the skip through a swinging hopper and at the top the skip dumps into cars. The incline is stulled. See Plate IX, Figs. *a*, *b* and *c*. The hoistway is 5 by 5 feet and the manway 3 by 5 feet with partition, steps and hand-rails. The total excavation is 5 by 11 feet. Cross-sills 4″ by 8″ are spiked against the foot of the stulls and the track is laid on stringers, with guide planks and side planks to prevent derailment. A ¼ inch wire bell rope runs in side pulleys within reach from the skip. A 1¼ inch iron pipe speaking tube is fitted with a T at each level. It is also used to prevent the skip being rung away when in use by rapping on the pipe. The incline is sunk for a new lift without timbering, with a temporary track in the middle and then dressed and timbered from the bottom up. For hoisting water, the skip is furnished with two flap valves, which are replaced by a dead plate when hoisting rock. When hoisting water a hopper on wheels at the collar directs the water into settling tanks. See Freeland, Isabella Incline, *Mg. & Sci. Press*, June 22, 1895.

The Della S. and Alta-Argent inclines from Cowenhoven tunnel, Aspen, designed by D. W. Brunton, Mgr. are about 56 degrees pitch and 6 by 10 feet on edge, the the manway and pumpway being above the hoistway which is 5 by 6 feet. The tunnel cars described above are hoisted on an inclined cage. This plan enables the

STOPES.

The timbering of the stopes of precious metal mines as ordinarily practiced depends principally upon the size, shape and inclination of the ore-bodies, and the firmness of the country rock, for these conditions determine the method of mining. For the present purpose ore-bodies may be grouped as to shape into three classes; 1st. A flat or gently inclined continuous or interrupted sheet of moderate thickness; 2nd. The same vertical or pitching strongly; and 3rd. Masses, pipes, and great local thickening in a sheet. Sometimes all these varieties may be seen in one mine.

FIRST.—FLAT THIN DEPOSITS.

Ore-bodies of this sort are often seen in the so-called contact mines of Leadville, Red Cliff and Rico and in deposits following lines of stratification. They are worked to the rise if possible.

Where the ore is continuous it will be worked by a system resembling long-wall in coal mining, either advancing or retreating. Where the ore is interrupted the method will resemble pillar and room, the pillars being irregularly placed and consisting of poor ore or waste rock left in place. Where the roof is firm no timbering at all may be required, or at most an occasional prop under a threatening rock. If timber is used some of the posts may be drawn if the stope is to be abandoned.

With a tender roof, posts and head boards will be used for a height up to about 8 feet. With a heavy roof or for a local thickening up to about 16 feet cribs will be used from 7 to 16 feet square. Filling with waste will steady them. They will have runways between and may be lagged from crib to crib. When filled they generally fail by bursting near the bottom.

Where the roof is bad, but the deposit nearly plane and of a fairly uniform thickness, the ore may be won by a succession of parallel contiguous drifts, timbered with drift sets, consisting of posts and lagged caps, each post carrying the ends of two caps, and steadied by collar braces to the last set. This plan admits of considerable irregularity. The waste coming from underground ore-sorting in the stope is filled back, if there be room for it. It is advisable to fill exhausted stopes in bad ground to prevent extensive movement in the country rock which may bring weight upon or wreck neighboring stopes, main levels or constructions on the surface. In bad ground the timbers are lost.

SECOND.—STEEP THIN DEPOSITS.

Ore-bodies of this shape are commonly found in fissure veins, dykes or on the edge of dykes, as in Gilpin or Clear Creek counties and in Rico and Cripple Creek, and sometimes in steep contacts and deposits following pitching stratification planes, as in Aspen. They may be worked underhand or overhand.

In underhand stoping a winze through the stope and connecting with the next lower level is advisable, as it does away with the windlassing and assists in ventilating and draining the workings. Underhand stoping may be resorted to before the level below is driven in case of necessity. It is not, however, economical nor systematic mining and is one method of "gouging the eyes out of the mine." It makes easier drilling and may be useful in a country like Mexico, where the natives rarely become expert at drilling "uppers." Where the ore is narrow and rich it may be adopted in small mines, as the ore can then be readily kept from the waste filling of the stope. The floor may be swept with steel wire brushes.

If the walls be good and the waste removed, or if the vein is of a width requiring the breaking of neither of the walls, the stope may be worked without timber. But if the waste be stored in the stope as made, more timber is required than in the other method. The ground is broken from the top of the winze each way in benches of about 6 feet, like two sets of stairs.

Overhand stoping is the more generally used, as it is the faster and cheaper. The ore, waste and water fall away from the breast. In a narrow vein giving considerable waste, the stope may be filled to within 5 or 6 feet of the top, as made, giving a convenient footing for the miners, the excess, if any, being sent out. To collect the ore, canvas is laid on the waste and protected by rough plank. In narrow veins stulled millholes about 3 feet wide are run up at intervals of about 25 feet to afford access and for throwing down ore and the excess of waste. The end breast or raise stopes are provided with ladders. The main line of stulls is placed 11 feet above the track. Under each millhole is a plat with loose cross boards over the car track, laid upon three horizontal spreaders 6 feet above the track, to keep the ore off the main road and to afford a loading chute. In a vein wider than 4 feet the millholes will be cribbed. They may have two compartments, one for a ladder way. About 3 feet square is sufficient, and they may then be climbed without a ladder by straddling the hole.

When the vein makes but little waste, the opening must be stulled to afford a platform for the miners. Where the walls are good many of the timbers may be recovered when the stope is abandoned. It is then filled with waste from the level above. Where the roof is bad the stulls will carry wall plates and lagging on one or both walls, with braces as required.

When the vein is moderately wide with good walls and makes but little waste, the broken ore may lie in the stope, only enough being drawn off to keep the top about 6 feet from the breast. This plan requires no mill holes, for when the stope is finished the ore remaining is all drawn off. The flat chutes and the main line of stulls is the only timbering required.

Where the vein is of moderate width and is soft or has a soft gouge in it, that will be taken out first in order to have some open space to shoot to, using a gouger if the soft streak is narrow. Where the vein is harder than the walls and especially if it be "frozen" on one or both walls, the softer wall will be shot first and then the ore stripped from the remaining wall by pop shots. Where they are of nearly equal hardness it will be best to shoot the ore first if it be big enough to get a proper shot into and then take out enough of the footwall for convenience of working. But if the vein is very narrow and rich and adheres strongly to the footwall, the hanging wall may be broken first and then the ore stripped.

THIRD.—MASSES.

Ore bodies of large and irregular dimensions occur frequently in a limestone formation, such as Leadville and Aspen, and in enlargements in fissure veins and contacts. Where they reach the surface open-cut work is resorted to without timbering, as deep as the walls will stand, or until the cost of removing the overburden is prohibitory in a flat deposit. It is possible that in exceptional cases the caving or filling systems used with success in the Lake Superior iron mines might be employed.

Having regard to the peculiar conditions here the square set system is the only one of general application. Precious metal ore masses are extremely irregular and the prices obtained for the ores vary from year to year. It is often necessary after stopping work at a certain place to resume it. New discoveries in the neighborhood may alter the probabilities of ore in any given

-direction. The ground may be reworked to some extent with square sets, if not caved, while with other methods the ground must be abandoned as mined.

SQUARE SETS.

The origin of the system is a simple and natural extension and refinement of the practice of running contiguous parallel drifts in the ore and in two or more stories when the thickness of the ore required it. The first step in the way of improvement was the obvious one of making the two butting caps rest upon the same post, and to make the collar braces of equal strength to that of the other members. The regular use of such sets and their framing on the surface to standard dimensions appears to have been first introduced on the Comstock lode by Phillip Diedesheimer, Superintendent of the Ophir mine in 1860.

The sets may be so framed that the posts, caps, or ties run through and touch, the continuous longitudinal grain of the timber being laid in the direction of the greatest pressure. In very heavy ground this is important, but in most cases it is sufficient and more convenient to let the caps run through. The pieces touching on end grain are cut a trifle scant to equalize the pressure. The caps are set the narrow way of the ore body. The sill floor set is usually one foot higher than the regular set. Where the posts run through, a special lead or cap sill must be used in starting a run of sets, but where the caps run through it is not always necessary.

Where the sill floor is laid upon a large body of ore, which is to be mined from the next lower level, sills covering several sets should be used. No matter what care be taken in starting the next lower nest of sets, it is not likely that they will exactly join. Long sills render less difficult and dangerous the work of taking up the weight as the two nests connect. In coming up from below the posts of the top row of the lower nest are cut so as to leave a space of about 2 feet between the two nests. Long heavy stringers are laid on the lower nest to break joints and the intersections of the upper nest caught up one at a time with blocks and wedges.

Where the walls are bad, plates should be used covering several sets and joined by special pieces to the regular sets. With a good roof it is sufficient to securely block the sets at each intersection in the same way as at the sides of the stope.

Where oblique pressure is expected or develops, plain diagonals with a double chamfer at each end must be fitted and wedged in the sets already in position, which may be inclined to cant. Two diagonals placed like an A will permit a single post to be removed in order to gently divert a car track running through the stope. Where the posts show a tendency to cut into the caps, they may be assisted by two or four helpers or false posts ½ the size of the main post and placed around it.

The sets usually fail by crushing and racking so that the caps slip off the posts. To prevent this, solid cribs of timber in a row of two or more sets wide are placed in the sets crosswise of the ore body from wall to wall.

Another crib may be built further on and the space filled with waste. Cribs are also important under the main workings.

The whole floor of a large ore body must not be opened at once as too much weight is brought on the timbers. It is safer to take out vertical slices crosswise of the ore body from level to level and three or four sets thick in succession. In very large bodies pillars may be left which can be robbed as the mine is gradually abandoned. But if sufficient weight comes upon the pillars to crush and splinter them, serious trouble will be encountered on taking them out afterward.

The system is designed for working overhand although with care a small pothole may be worked underhand and timbered. With a rolling bottom, short posts on foot pieces may be used sparingly instead of shooting enough waste to hold a complete set. A run of cells may be readily lined for a chute. In starting a nest it is not well to work in opposite directions at the same time as the shots may shift the timbers.

After a nest of sets has crushed and caved, it may be necessary to open the ground again. There will usually be a heap of loose shifting rock and timber in the bottom of the old stope and a large open space above having a shaky roof. About the only thing to be done is to fill and level off a floor and cover it with a mattress or solid filled crib of timber to serve as a foundation for sets or open cribs. In other cases the hole may be filled and mined around by spiling and cribbing from raises in the neighboring solid rock, or similar special methods suggested by the particular circumstances and the relative location of the spot it is desired to reach.

The timbers may be snubbed down from the level above through a winze or taken up with a windlass or small hoist. On abandoning a stope most of the flooring is taken up leaving enough to enable an inspection to be made. If no further prospecting is intended from the stope, it may be filled with waste from above to prevent extensive movement of the ground. In exceptional cases the sets may be robbed.

Of available timber red spruce is more durable than yellow pine, and that, than white spruce. The sets are framed by machinery. Englebach of Leadville makes a four saw machine which uses square timber. The Hendey framer an eight saw machine is made by the Denver Engineering Works. Round posts can be cut on the latter giving additional support to the caps and ties.

In starting the system in a mine some thought should be given to the style and dimensions, as it is inconvenient to change the patterns when once adopted. The height should be about 6 feet in the clear allowing for the flooring of 3 or 4 inch plank, and the width from 4 to 5 feet. The usual sizes of timber are 10 and 12 inch according to the probable size of the stope and the character of the walls. One small mine uses 8-inch sets. Larger sizes will be used in special cases. The 10-inch timber is to be preferred for economy and ease of handling if the ground will permit.

DETAILS OF SQUARE SETS.

Plate II., Fig. 4, shows the square set used by the Moyer and other mines of the Iron Silver Company of Leadville, which has shipped 125,000 tons in a year. The tenons on the posts touch and the ties are plain. The lower tenon is short to prevent much accumulation of dirt in the built up mortice. The flooring is 6″ x 8″ x 5′ 0″. The diagonal braces are 10″ x 10″. Centres to centres are 5, 6 and 7 ft.

Plate III, Fig. a, shows the set used by the Aspen, Durant, Regent and Smuggler mines at Aspen, shipping about 75,000 tons a year. The posts touch and may be round or square. The cap sill is used on the sill floor for a single row of sets, and the lead sill for further extensions sidewise.

Plate VI, Fig. 8 shows the set largely used at the Mollie Gibson mine at Aspen. The caps touch, the caps and posts are entirely symmetrical and the tie also, in but two directions however.

The set used by the Little Johnny mine of the Ibex company, Leadville, shipping about 75,000 tons a year is of 10 inch timber, except the tie. It is 4′ 4″ cap way by 4′ 10″ by 6′ 10″ centers, and 3′ 6″, 4 feet and 6 feet in the clear. The caps touch and the framing resembles that of the Mollie shown already. The posts are 6′ 4″ over all with 6 by 6 by 2 inch tenons. The ties are plain 6 by 10 inch timber and 4′ 4″ long. The caps are 4′ 4″ over all with 6 by 6 by 3 inch tenons. These sets are also used for drifts.

The set used at the El Paso mine of the Union Leasing company at Leadville, shipping about 25,000 tons a year is also of 10 inch timber except the tie. It is 5′ 4″ by 5′ 4″ by 7′ 4″ centers and 4′ 6″ by 4′ 6″ by 6′ 6″ in the clear. The caps touch and the framing is like the Johnny. The posts are 6′ 8″ over all with 8 by 8 by 1 inch tenons. The caps are 5′ 4″ over all with 8 by 8 by 4 inch tenons. The ties are plain of 8 by 10 inch timber and 4′ 8″ long. If full sized ties are deemed necessary they are to be notched at the corners like those of the Mollie.

PLATE IX.

These last three styles possess many advantages and can be recommended. They may be readily designed for 12 inch timber or larger and for round posts. It is not necessary that they should be cut from sawed timber without waste as large amounts of blocking and wedges are used. The wedges are 3 by 4 by 14 inches.

LADDERS AND STEPS.

Vertical ladders may be permitted in a pumpway for occasional use and for a limited height. In general they should be set at least 10 degrees from the perpendicular. 12 inches wide in the clear is enough for the rung but the manway must be at least 24 inches wide, better 30 inches to allow for the play of the shoulders in climbing. The platform holes should be 24 inches in the clear from the face of the ladder and the road itself about 30 inches. Ladders will be used with inclinations over 60 degrees. The distance of the rungs or slats is 12 inches for inclined ladders and short stretches. Steep ladders have spaces of 11 inches, and for vertical ladders or long stretches 10 inches for the minimum. Plate VI, Fig. c shows a cheap and serviceable ladder for general use.

It is more convenient to use steps and hand rails in inclines for pitches less than 60 degrees. From 60 to 45 degrees the tread should be six inches and the slope distance between 11 and 12 inches. The width of the step in the clear should be 13 to 14 inches. 6 feet vertical headroom should be allowed.

Plate VI, Fig. d shows a flight of loose steps designed for the Aspen square set. It consists of 9 steps, just reaching from floor to floor by resting on the caps or ties, either with or without the flooring.

With pitches from 45 to 20 degrees the ancient carpenter's rule applies, twice the rise plus the tread equals 24 all in inches. Below 20 degrees nothing is required although sometimes a plank walk with cleats at equivalent intervals is used.

Uniformity in the ladders and steps both in interval and arrangement in the shafts and inclines will prevent accidents and increase the speed and ease of travel.

The general treatises and pocket-books on mining rarely give much space to the details of the dimensions and use of the various styles of timbering. The several excellent text-books on tunnelling give the special methods demanded by the larger work.

Many valuable papers bearing on this subject may be found in the Transactions of the American Institute of Mining Engineers and in the publications of other engineering societies.

TWO SOUTHERN MINE DISASTERS.

One at Cumnock, N. C., Results in the Death of Thirty-five men, and the Other at Dayton, Tenn., Kills Thirty Men.

An explosion, supposedly of fire-damp, at the Old Egypt Mine at Cumnock, N. C., on the 19th ult. resulted in the death of thirty-five men. The mine is an old one, having been first opened about fifty years ago. It was only worked a short time, and was then abandoned, till, during the civil war it was worked by the Confederate Government to secure coal for blockade runners.

A few months ago it was bought by the present owners, who have spent a great deal of money in re-opening and improving the property. The opening out of the mine proved that the coal improved in quality as the workings extended further into the bed.

The mine was inspected by the fire-boss at six o'clock, was reported free of gas, and sixty-six men went down the pit. At eight o'clock the mine was again reported free of gas. A few minutes after eight o'clock, an explosion occured that killed all of the men in one of the two divisions of the mine, and two who were in the other division. Those not killed, thirty-one in number groped their way to the shaft in the dark, and were speedily hoisted to the surface. The shaft was not injured.

At first it was supposed that 250 lbs. of dynamite, stored in a closet in the mine, had exploded, but examination proved that such was not the case, as the dynamite was found all right.

As usual there are numerous rumors as to the cause of the accidents. One rumor states that a man was slightly burned by an explosion of gas the night before, and that there was gas found on the morning of the accident, and that each man was instructed to "brush" the gas out of his working place. If there was enough standing gas in the working places to warrant the men being instructed to "brush" it out, somebody is morally responsible for the death of the victims. The removal of gas by "brushing" is wisely prohibited by both mine laws of Pennsylvania, and it should be prohibited in every state. If there actually was no gas found by the fire-boss, when he made his examination, the disaster was either caused by a sudden outburst of gas, or by an explosion of coal dust. What the cause actually was will be hard to determine as all the men in the affected portion of the mine were killed.

The disaster at Dayton, Tenn., occured in the Nelson Mine, operated by the Dayton Coal & Iron Co., on the morning of the 20th ult. It resulted in the death of thirty men. The telegraphic reports of this accident are so conflicting and contain so many inconsistent statements, evidently by men devoid of any mining knowledge, that we refrain at this writing, from trying to sift out a probable cause for the accident.

Acknowledgement.

We have received from the Jos. Dixon Crucible Co. of Jersey City, a box of assorted Dixon American Pencils, with the compliments of the season. If there is any class of men who appreciate good smooth pencils, it is editors, and on account of the uniform good quality of Dixon pencils, we use no other kind for editorial work. Our force of draughtsmen also use Dixon drawing pencils in preference to any other make. In fact, among the ninety people in the offices of The Colliery Engineer Co., no other brand of lead pencils is used for any purpose.

The Westinghouse Electric Co.

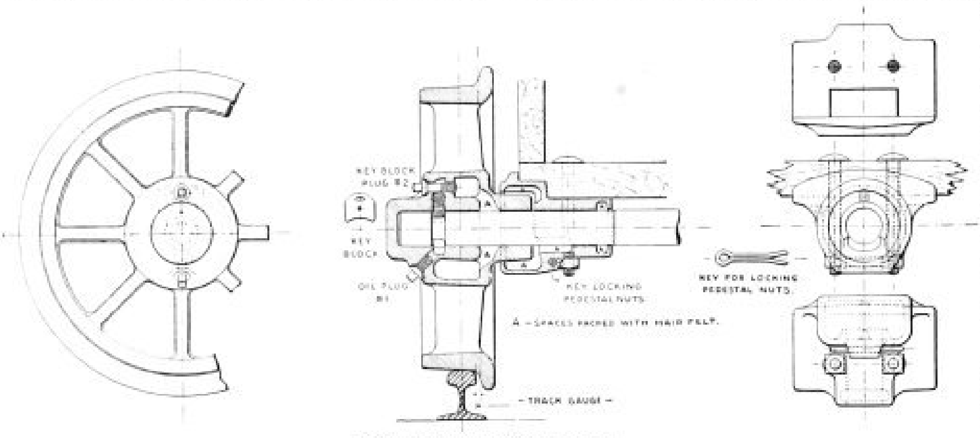
The Westinghouse Electric and Manufacturing Co. of Pittsburgh, Pa., the sole owners of the valuable Tesla patents, have decided to make a vigorous fight for the mining trade in electrical machinery. To speak of Westinghouse electrical appliances as first class, is superfluous. Their success is known to all mine managers. The advertisement that appears, for the first time, in this issue, is evidence that the company is prepared to furnish first class mining machinery that will compete in every way with any now on the market.

THE FAUGHT PATENT WHEEL FOR MINE CARS.

A New Self-Oiling Wheel that is Worthy the Attention of Mine Managers.

During a recent visit to the extensive and well known car wheel works of Messrs. A. Whitney & Sons of Phila., we were shown the drawings of an improved self-oiling mine car wheel, which seemed to contain many valuable features. We therefore made arrangements with Messrs. Whitney & Sons to illustrate and describe the wheel. For many years this firm has made a special study of the requirements of mine railways. An experience of nearly 50 years in the manufacture of chilled car wheels for all varieties of service peculiarly fits them for such study. It is their belief that true economy in this service demands the best material and workmanship and also that to insure the highest efficiency and durability, patterns carefully designed on scientific principles must be used.

Under this belief they have introduced a self-oiling wheel which has many points of the highest excellence. The wheel, in combination with its pedestal and other fixtures is the invention of Mr. Luther R. Faught, their mechanical engineer, and its construction, in its latest improved form is illustrated herewith.



FAUGHT PATENT MINE CAR WHEEL.

The wheels are cast with the outer hub solidly enclosing the end of the axle. The inner hub enters a dust collar in the pedestal casting lined with a broad band of hair felt, which serves to exclude all dust and grit from the wearing parts, and prevents leakage of oil. With their standard wheel a round axle is used which can turn in the pedestal when on curves. This diminishes friction and equalizes the wear on the axle. At the inner end of the pedestal there is a smaller band of felt acting as a further protection against dust and leakage. Sufficient oil flows along the axle into the pedestal to lubricate the axle bearing.

The wheel is held on the axle by the "key block" socketed in the wheel and entering a groove turned near the end of the axle. The key block is retained in position by the horizontal "key block plug." By removing this plug and revolving the wheel so that the hole is down, the block drops away from the groove allowing the wheel to be pulled off. The wheel is replaced by reversing this operation, first placing the key block in its socket in the wheel, by the aid of a pointed stick inserted in the hole in the key block.

Oil is introduced into the annular chamber in the hub through the oil hole entering the wheel at an angle. This hole is closed by the "oil plug." Both plugs are provided with leather washers so that when screwed into place, the holes are closed *air tight*. The leakage of oil is thus to a great extent prevented by *atmospheric pressure* and any slight flow being *outward* only, the chances for dust working into the wearing parts are greatly diminished.

Should the oil plug, however, be accidently left out, the main body of oil will be retained in the cavity for a long time, as no oil can run out of the oil hole without first rising to a level with the lower side of the axle.

To meet an objection which is sometimes raised to the loss of time in oiling, from the necessity of removing and replacing the oil plug, a new device has been recently made experimentally. This consists of a "self closing oil plug" so constructed that on inserting the spout of an oil can or syringe into the oil hole, a valve controlled by a spring is pushed inward allowing the oil to enter, and on withdrawing the spout the valve again closes the opening.

Thorough lubrication of the entire length of bearing is ensured by two openings connecting the rear end of the oil cavity with the bore of wheel. It has sometimes been found that when wheels run at a high rate of speed for a considerable time, the bearings have a tendency to run dry because the oil, by centrifugal force, is thrown toward the outer walls of the oil cavity. To obviate any trouble of this kind, strips of felt packing are inserted in the two above mentioned openings, their object being to act as wicks to draw the oil into contact with the bearing surfaces.

The length of bearing of the wheel on its axle is very much more than usual with loose wheels. The position of the hub relative to the tread is such as to bring its centre directly over the rail. This obviates the tendency of a short hub to "cant" on the axle, with the consequent cutting of both wheel and axle. These two features in connection with close and accurate fitting greatly prolong the life of both wheels and axles. The long bearing, however, is not obtained by lengthening the axle or diminishing the width of car bottom, but as the usual lynch pin is dispensed with, the additional total length of axle it requires is all available for bearing surface. As an actual fact there is a saving in the total length of axle, a pair of these wheels measuring less from out to out than those fitted with lynch pins in the ordinary manner.

The pedestal castings are so constructed as to do away with the collar usually welded on mine car axles. A split key on the lower side locks the nuts of the pedestal bolts so that they cannot become loose from jarring. In cases where the regular form of pedestal is not adapted to the construction of car bottom, special pedestals can be made to suit all requirements.

Though the use of round axles is recommended, where it is desired to have the support of the car bottom which a square axle affords, this form can be used.

In the manufacture of these wheels, the very best car wheel irons are used under chemical and physical tests, in the firm's own laboratory and shops. The material is the same as used in their heavy wheels for freight and passenger cars which must stand the severe inspection and tests required by the principal railroad companies. All wheels are thoroughly annealed in furnaces especially constructed for the purpose. Carefully proportioned patterns are used, adapted for each diameter of axle and for the service intended. Fitting is done by standard gauges, all parts being interchangeable and both material and workmanship are guaranteed against defects.

Not only are the treads and flanges well chilled to resist hard wear on the rails, but the spokes and hubs are very strong and tough to stand the most severe shocks in rough service. These two most important qualities are supplemented and made fully effective by the efficiency of the oiling arrangement and the protection of wearing parts. The result is a wheel perfect in all its parts and which will give the longest possible service, no one part wearing out before the rest.

From the above description it appears that Messrs. A. Whitney & Sons are using every known means to produce the most durable, efficient and economical mine car wheels possible. Nearly 30,000 of the closed hub wheels have been put in use under most severe conditions in all parts of the country and they invariably maintain the points of excellence claimed by the makers. One large user in the far West, after holding for a year a supply of *extra* wheels ordered "to replace any that might be broken or worn out," ordered sufficient new axles to utilize these wheels, stating that "as none had broken or worn out and showed no sign of doing so, they had concluded not to hold the wheels any longer for repairs." This appears to be the experience of most users as but few *extra* wheels are ordered.

Another writes that after most severe service for a year he "examined the axles and the hub, and found no wearing of the surfaces in either place and the tread was as good, not worn in the least, as the day they were first run out. Had I not seen the wheels I should not have thought it possible in our mines that anything could stand so long." Still another points with pride to the sleek condition of his mules who, he says, are growing fat as a result of the easy running of the Faught wheels.

Some of the various types of Whitney wheels have been, and are in use in practically all the mining fields on this continent, and they are everywhere held as the standard in quality. Hundreds of letters from mine managers attest their appreciation of Whitney wheels. The following is a recent one, expressing an opinion of the Faught Patent Closed Wheels. The wheels referred to by Mr. Phillips are not exactly the same as the wheel we illustrate. The latter is a further improvement on the kind Mr. Phillips purchased:

CENTRAL JELLICO COAL COMPANY.

Pleasant View, Whitley Co., Ky., Dec. 9, 1895.

MESSRS. A. WHITNEY & SONS,
Philadelphia Pa.

DEAR SIRS:—In reply to yours of recent date, we bought of you, something over two years ago, (June 1893) enough wheels and axles of the Faught Patent Closed Hub Self Oiling for forty mine cars. They have been in constant service ever since and are apparently just as good as when first bought. We have several long and heavy grades which call for a great deal of spragging, this, of course, makes it very hard on the face or tread of wheels, but I have found these wheels in no shape, whatever, worn. Also the round axles being able to turn when necessary saves them from wearing and bending, always lubricating themselves and hub of wheels, so there seems to be no cutting on either axles or hubs. We find it takes less than half the amount of lubricating oils to keep them in good running order, which is quite an item to us. Also we have no trouble with broken lynch pins in your wheels which causes us much trouble with most other makes. We are using several other makes of wheels and axles but find the A. Whitney & Sons much superior to all others which we have tried.

We will be ordering several sets of your wheels and axles this coming Spring and Summer to replace other makes which have worn out and been of little service to us.

Yours respectfully,
THE CENTRAL JELLICO COAL CO.,
Per John Phillips, Supt.

DRY STEAM.

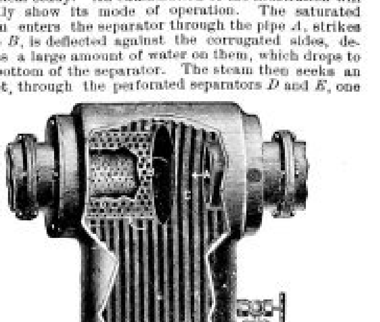
Its Necessity and How to Ensure It.

The length of steam pipe lines at mines is generally such as to materially reduce the efficiency of the power, and often to cause breakages due to the use of saturated steam in engines and pumps. The covering of steam pipe lines with a good steam pipe covering naturally reduces condensation greatly, and enhances the value and safety of the power, but such covering does not *entirely* remedy the evils of condensation. No reputable maker of pipe covering will make such a claim.

There is but one way to entirely remedy the evil, and that is to prevent condensation as much as possible by the use of a good covering and then complete the work by using a first class separator. When the line is a short one, and steam is plentiful the separator alone will do the work, but best results are obtained in most instances by the use of both covering and separators.

Reputable makers of steam separators will endorse this statement, and the practical experience of many large steam users has demonstrated the fact.

There are many types of separators on the market of more or less value, and it is important that our readers should be informed as to the existance of one that is extremely simple in construction, and very efficient in operation. It is known as Robertson's Steam Separator, and it combines every necessary feature in such a device without those objections so noticeable in most others. This separator is the outgrowth of years of experiments and practical study. An examination of the illustration will readily show its mode of operation. The saturated steam enters the separator through the pipe *A*, strikes plate *B*, is deflected against the corrugated sides, deposits a large amount of water on them, which drops to the bottom of the separator. The steam then seeks an outlet, through the perforated separators *D* and *E*, one within the other, is again broken up, deposits what little moisture remains in it, and passes on to the cylinder perfectly dry, and does the most efficient work in a perfectly safe manner. The water taken from the steam is drawn off through the valve at the bottom, the necessity for this operation being made apparent by the water column. This separator is manufactured only by the Hine and Robertson Co., 48 Cortlandt St., New York. It is not an expensive contrivance, and is worthy the attention of all mine managers using steam power.



ROBERTSON'S STEAM SEPARATOR.

H. E. Collins & Co., Pittsburgh, Pa., sole sales agents for the Cahall Vertical Water Tube Boiler, manufactured by the Aultman & Taylor Machinery Co., Mansfield, Ohio, report the following recent sales of Cahall boilers: Douglas Furnaces, Sharpsville, Pa., second order, 250 H. P.; Mahoning Valley Iron Co., Youngstown, Ohio, third order, 300 H. P.; Michigan Alkali Co., Wyandotte, Mich., third order, 250 H. P.; Shoenberger Steel Co., Pittsburgh, seventh order, 500 H. P.; Traders Paper Co., Lockport, N. Y., 500 H. P.; McKinnon, Dash & Hardware Co., Troy, Ohio, 100 H. P. The boilers for the Douglas Furnaces and the Shoenberger Steel Co., are for blast furnace gas,—those for the Mahoning Valley Iron Co., are for the utilization of waste heats from heating furnaces, while the others above mentioned are of the standard direct fired type.

THE CAUSE OF MINE EXPLOSIONS.

EFFECTS PRODUCED BY THE SUDDEN COMPRESSION OF THE AIR IN MINES.

Description of Unusual Explosions in Coal Mines. With Conclusions Reached After Thorough Examinations and Study of the Conditions Existing Subsequent to the Explosions.

(James Ashworth, M. E., in *The Colliery Guardian.*)

On the 18th of July of the present year a most unusual accident occurred at the South Mine of the Broken Hill, South Australia, by which at least nine men lost their lives. Mr. J. B. Giuyas, the general manager of the mine, thus describes the occurrence:—

We had indications yesterday at about noon, that the ground in the north sulphide stopes at the No. 4 level was affected. I gave instructions to the underground foreman to warn the men of the fact. This was done at the time of the accident, and they were fully 200 ft. from where the creep took place. No doubt they were loitering and talking, feeling perfectly secure,as I would have done had I been there—in fact I would not have been afraid to have stood within 20 ft. of the break. The only explanation I can offer as to the cause of the accident is that our ore is full of gas, which is held in the crevices, and I think that when the break came it forced the air through the tunnel like a man putting a ram-rod into a pop-gun. Had the men desired they could easily have reached the mouth of the shaft, but they very reasonably felt safe where they were. As it transpired, a safer place for the men would have been the No. 1 cross-cut, where there is a deep winze, but they never thought of that. When the creep took place it forced the air, which being charged so heavily with gas was like a solid body, along the only outlet—namely, the level—and the men who were gathered there were knocked over with terrible force and killed. It is marvellous how one man—John Treloar—escaped, as he was one of the nearest to the creep. Possibly he got behind a post, and thus escaped the current of air. I have never in my experience of mining heard of such a disaster. Of course in coal mines firedamp sometimes causes the death of large numbers of men, and I have known a dam of water to break through and drown men engaged in the workings, but the death of men in a silver mine through concussion of air is something phenomenal. The South Mine has been singularly free from fatal accidents, only two men having previously met their death in it. Richard Mortimer, who was in the hospital, says that he was standing near the plat in the mine when he was suddenly lifted off his feet and instantly lost consciousness. A youth who was engaged near the mouth of the shaft at the No. 4 level pumping air up to the men working in the stopes, had a narrow escape. When the creep took place the air came along the cross-cut to the shaft with such force that it took him off his feet, and he fell with his feet dangling down the shaft. At the inquest the evidence showed that the men received ample warning, but remained in the level chatting and smoking, and one man who escaped injury deposed that they were all about 300 ft. from the stope when they heard a sound like a peal of thunder, followed by a rushing noise. Being an old coal miner, he fell flat on his face and thus escaped death.

LLANERCH COLLIERY EXPLOSION.

No information is afforded as to what kind of gas is referred to by Mr. Giuyas, but it cannot have been explosive nor yet poisonous, as no mention is made of any gas by those who escaped, and the effects may therefore be considered as entirely mechanical and resulting from the creep and fall.

If, then, such excessive violence can be exerted by a sudden compression of the ventilating current and without the assistance of explosives or inflammable gas, it becomes quite clear that if the ventilating current of any mine is suddenly and violently compressed, we shall on reference to the published details and plans of explosions in coal mines be able to identify some of the indications which are due to compression, and also possibly revise some of our notions as to how these accidents become so widespread and so fatal to life.

One of the first conclusions that we are forced to perceive and to adopt is that no fall of roof can take place until after the compression stage, excepting only where gas is exploded by the flame of the initiatory explosion.

The falls of roof, excepting only those caused by direct violence, must then be due to the sudden expansion of the gas or air which has been compressed into the crevices and vacancies above the roadways and which will endeavor to find an exit in an equally sudden manner as soon as the condensation and vacuum stage commences.

In the Llanerch accident the compressive effect was very noticeable in all the narrow headings on the lower side and ends of the levels,where nearly all the men lost their lives in their working places,whereas those on the higher side having the elasticity of a larger area of reserve air to protect them, were, with very few exceptions, enabled to run some considerable distance outbye before succumbing to the after-damp. Compression in this case was entirely due to the accidental ignition of a small pocket of fire-damp which had collected in a hole above some new timbering in No. 4 level. The extent and completeness of the accident is very astonishing when it is observed that all the workmen used candles only, and therefore explosive conditions could not have been present in the ventilating air-current. And supposing that a quantity of gas had been continuously escaping from No. 4 level, this would have been entirely nullified by the large volume of carbonic acid gas created by the candles and the breathing of men and animals, and therefore there could not have been explosive conditions present in the ventilating air-current.

In the Camerton and Timsbury accidents the conditions were so very much alike in both cases, as far as regards ventilation, humidity of the air, dust, the explosive used and its mode of application, that the more recent explosion at Timsbury will be cited as setting forth the influence of air-compression in a mine quite free from fire-damp.

In the evening of the 6th of February last, seven men were engaged in making road repairs on the through road between the Upper and the Lower Conygre pits, and on the roads in the Top Little vein, which joined the through road at a point about half-way between Upper and Lower Conygre. About half-way between this

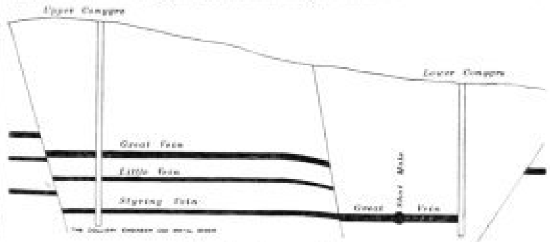


FIG. 2. CONYGRE PITS.

junction and the Lower Conygre pits, an experienced man named James Carter had to prepare and fire a shot to make more height for the horses. His instructions were to charge and fire a hole having a depth of only 13 in., which had been drilled in the roof some years previously. John Gage, an examiner, who lost his life, was to examine the place before Carter charged the hole, and doubtless did so. Carter was warned by G. Flower not to use the clay out of the road for tamping, because it was saturated with oil which had dropped from the trams and contained coaldust, and also because when he used a similar mixture at Camerton twenty years before, it filled the heading with flame. Whether Carter observed these instructions cannot be stated with accuracy, but when his body was found he had two lumps of this oily clay with him. The road was neither dry nor dusty, because on the 29th of January 200 to 300 yards of it had been watered preparatory to firing two shots on the 30th of January and two others on the 2nd of February. All of these shots were within 30 to 50 yards of the shot fired by Carter. The current of air passing along this road at the time of the accident was estimated to have been about 10,000 ft. per minute, with a velocity of 6 ft. per second. The shot-hole had a diameter of 1¼ in., and about 5 in. of its length was believed to have been filled with gunpowder and 8 in. with tamping. About nine o'clock two men who were at work near the West pit at Lower Conygre noticed smoke, and also a brattice door move, and proceeded to ascertain its origin, but as they could not get further than 40 yards along the through road, they returned to the pit, where they were met by the undermanager and bailiff, who had been warned that something was wrong by the engineman at Upper Conygre, who had heard a noise and had also seen smoke thick with dust coming from the top of the pit. Carter's body was found in a kneeling position in a manhole about 80 yards on the in-bye side of where he had fired the shot, and it is interesting to note that the man who fired the fatal shot at Camerton was also found in a similar position, and in both cases the men were severely burned.

DAMAGE BY CARTER'S SHOT.

On the out-bye side of Carter's shot very little damage was done, and even the ventilation doors near the pit were uninjured, but inbye there were heavy falls on the road, the doors and trams were all blown towards the Upper Conygre pits, near which four horses were killed and their hair singed, and two men were also killed and burned. One of these who was near the Upper Conygre

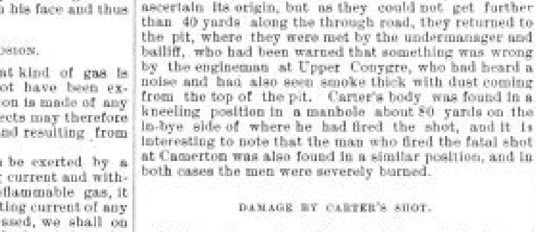

FIG. 1. LLANERCH COLLIERY.

downcast had a leg broken, and his clothes torn off and carried fifteen yards away.

About half way along the through road the intake air was led round through the Top Little vein workings and brought back again into the through road, about 40 yards further inbye, the separation of the two air-currents being affected by a pair of wooden doors placed in the through road. It is quite clear that the highly-heated gases from the after effects of Carter's shot could not freely expand and escape by reason of these doors and of the trams which were standing close by in the siding at the top of Peter's incline, and therefore whilst sufficient energy was being generated to force these doors a distance of fifteen yards, the whole power of this great air compression fell on the Top Little vein workings with the result that all the doors in the gate roads were driven inwards for distances varying from 15 to 30 yards, four men were killed instantly (three of them being severely burned), and small patches of coaldust were found in three places only. With respect to the question of burning, Mr. Martin, the inspector of mines, says that the indications of flame were few, and only noticeable in the places already referred to. After the doors in the through road gave way, the free expansion of the explosive force was further opposed by the devious character of the road, the small diameter of the shafts, and by the cages in the shafts. These cages must have been lifted up the shafts some distance, and then when falling back and brought to a sudden standstill by the ropes caused such a jar as to break several teeth out of the cogwheels of the winding engine and thus render it useless.

THE CAUSE OF THE EXPLOSION.

As the originating cause of the accident was undoubtedly the shot fired by Carter, it remains to be discovered why the effects were so widespread and fatal, when blasting had been carried on in the mine without any particular precautions for a generation and without disaster.

One of the first queries which suggested itself to the writer was in respect to the quality of the powder, particularly as the same make of powder was in use at the Camerton Colliery at the time of the explosion there on the 13th of November, 1893. It has, however, been proved by actual analysis that this powder was of much better quality than the miners' blasting powder which is ordinarily used in coal mines; it was, in fact, a loose powder, of the size of rifle grain, and had the following composition, viz.:

Nitrate of potassium	72.3
Sulphur	11.3
Charcoal	15.3
Moisture	0.9
	100.0

For this anaylsis, and also that of the oily clay to be referred to later on, the writer is indebted to the courtesy of the consulting engineer of the Timsbury Collieries, Mr. John Batey, C. E.

The heat produced by the explosion of ordinary miners' blasting powder, when confined, is about 2,225 degs. Cent., and that of Government rifle grain—which in composition more nearly approaches the powder in question—3,340 degs. Cent. As part of the heat created by the combustion of the gunpowder used by Carter would be expended in breaking down the small piece of rock which was detached from the roof by the shot, it may be assumed, as was done by the analyst, that the heat of the gases set free was about 2,200 degs. Cent. and that the volume of these gases was 21,700 cubic inches.

CARTER STEMMED WITH OILY CLAY.

Carter is suspected of having used the oily clay, two lumps of which were found near his body after the explosion, for tamping his shot, and therefore this was also analysed, and it was found that when it was heated up to 500 degs. Cent., in a closed vessel, and measured at 0 deg. Cent., and 760 mm. barometer, it evolved 100 times its own volume of gas, and that this gas consisted of an inflammable mixture H, CO, CH_4, and CO_2, ethylene, and vapors of some of the heavier hydrocarbons. This oily clay was so inflammable that it was easily ignited by a match when produced at the inquest. Thus we find that we have very highly heated gases from fired gunpowder projected into the intake air in the same direction as that of the air-current, and therefore exerting the very large unused force of the powder to push that current along at a very highly increased velocity. At this point it is to be noted that the combustion of powder is not an instantaneous action, and therefore so soon as sufficient force has been developed to overcome the line of least resistance, the rest of the charge completes its combustion outside the shot-hole, and therefore in the mine atmosphere. The agitation of the air-current caused by this action would, as a matter of course, disturb any fine dust within reach of its flame and vibrations, and particularly that which had been unknowingly collecting for many years in a hollow place above the roof timbers, only 8 yards from the shot. This dust would at once become mixed up with the inflamed gases from the powder, as well as with those distilled by the heat from the oily clay of the tamping, and likewise of the roadway also, and the whole of this mixture would become the basis of another explosion. Doubtless this large volume of explosive material was ignited either directly by the residual heat of the powder charge, or from this heat inflaming the oily clay and some powder which would doubtless be spilled in charging the shot-hole.

THE INTENSITY OF THE SECOND EXPLOSION.

The intensity of this second explosion would be very great, because all the ingredient parts were gaseous excepting only the dust, and as a consequence of the resistance afforded by the force of the incoming air-current backed up by a door near the shaft, by the small diameter of the shafts and the winding cages, its force would be exerted on the line of least resistance, viz., the air-current passing inbye. These influences were further strengthened by the fact that this second explosion took place close to the foot of Peter's gug or incline which rising at a sharp angle, crossed a 70-fathom fault and offered a natural and upward course for the expanding and explosive gases, until they met with further resistance at the top of the incline, where the full and empty trams in the siding, the jig drum, and the pair of wooden doors beyond offered such a strong opposition that the accumulated pressure was driven still further uphill into the Top Little vein workings. This effect continued until the double doors gave way when the pressure at once commenced to decrease, and the pent-up and highly-heated products of combustion quickly found a vent by escaping like steam out of a safety valve at the Upper Conygre pit shafts.

By this description of the probable progress of the explosion and its after effects, it must be understood that the speed of the explosion from the moment of the second or incubatory explosion is calculated to travel at a speed nearly approaching to that of detonation, and that this speed is attained as a consequence of the high and sudden compression of the air-current created by the initial explosion or blown-out shot, which so compresses the air that it detonates the oxygen in the presence of nitrogen, coal-dust and watery vapor, and that consequently as soon as the compression stage is complete the explosive effects also cease.

That this explosion, and also that at Camerton, was not one of coaldust in the sense in which such explosions are popularly supposed to take place, is amply proved by the experiments made by Mr. Henry Hall, which showed that the coaldust from the seams of the Radstock coalfield could not be directly inflamed or exploded by the firing of gunpowder.

COAL DUST DOES NOT EXPLODE.

The next case to be quoted is that of the explosion at the Albion Colliery on the 23rd of June, 1894. Here the conditions were entirely different from those of the last case because Mr. Hall's experiments with gunpowder fired in the presence of coaldust from this mine had already proved that it was the most easily inflamed, and also the most explosive of all the coaldusts tested by him.

For the purpose of the present argument it will be assumed that the explosion originated at the point on Grover's level selected by Mr. Robson and the other inspectors of mines who reported on this accident, and that the originating cause was as they supposed it to be, viz., the flame from a gelatine-dynamite or gelignite cartridge fired either in the arm or in one of the legs of a setting of timber which was being taken out for the purpose of renewal. The heat developed by gelatine-dynamite is stated to be 3,220 degs. Cent., or 5,828 degs. Fahr., and of the products of detonation 46 per cent. to be again combustible and 54 per cent. incombustible; it is therefore clear that the explosive will produce a large volume of very hot flame. Whether the flame ignited both gas and dust above the timbering or only the dust on the floor of the roadway is not of much importance, as similar results might follow in either case. An accident which happened in North Staffordshire will show how easily certain coaldusts may be ignited. At the mine in question the men were driving a heading, and a shot hole was drilled in the ordinary way about 10 in. above the floor, 3 ft. 6 in. deep, about 2 in. in diameter, and charged with nearly a pound of blasting powder. The ventilating air-current was blowing straight onto the shot-hole, and was free from gas. The shot was fired by a squib, but after the contractor had lighted it he found that he had forgotten to take away the dust from the front of the hole and warning his mate, they covered themselves up as well as they could, but even then got a severe burning. Another man who was 50 yards away on the intake side was very badly burned, although he was dressed ready to go out of the pit. As this shot did its work very well, it is clear that the ignition of the dust was caused by the squib or by flame escaping through the squib hole.

If then a so small and comparatively cool flame, when compared with that of gelatine-dynamite, will ignite coaldust, it is not to be wondered at that an explosion such as that at the Albion Colliery should be originated in the way suggested by the inspectors. A space of about 90 yards on either side of the shot presented no indications of great violence, but within it was developed the great mechanical force and tremendous air pressure which constituted the principal factor in carrying destruction into every corner of the mine. There was, however, another factor which comes into the account, and which may have exercised an important place in the effects produced, and that was the firing of one out of five shots in some timber about 120 yards further inbye by the flame or by a detonating vibration from the first shot.

Within a radius of 165 to 275 yards inbye of the first shot the dismemberment and bodily injuries were extremely severe, and further inbye the scorching and coking effects in Nos. 1 and 2 districts were more evident than in any other part of the pit. Seeing that all the heavy coking effects were at or near the coal face and not on the main roadways where they might have been expected to be found in conjunction with the greatest dust and heat, it seems to be convincing proof that the effects where those due to the spontaneous combustion of coaldust in the presence of highly compressed oxygen and not actual flame. When we turn to other districts of the mine we find no coking indicated in No. 3 district, but one case of the scorching of timber in James' heading and one man with his limbs torn off at the junction of Serjeant's and Dudson's headings. This case is very remarkable when considered in conjunction with another case in No. 7 district, where a head and a foot were torn off. Both cases were at a distance of 76 chains from the shot on Grover's level, and both were in the immediate neighborhood of ventilating doors. It would appear, therefore, that when the ventilation doors gave way under the great air pressure, the sudden rush and expansion of air caused the mechanical effect which produced the mutilation.

In the working places furthest away from the pit in No. 4, and likewise in Nos. 6, 7 and 8 districts, coked dust was found on the timbers, but in No. 5 or Pant Ddu district no heat or coking effects were reported. Although nearly all the men were asphyxiated in this dip whilst endeavoring to escape, the horses left by these men in the workings were found alive and unhurt.

If this explosion had been one in which coaldust was the principal explosive agent, it would naturally follow that the afterdamp resulting from its incomplete combustion would contain a large percentage of carbon monoxide, but in this case there is no evidence to show the presence of any appreciable quantity of this very poisonous gas. Fortunately, through the very careful investigations and observations of Dr. J. Shaw Lyttle, of Cilfynydd, and his assistant, both of whom went down the pit to afford immediate relief to the unfortunate people, assisted also, a few days afterwards, by Dr. Haldane, of Oxford, who is well known from his investigations into the effects of CO and CO_2 on the human system, it is possible to throw some strong inferential light on the character of the explosion as well as on that of the afterdamp, and to show that these were primarily influenced by the great and sudden air compression exerted by the first stage of the disaster.

Commencing from the shot on Grover's level, the people for nearly 100 yards on either side of it were, as at Altofts, almost instantly killed although only slightly burned. Whether the cause of death was "shock," "excessive air pressure" or "asphyxiation" cannot be asserted with confidence, but the result in every case was almost instantaneous death.

Further inbye there was more burning and mutilation than nearer to the shot, but equally sudden death. Outbye near the junction of Dudson's heading with Grover's level, ten dead, and three living persons were found. Of these one died almost immediately, another was found badly burned and with both arms fast under his horse, and both fractured. With respect to the above cases D. Lyttle remarks that they showed no symptoms which could be put down to afterdamp. Coked dust and scorched timber were only found in the working-places at the extreme end of the level.

Exigences of space forbid the insertion of details showing the effect of the explosion on human life along the same line of fire in the Cilfynydd level. Evidence shows the erratic effects of the explosion from end to end of this almost straight line.

EFFECTS OF THE AFTERDAMP ON THE RESCUERS.

The effect of the air of the mine on the rescuers was in almost every case to make the eyes smart, to cause great thirst, and to very considerably affect the speech of everyone.

William Gamett who went down in the first cage described the burning smell as "sulphury" and the effect of the air was to make them faint, dizzy, and sleepy. The smell in the returns was described as being like matches and like flannel which had been burning, and had been put out again.

Dr. Lyttle's assistant was suprised to find that all the injured men from Grover's side seemed to lose consciousness and would not readily answer questions when taken out of the pit.

THE COMPOSITION OF THE AFTERDAMP.

It is possible from details that have been made available, to arrive at some general symptoms from which the composition of the afterdamp may be inferred from its effects. Every part of the pit shows that whatever the percentage of carbon monoxide present in the afterdamp, it must have been less in volume than the half of of one per cent., because men were found alive on the direct line of the blast, and in many places far removed from one another the men gathered in groups in their endeavors to escape.

Dr. Haldane examined the blood of some of the horses for carbon monoxide, and as in the cases of human beings examined by him, no trace of carbon monoxide could be found.

If then this gas is only present in such an insignificant quantity that its presence is neither indicated in the blood of human beings or animals, and also that persons are brought out of the pit alive after being in the direct line of the explosion effects, what gas or gases are those which produce the extremely serious head symptoms described by Dr. Lyttle? The descriptions given by the two survivors Howells and Blumford cannot be relied on with confidence, when it is noted that neither were fully conscious when found by the explorers, and that none of the other survivors could recollect anything which occurred on the day of the explosion. Now if this and many other explosions are considered from a new point of view, which has already been suggested in the course of the foregoing descriptions, namely, that the explosion is really one of compressed oxygen, which may have a velocity of high detonating speed, it is not difficult to imagine how some of the conflicting indications immediately become intelligible.

HOW COMPRESSION PRODUCES AN EXPLOSION.

The course of events that would produce compression are: (1) A shot of some flame-producing explosive, either properly or improperly tamped. (2) A blown out shot, or an over-powdered shot, or a large and very hot flame from the insufficient tamping of some high explosive, which produces a large volume of carbonic oxide gas, and therefore a large and very hot flame outside the shot hole after the shot has done its work. (3) A considerable area of the mine roadway filled with the normal quantity of fine dust always present in the air of a dusty mine, added to that which may have been disturbed from the floor, sides and timbering by the air vibration set in motion by the shot. (4) The explosion of this mixture of dust, air and inflammable gases from the explosive, which considered as a shot would be equal to the cubic contents of a cartridge 150 yards long, and having an area equal to that enclosed by the perimeter of the roadway, and ignited by the residual heat of the explosive or by the actual flame from some of the partly inflamed or unconsumed portions of the explosive. (5) The compression of the whole of the air within the mine and its ignition or detonation by the explosion.

The experiments made by Mr. Henry Hall, H. M. inspector of mines, proved the correctness of the fourth sequence, but were not on a sufficiently large scale to show the effects of the fifth. From observations made by Dr. J. Shaw Lyttle, it is evident that afterdamp cannot be largely composed of carbon monoxide, as has been assumed in the absence of actual proof on the contrary, but that there is some gas or gases in the afterdamp which are of a deadly nature is also fully demonstrated, and therefore it remains to be discovered what these gases are. The principal indication in the afterdamp at the Albion Colliery was the irritation of the throat and eyes. At Camerton Mr. Garthwaite said, the air was "suffocating, pungent and irritating," and Mr. Stuart referring to the same explosion, says that it was a significient fact that carbon dioxide could not be detected in the path of the explosion.

If then no carbonic oxide could be detected in the case of the Albion explosion, and no carbon dioxide could be detected in the case of the Camerton, and as both cases are accepted as being examples of coaldust explosions, it becomes necessary to ascertain as soon as possible what part coaldust really plays in what are now called coaldust explosions.

The writer suggests that the indications he has given, point to one general conclusion, namely, that coaldust does not enter into combustion during the outward progress of the explosion, and afterwards it passes through a stage of partial distillation due to the residual heat of the explosion. This suggestion appears to be strongly justified by the finding of coked dust and moreover the only cases of coked dust found were in the Top Little vein workings at Timsbury, where the residual heat would remain for the longest time, because it was at the highest altitude.

The writer now suggests that the fatal gases are oxides of nitrogen, and he does so with very great confidence, because some years ago, after suffering from this irritation on two occasions, he suggested to the late Dr. Camelly, then of Owen's College, Manchester, that it was due to ammonia, the doctor however, did not agree with the suggestion, and took a great deal of trouble to prove that it was almost impossible for ammonia to be formed under such conditions, but that oxides of nitrogen were formed, and caused the irritation, which was distinctly due to these oxides.

EXAMINATION QUESTIONS.

THE MINE FOREMEN'S EXAMINATION IN THE BITUMINOUS FIELDS OF PENNA. JAN. 22, 1895.

Correct Answers to the Questions, Prepared Especially for the Use of Mining Students. Practical Mining Points Explained.

QUES. 14. What special requirements do you consider should be observed in the erection of a ventilating furnace or a ventilating fan?

ANS. In each case due attention must be given to the requirements of an efficient ventilation for the removal of all dangerous gases from the mine; and to secure this result, three special requirements must be secured: first, a sufficient velocity of the current for the removal of gases; second, a sufficient volume to provide sufficient fresh air for each separate district in the the mine; and third, the ventilating pressure must be equal to the resistance due to the air current required.

To secure this efficiency, the fire-grate surface must be equal to the work to be done by a furnace, and in the case of the machine ventilator, the fan must be large enough to obtain the air required by not more than 70 revolutions per minute of the engine.

QUES. 15. How would you proceed legally to guard the health and safety of the miners, and the security of a mine placed under your charge?

ANS. Comply yourself, and see that others do likewise, in carrying out all the provisions of the "General and Special Rules," and all the "Sections" of the Act Relating to The Bituminous Coal Mines of Pennsylvania.

QUES. 16. In a mine where underblasting is required and 75 men are employed, the ventilation is 10,000 cubic feet of air per minute.

Will you then explain fully how many splits you would make and say what velocity the air currents of this mine should have for the removal of black-damp?

ANS. If you are "underblasting" and require to remove black-damp, the quantity of air given namely, 10,000 cubic feet per minute cannot do what is required. Let us first notice Section 2, Article IV of the Act Relating to The Bituminous Coal Mines of Pennsylvania.

"After May thirteenth, one thousand eight hundred and ninety-four, not more than sixty-five (65) persons shall be permitted to work in the same air-current. Provided, That a larger number not exceeding one hundred may be allowed by the mine inspector when in his judgment it is impracticable to comply with the foregoing requirement."

As 75 is ten more than the number that can work in one, or an undivided current, the 10,000 cubic feet of air per minute must be split into two separate currents and say 5000 cubic feet for each, and let the maximum area of section of the current be 35 square feet, then $\frac{5000}{35} = 143 =$ the velocity of the air per minute, such a velocity would neither remove the fumes of the powder nor remove black-damp, because this heavy gas requires a velocity of at least 5 feet per second or 300 feet per minute, to remove it.

QUES. 17. What are the causes of "blown out" shots, and what are the dangers attending them?

ANS. There are several causes of shots being blown out; first, an excessive charge of powder with a short length of stemming is a common cause; second, when the shot hole is too long for the holing; third, when the shortest line from the shot to the face is through the stemming; fourth, when the diameter of the hole is too large for the length of the stemming; fifth, powerful charges in holes of large diameter, blow out more frequently than when the diameter of the hole is properly proportioned to the charge.

The dangers arising from these shots are caused by the long tongues of flame; they project very often into explosive mixtures of gas and air, and the blast of these local explosions often sweeps up large quantities of coal dust, that saturates the fresh air with fuel for further ignition, and so the danger augments.

QUES. 18. In your opinion is it necessary or desirable to maintain the ventilation of a mine when it is idle? Give your reasons in full.

ANS. Even when no cattle are stabled underground the ventilation of a mine ought to be continued when it is idle.

To prove the importance of this conclusion, suppose the ventilation to be stopped for 24 hours; during this period the light inflamable gases will collect in large volumes in all the upgrade chambers, and if any unknown gob-fire exists a destructive explosion will most likely occur when the fan is started, because at that period the fresh air and fire-damp are mixed in explosive proportions, and if this mixture should reach the region of the fire, either by a current or wave motion, a blast is sure to ensue.

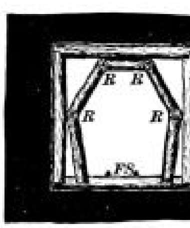
Again several cases are on record where an explosion has occurred in the fan house on starting the ventilation after a stoppage; and indeed an explosion would travel down the upcast shaft into the mine, from a light in the open air in the neighborhood of the fan at bank.

Again the gases that accumulate in the chambers and the gob are sluggish and difficult to remove, and it is always at the periods of removal that dangerous mixtures are made, consequently after a fan has been standing for 24 hours, the mine is not safe some hours after it has started again. Therefore the ventilation should not be stopped when the mine is idle. Section 3, Article IV of The Act Relating to The Bituminous Coal Mines of Pennsylvania, provides that:

"All ventilating fans shall be kept in operation continuously night and day, unless operations are *indefinitely suspended*, except written permission is given by the mine inspector of the district to stop the same," etc., etc.

QUES. 19. Explain and show how you would set props, both in a level and in a pitching coal vein. Also explain with a sketch how you would frame a double set of timbers.

ANS. A prop will carry the greatest weight, or resist the greatest compressive strain, when it is shortest, and, therefore, lies in the shortest line between the floor and the roof. I would, therefore, set props both on a level and on a pitch at right angles to the roof and the floor. The sketch shows how to frame a set of double timbers to resist a considerable side pressure. It will be seen that the principal set is made of notched timbers, and that it is inset with lighter timbers all tied at the top and side butts with longitudinal ties, as at *R, R, R, R.*



QUES. 20. How do gob fires originate in coal mines, and what are the best means of extinguishing them, and how would you guard against them?

ANS. Gob fires are the result of spontaneous combustion, or fire produced by chemical action. Some chemists assert that the initial cause must be sought for in the oxidation of coal, but carbon has never been known to ignite or oxidize in oxygen, excepting at a higher temperature than the ignition one of sulphur; there can therefore, be no doubt that the initial chemical action takes place in the presence of oxygen and sulphur. Rotten timber that has been saturated with sulphurous mine water and afterwards dried, takes fire, and has been known to be a prime cause of a gob-fire.

Gob-fires that cannot be treated with water, can only be extinguished by isolation from the oxygen of the air, and to cut them off from the air they are surrounded with barriers of clay or sand, and where possible and convenient they are isolated with double stoppings, packed close in between with clay.

To guard against them, above everything take care that no timber is left in the gob.

QUES. 21. What should be the volume of air for a mine producing 1,600 tons of coal per day, and what would be the effective horse power of the ventilator with a 1 inch water-guage?

ANS. As the legal allowance of air per man would not be sufficient to dilute and remove dangerous gases, the volume of air should not be less than 200,000 cubic feet per minute, and the effective horse power of the ventilation would therefore be $\frac{200,000 \times 1 \times 5.2}{33,000} = 31.5$ H. P.

QUES. 22. If you were employed to manage the inside operations of a new coal field, how would you proceed with the development so as to cause no loss of coal, or the mine to be over run with creep, and also to secure the health and safety of the employes and the security of the mine property? Answer fully.

ANS. Before this question could be answered by a practical man he would insist on seeing the portion of the mine available, and then he would furnish a correct and satisfactory answer.

As no particulars are given of the thickness or depth of the seam, the hardness or softness of the coal, the nature of the roof and floor, the pitch of the vein, the wetness or dryness of the strata, or the approaches to the seam by shafts, tunnels, or drifts, and as there has to be "*no loss of coal*," and the candidate has to "*Answer fully*," the only reply that can be given by a shrewd miner who is master of his subject in theory and practice and is fit therefore to be a mine foreman, is, No answer can be given.

QUES. 23. What rule would guide you in laying off the workings in a new mine property, so as to obtain a large percentage of lump coal, with an economical use of props, timbers and road material?

ANS. It is a general fact that where the pressure is set unduly on the props, it also falls unduly on the coal and crushes it, and further, when the system of working does not suit the natural conditions, more working places are required for a given output, and this renders the use of more road materials necessary.

The rule that would guide me would be to advance up-grade with the long-wall face in soft bituminous coal, and in breast and pillar I would drive the breasts up the pitch, and thus prevent the crush of the pillars in advancing up grade in their removal.

The treatment required in the extraction of the bituminous seams, is different to that required for the anthracite ones.

QUES. 24. If you were employed to manage an old mine over-run with creep, and the road ways were in a dangerous condition, and the drainage and ventilation were very defective, how would you proceed to improve the condition of the mine?

ANS. Neither the drainage nor the ventilation could be improved until the creep was stopped, because the levels of the water course would be continually altering, and no stoppings or doors could be kept airtight. Again, the return air-ways could not be kept open, because the floor would be lifting, and the roads closing, and if the seam produced much fire-damp no one would be safe in the mine, and if it was over-run with creep, it would cost more than the mine was worth to stop it, therefore the best course would be to let the mine alone until the creep subsided.

The Fire Boss' Examination.

QUES. 1. What are the lawful duties of a fire boss?

ANS. The lawful duties of a fire boss are fully set forth in The Act Relating to The Bituminous Mines of Pennsylvania, as in Article V, Section 1, 4, 7, 8; Article VIII, Section 5; Article XV, Section 1; Article XX, Rule 9.

QUES. 2. How would you ascertain if a safety-lamp is in proper and safe condition for use?

ANS. When the lamp station is at the surface, I would first examine the meshes of the gauze cylinders, to see if they were free from broken wires, soot, coal dust and oil flakes; second, I would examine the asbestos packing rings to see if they were in good order and capable of making an air and gas tight joint; third, I would light the lamp and see that all the parts were in their place, and that the screw joints were tight; fourth, I would test the lamp in the tester provided for that purpose.

QUES. 3. In what part of a mine and under what conditions would you expect to discover explosive gas?

ANS. At the face of a breast or chamber advancing upgrade, or in the cavities of the fallen roof, along the edges of goaves, in all up-grade workings, and in the return air currents, and especially when the volume of the ventilating current is not sufficient, or the velocity of the current is too slow for mixing with, and carrying off the fire-damp.

QUES. 4. Is it any safety in gaseous mines, to have a furnace with a high double arch (or in other words) a large space above the furnace fire leading to the furnace shaft?

ANS. Yes the high double arch of a furnace allows the return air of the mine a free and unobstructed passage into the shaft, and thereby reduces the resistance, and increases the volume of the air per minute circulating round the mine.

QUES. 5. What would be your method of preventing an accumulation of explosive gas, in the worked out parts of a coal mine?

ANS. I would ventilate the gob, by allowing fresh air to have free access to the bottom or lowest edge, and have a return airway running along the top edge of the gob to carry off the lighter gas as it ascends.

QUES. 6. Under what conditions would the use of open lights be safe in gaseous mines, and under what conditions would you forbid the use of open lights in such a mine?

ANS. If the mine is *gaseous* open or naked light can never be used, and on the authority of The Act Relating to the Bituminous Coal Mines of Pennsylvania, Article V, Section 5, I would forbid them for the reasons herein given.

"All entries, tunnels, airways, traveling ways and other working places of a mine where explosive gas is being generated in such quantities as can be detected by the ordinary safety lamp, and pillar workings and other working places in any mine where a sudden inflow of said explosive gas is likely to be encountered (by reason of the subsidence of the overlying strata or from any other causes), shall be worked exclusively with locked safety lamps. The use of open lights is also prohibited in all working places, roadways or other parts of the mine through which fire-damp might be carried in the air current in dangerous quantities.

QUES. 7. Are there any circumstances under which you would not enter on the record book, gas found by you in the morning?

ANS. According to the provisions of the Act, Article VI, Section 8, there are no circumstances under which you would not enter on the record book gas found in the morning.

QUES. 8. At what velocity should the air-current move through the workings of a mine generating explosive gas?

ANS. The velocity should never be less than 5 feet per second, or 300 feet per minute in the working places.

QUES. 9. How many men would you set to work in a section of a gaseous mine passing 1,200,000 cubic feet of air per hour, and discharging 1,500 cubic feet of gas per minute?

ANS. The air returning from this section of the mine, already contains 7.5 per cent. of fire-damp as

$$\frac{1,500 \times 100}{20,000} = 7.5 \text{ per cent. of gas for } \frac{1,200,000}{60} =$$

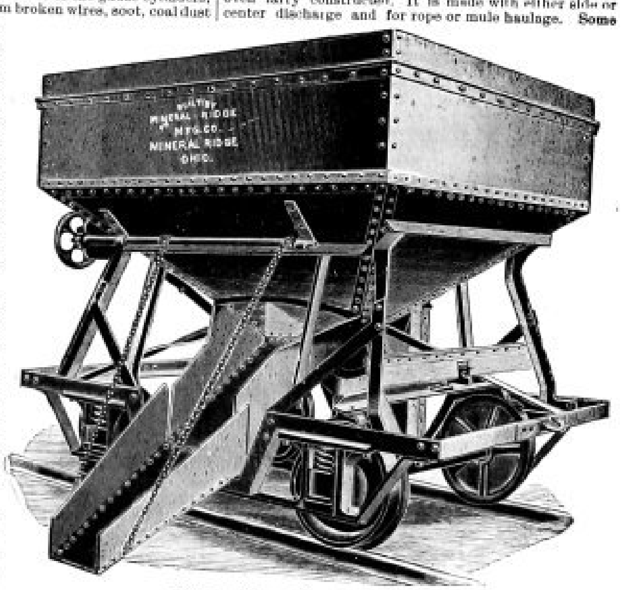
20,000 cubic feet of air per minute, and as air and gas mixed, only cease to be explosive when the percentage of gas is 6.6. I would forbid any men working in the mine when the percentage of gas 7.5 makes an explosive mixture.

QUES. 10. What are the dangers usually encountered on entering a mine after an explosion and how would you proceed to overcome them? Explain fully.

ANS. The first danger arises from the fallen roof, and the broken timber; the second arises from the disarrangement of ventilation by the blowing up of overcasts, and the blowing out of stoppings; and the third arises from the danger of inhaling after-damp. By carefully proceeding to clear away the falls from the roof, and securing the roads with timber, the first danger can be minimized, and the second and third can be prevented by observing the following rule "Take care to travel with the wind, but never against it."

An Improved Coke Oven Larry.

We illustrate herewith an improved Coke Oven Larry, manufactured by the Mineral Ridge Manufacturing Co., Mineral Ridge, Ohio. It is claimed to be one of the most efficient and most durable, if not the best coke oven larry constructed. It is made with either side or center discharge and for rope or mule haulage. Some of the largest producers of coke in the country use them in preference to any other type of larry—one firm alone, The Rochester and Pittsburgh Coal & Iron Co. has bought thirteen of them in the last four years, and Mr. L. W. Robinson, the General Manager of the company speaks of them in the highest terms.



MINERAL RIDGE COKE OVEN LARRY.

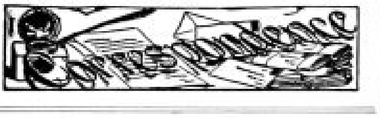
The larries are built under the supervision of Mr. Theodore Thomas, who has had fifteen years experience in the manufacture of all kinds of coke and mine supplies, and who has given the question of the construction of an efficient and durable larry a great deal of study. The Mineral Ridge Manufacturing Co. report that they are receiving orders from every state in the Union, and are even exporting these larries to Mexico. They use nothing but the best iron and steel in their construction and nothing is left undone to make them, as is indeed all their mine equipment, first-class in every respect.

Their shops at Mineral Ridge are equipped to construct anything in the line of tipples, either iron or steel, mine cars, car wheels, drums for self-acting planes, or in fact anything that is needed in the line of mine equipment.

It will pay our readers to write them for estimates when in need of equipments in their line.

Storage Batteries.

Experience seems to show that the use of storge batteries in central stations, affords a certain flexibility which makes them a desirable adjunct to the generating machinery and as this has become generally recognized, it has resulted in their adoption not only in central stations, but also by several of the larger manufacturing concerns in connection with their own power plants.—*Chas. T. Rittenhouse in Electric Power for December.*



This department is intended for the use of those who wish to express their views, or ask, or answer, questions on any subject relating to mining. Correspondents need not hesitate to write for supposed want of ability. If the ideas are expressed, we will cheerfully make any correction in composition that may be required. Communications should not be too lengthy, and personal reflections should be carefully avoided.

All communications should be accompanied with the proper name and address of the writer—not necessarily for publication, but as a guarantee of good faith.

The Editor is not responsible for views expressed in this Department.

☞ *Correspondence should be in as simple language, and as free of technical terms and formulæ as possible, consistent with clear solution.*

Questions on subjects not directly connected with mining will not be published.

MINING REVIVAL IN COLORADO.

Leadville Celebrates it in a Novel and Attractive Manner.

Editor Colliery Engineer and Metal Miner :

SIR:—Leadville is on the threshold of an era of prosperity greater than in its history. Its output for 1895 is in excess of any of the preceding thr.e years, and the value of the output for the year just closed shows an increase over 1894 of nearly 50%. There are 3,800 men employed in the mines, smelters and allied industries of the camp. A great deal of the earnings of the mine employes are going back into the mines through leases, properties that have been idle for years being operated now on leases by pools. Leasing is a feature now peculiar to the camp, the lessees ranging from small groups of miners, whose capital is their labor plus the grub stake of friends, to the big companies who have plenty of means to undertake a proposition of any calibre, and who employ many hundreds of men. The camp is on a sound footing without any boom, and an idle man is a *rara avis*. Even the store-keepers have caught the spirit of enterprise, and every dollar they can spare from their regular business goes into a leasing company. Things are very lively in the gold belt. The Ibex groups are making a steady output, the tonnage for 1895 being 47,000 tons of silicious ore, and development work keeps on with occasionally new discoveries. Other mines in the gold belt are making shipments, while numerous others are being exploited. Every foot of ground that has any mineral indications whatever is being located, and every now and then a new strike is reported. In the old silver contacts a steady and increasing out-put of silver ores is noted, and considerable underground exploitation goes on with results, so far, of exposing large bodies of ore, especially of carbonates. The Sears placer field has in the past year added a number of producers to the camp, and the "Down Town" district is not behind in assisting in the general revival. The smelters are running to near their full capacity and two idle smelters are to start up in January. Leadville is operating chiefly on its home capital and the camp is not seeking a newspaper boom, but it is just the same, in a healthy flourishing condition and will celebrate its recovery from the silver slump with a Winter Carnival. Probably no American mining community has ever had a similar jubilee on so grand a scale as that which surrounds the Ice Castle and which continues throughout January, February and March in a continuous series of entertainments, winter sports and rational revelry. It is under the auspices of the Chrystal Carnival Association which has erected a palace of ice at a cost of $25,000 and entered into an additional expense of $25,000 for the entertainments. The Director General, Tingley S. Wood, is a leading mine operator and has been mining in the Carbonate camp for nearly 18 years. The affair has a distinctive flavor of miners' enterprise, and starts out with appropriate eclat. The ice castle is a thing of beauty and will be a veritable Kobolds grotto of winter hilarity, though instead of being subterranean, it is situate on a ridge extending out from Leadville and among the clouds, 10,200 feet above sea level. The officers of the Chrystal Carnival Association are T. S. Wood, Director General; Chas. T. Limberg, Vice Pres; Wm. T. Temple, Secretary; and Frank X. Hogan, Treasurer. At the back of the association are the successful and wealthy miners of the camp.

Yours, etc.,
SIR KNOCKER.

Injustice of Mine Laws to Citizens of Other States Locating in Pennsylvania.

Editor Colliery Engineer and Metal Miner :

SIR:—As my subscription for your valuable journal expires with the present month, I beg to give notice that I do not intend to renew it.

I regret the necessity for this step, but I do not feel justified in devoting any more time to the study of a profession I cannot enter. The mine laws of Pennsylvania deny me one of the privileges of American citizenship in refusing to allow me to compete for a mine foreman's certificate, because I have not worked five years in Pennsylvania mines. I am without the influence, absolutely necessary in order to secure a position as mine superintendent, (which does not require a certificate), and I have no intention to return to the coal mines as a fire boss, for which I have a certificate, consequently, as I must remain outside of the only occupation I can truthfully claim to be familiar with, I have no longer any inducement to study.

My apparent inconsistency, in striving to obtain a certificate, or position as mine foreman, and at the same time, neglecting the assistance offered by your correspondence system of teaching the theory of mining, is readily explained by the fact that I was not working in the coalmines a the time, and my future course was uncertain, had it been otherwise, I would be very glad to have such an excellent opportunity to acquire a thorough technical education.

Thanking you sincerely for the interest you have taken in my case, and wishing increased prosperity to THE COLLIERY ENGINEER AND METAL MINER, the best journal I ever read. I am etc.,

Yours very respectfully,
EDWARD HALPIN,
Allegheny, Pa.

The 5th Root.

Editor Colliery Engineer and Metal Miner :

SIR:—As a practical rule for finding the fifth root of a number without the aid of logarithms, has been asked for by men preparing for the Managers examination, I submit this rule to your subscribers:

For numbers less than 32 find the difference between given number and 32 and call it the difference. Place this difference over 80 to form the first fraction. Multiply the first numerator by the difference and place over 6,400 for second fraction. Multiply the second numerator by 3 times the difference and place over 1,024,000 to form the third fraction. Multiply the third numerator by 7 times the difference and place over 327,680,000 for the fourth fraction. Multiply the fourth numerator by 19 times the difference and write over 262,144,000,000 to form the fifth fraction. Multiply the fifth numerator by difference and write over 10,485,760,000,000 for the sixth fraction, etc. Reduce all the fractions to four decimal places and add. Substract this answer from 2 and your answer will be correct to two or more decimal places. If the given number is small use all the fractions. If nearly as large as 32 only two or three are necessary.

Example.—$3^2 = \sqrt[5]{3^2} = \sqrt[5]{9}$. Difference = 23.

$\frac{23}{80} = .2875$

$23 \times 23 = \frac{529}{6400} = .0826 +$

$529 \times 23 \times 3 = \frac{36501}{1024000} = .0356 +$

$36501 \times 23 \times 7 = \frac{587661}{327680000} = .0179 +$

$587661 \times 23 \times 19 = \frac{256810857}{262144000000} = .0097 +$

5th numerator $\times 23 = \frac{5906631971l}{10485760000000} = .0056 +$

6th numerator $\times 23 \times 29 = \frac{39397235247237}{1174405120000000} = .0033 +$

Sum = .4424 + Subtract from 2.

Answer = 1.5575. Correct to two decimal places.

Again, $\sqrt[5]{27}$ Difference is 5.

$\frac{5}{80} = .0625$

$5 \times 5 = \frac{25}{6400} = .0039 +$

$25 \times 5 \times 3 = \frac{375}{1024000} = .0003 +$

Sum = .0668 + Subtract from 2.

Answer = 1.9331. Correct to three decimals.

A similar rule can be given for numbers between 32 and 243.

W. W. TORRY,
Springhill, N. Scotia.

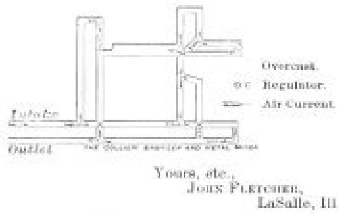
Ventilation.

Editor Colliery Engineer and Metal Miner:

SIR:—In the December issue of this journal, "Ajax" gives a drawing of double entry system and requests that some of your readers give plans for ventilating the same with the least number of doors and without doors."

I think that Ajax might have showed a few cross-cuts on his drawing between the entries.

I submit the following answer showing how it can be ventilated without doors:



Yours, etc.,
JOHN FLETCHER,
LaSalle, Ill.

What Electricity Can Do.

Some idea of the diversity of uses to which electric motors are now being put and the rapid spread of electricity in different directions may be gathered by glancing at the list of orders for motors received in the Power & Mining Department of the General Electric Company, during one month this summer:

Operating mining machinery, shoe factory, operating a yarn factory; a tannery; a powder mill; a watch factory; iron working machinery; a foundry; hoists for electric cranes; ventilator on a gun boat; propelling electric launches; the operation of elevators; blowing church organs; operating woolen mills.

These orders are scattered throughout the following States: California, Colorado, Indiana, Ohio, Connecticut, Michigan, Pennsylvania, Rhode Island, Wisconsin and New York; Lima, in Peru and Rio de Janeiro in Brazil.

PRIZE CONTEST.

PRIZES GIVEN FOR THE BEST ANSWERS TO QUESTIONS RELATING TO MINING.

For the best answer to each of the following questions, the value of $1.00 in any of the books in our book catalogue, or six months' subscription to THE COLLIERY ENGINEER AND METAL MINER.

For the second best answer to each question, the value of 50 cents in any of the books in our book catalogue, or three months' subscription to THE COLLIERY ENGINEER AND METAL MINER.

Both prizes for answers to the same question will not be awarded to any one person.

Conditions.

First—Competitors must be subscribers to THE COLLIERY ENGINEER AND METAL MINER.

Second—The name and address in full of the contestant must be signed to each answer, and each answer must be on a separate paper.

Third—Answers must be written in ink on one side of the paper only.

Fourth—"Competition Contest" must be written on the envelope in which the answers are sent to us.

Fifth—One person may compete in all the questions.

Sixth—Our decision as to the merits of the answers shall be final.

Seventh—Answers must be mailed us not later than one month after publication.

Eighth—The publication of the answers and names of persons to whom the prizes are awarded shall be considered sufficient notification. Successful competitors are requested to notify us as soon as possible as to what disposal they wish to make of their prizes.

Competition Questions for January.

QUES. 199. In the construction of our new safety lamp, do you think we should adopt the principle of the tubular poles that are the distinguishing feature of the Gray lamp. This lamp is preferred for gas testing because it can detect a thin stratum of gas just under the roof of the seam. A shunt is provided in some "makes" of this lamp, to cut off the supply of air down the poles, and admit the supply above the glass cylinder, as in the Marsaut lamp, when it is not required to test for gas near the roof. Now I should like you to answer me three questions to aid me in deciding the point at issue:

First. Why is the supply of air from the poles cut off when the lamp is in ordinary use?

Second. When the lamp is fed with air from the poles, if you give it a quick sudden drop the light goes out. How is this?

Third. When the lamp is carried in air charged with gas, if you move it quickly and suddenly upward, it fills with flame. How is this?

QUES. 200. We are going to prospect for coal, and at first we will only search for indications by examining the exposed rocks, and therefore we must get up in good shape our paleontology, in so far as the fossils that characterize the Silurian, the Devonian, the Carboniferous and the Triassic formations are concerned. Will you then assist us by naming the examples that we ought to know, and give them under four heads:

First. Negative examples, as of the fauna of the Silurian and Devonian series.

Second. Positive examples, as of the fauna of the Carboniferous and Triassic formations.

Third. Negative examples, as of the flora of the Silurian and Devonian formations.

Fourth. Positive examples, as of the flora of the Triassic and Carboniferous formations.

QUES. 201. In M. Murgue's theory of the equivalent orifice, the following equation is given: $A = \frac{A\,Q}{\sqrt{W\,G}}$, and I will be obliged if you will inform me how he gets A for a constant. I know he takes the *vena contracta* at .62 and that A is the square feet in the equivalent orifice, Q is the quantity of air in thousands of cubic feet per minute and $W\,G$ is the water guage.

QUES. 202. We have a seam of coal with a soft wet floor, and the immediate roof is a slate 2 feet thick and it falls. The seam is 4 feet thick, is at a depth of 612 feet, and consists of a soft coking coal lying nearly level.

We have tried longwall working and it has proved a great failure, as the packs sink into the floor. We have 700 acres available and the field is nearly square. The coal is valuable for coke making and we cannot give it up, then will you send us a neat plot of how you would work it. You might locate your shafts in the middle of the field, and give us the sizes of your roads, and pillars, if any.

QUES. 203. The same coal seam is pitching heavy in one region and in another it is lying quite level. The thickness and quality of the coals are however equal in the two cases, and we wish to invest in one of them, which do you prefer and why?

QUES. 204. We have three mines all working the same vein, and we will call them A, B and C. The cover, the floor, and the depth and thickness of the coal are in all the cases about equal and the system of working this 4 foot vein is the same at each mine, and that is longwall advancing. Now the superintendent at A, works on the principle of having plenty of "pit room" or a working face far in excess of that required for immediate use. The superintendent at B keeps no more working face open than is required for immediate use but believes in having all ready for unexpected events. The superintendent at C does not believe in plans for future working, "because" says he, some one may come after him and reap the harvest of his labor. This being a good presentation of the three cases, will you please give them your close attention, and let me know at your earliest how it is that only one of these mines pays the company, while the other two are a "dead" loss, and be careful to say which mine pays, and show the reasons why it does so.

Answers to Questions which Appeared in November and Previous Issues, and for which Prizes Have Been Awarded.

QUES. 175. There is at present a ready market and a good price for fire-bricks; flooring tiles for fire-proof buildings; common bricks for filling and backing; glazed and unglazed facing bricks; sewer pipes and drain traps.

Our Coal Mining Company wish to share in this manufacture and trade, and have desired me to make sample bricks out of the underclays of five different coal seams we are working. I have done so with the following results: Clay of seam *A* makes a hard strong red brick coarse in the grain; Clay of seam *B* contains iron balls, but the dressed clay makes a soft white brick that is very porous; clay of seam *C* makes a soft white brick that is very porous and speckled with blackish brown spots; clay of seam *D* makes a hard coarse grained brick, and of a black and bluish color; clay of seam *E* makes a white brick that is very strong and fine in the grain. Now I desire to know two things to enable me to make a satisfactory report to the company.

First. What classes of goods are each of the clays best adapted for making?

Second. What are the constituents in the clays that give to the bricks their different characteristics?

ANS. *First.*—*A* would make good sewer pipes.

B would make fire-bricks and good flooring tiles.

C would make a very good grade of fire-bricks and could be classed as No. 1.

D would make good filling bricks or would resist atmospheric influences in exposed situations.

E would make good facing bricks.

Second. All clays contain more or less of the following impurities: pottania, sodium, calcium, iron and magnesium.

The best or No. 1 clays contain only traces of these however, and the greater the proportion of the impurities present, the harder are the bricks, and the greater is their fusibility. Such brick are an iron red or brown in color, and when highly heated in burning, have a glassy appearance when cold.

The chief constituents of fire clay are: kaolinite that is infusible and shrinks, and quartz that does not shrink.

J. JENKINS,
Dingess, W. Virginia.

Second, GEO. BROWN,
Falls Creek,
Clearfield Co., Pa.

QUES. 176. Here are two samples of bituminous coals, and in chemical composition they are both alike, and even make cokes that are alike, after they have been ground small and steeped in hot water. Hot water dissolves out of sample *A*, nitre, and out of sample *B*, common salt, and what I want to know is this, what effect will nitre have on the coking of sample *A*, and what effect will common salt have on the coking of sample *B*.

ANS. Along with the nitre in *A*, there will be the bisulphide of iron or pyrites, and these conjointly will render the coal very inflammable and destroy the pitchy binding of true coke. The following experiment fully establishes the fact just noticed: When a carbonaceous substance like wood is steeped in a mixture of sulphuric and nitric acids, and dried, a scratch made on the wood, even with the finger nail causes the emission of flame.

Sample *B* will make a silvery coke because carbon will not burn in chlorine, the common salt being NaCl. It is claimed that common salt in coke desulphurizes it, but the samples tested do not justify this conclusion.

J. J. ORMSBEE,
Henry Ellen, Ala.

Second Prize, CHAS. E. BOWRON,
Tracy City, Tenn.

QUES. 180. The action of one of our mine pumps is very peculiar, and it will startle you when I tell you, that any increase above a certain speed of the piston reduces the lifting power of the pump, and at another increase of speed the pump loses the water altogether. Now as I would like you to explain the tricks of this peculiar pump I will give some particulars. When the pump piston is at the bottom of its stroke, it is 12 feet above the level of the supply water, and as the force to lift the keep valve and overcome the friction of the water moving through the tail of the pump is equal to a two-feet column of water, we may reckon the mean lift to be 14 feet. Will you then tell me two things.

First. What is the highest speed at which this pump can be run to obtain a maximum effect?

Second. At what piston speed does the pump lose the water altogether.

ANS. *First.* The speed of the piston must not exceed the velocity of the entering water, to obtain a maximum effect. A column of water 34 feet long will balance the pressure of the atmosphere. The velocity of water into a vacuum is 40 feet per second, or the square of the velocity per second is 1,600.

In the example the equivalent of the lift is 14 feet; then,

$$v = \sqrt{\frac{(34-14) \times 1,600}{(34+14)}} = \sqrt{\frac{20 \times 1,600}{48}} = 25.81$$

feet per second, the velocity of the water on entering the pump, when the piston attains its highest speed.

Second. If the slip of the valves in the pump is equal to 1 per cent., and the velocity of the piston in feet per minute is $25.81 \times 60 = 1548.6$, then when the piston speed is 100 times quicker than the speed of maximum effect or 154,860 feet per minute, the pump will entirely loose its water.

THOMAS D. SMITH,
Coal Valley, Pa.

Second Prize, DAVID P. BROWN,
Dunbar, Fayette Co., Pa.

QUES. 187. I am still busy with the invention of our proposed new safety lamp, and I still crave for a little of your assistance, which I have no doubt you will cheerfully give by answering the following three questions:

1st. What should be the diameter and length of the gauze cylinder if I use one; or if I use two, as is done in the case of the Marsaut, what would be the best dimensions for each of them, and give reasons why you prefer the sizes you name?

2d. What should be the sizes of the wires and meshes of the gauze, and how many lines should there be to the linear inch?

3d. What is the use of the bonnet or close shield, and should we adopt one in our new lamp?

ANS. *First.* The length of the gauze cylinder should not exceed 6 inches, or the diameter $1\frac{1}{2}$ inches, and where a double gauze cylinder is used, the outside one should be made a little larger to closely cover the one of the dimensions given.

Second. The number of meshes or openings per square inch should be 784, and the lines of wire per linear inch should be 28.

Third. The use of the bonnet is to screen the gauze cylinder from the effects of draughts of wind, that blow the flame through the meshes, and set up a fiery heat by the excess of air and gas that enters above the flame of the wick, or in short the bonnet is to limit the supply of air, to that required for the oil flame only.

JOHN FLETCHER,

Second Prize, JOS. VIRGIN, 428 Tonti Street,
Hollsopple, Pa. La Salle, Ill.

QUES. 188. We are going to try some experiments by exploding fire-damp in a close, strong vessel, made of steel, and strong enough to resist the greatest pressures to which it may be subjected. The fire-damp is a diffusion in which 10 volumes of air are saturated with one volume of marsh-gas. To the steel vessel we are going to attach a pressure gauge, and I will feel obliged if you will tell me what the pressure will be at the moment of the explosion and after the steel shell and its contents or remaining gases have cooled down to the present or actual temperature of the outside air?

ANS. The burning of one pound of CH_4 in air, should produce 26383 units of heat.

The one pound of CH_4 consists of .75 of a pound of carbon, requiring for its combustion 2 pounds of oxygen and .25 of a pound of hydrogen, requiring for its combustion 2 pounds of oxygen, and therefore to burn one pound of CH_4, 4 pounds of oxygen are required, or 17 pounds of air.

Taking the specific heats at constant volume, then the units of heat required to raise the temperature of each of the bodies in the resulting mixture one degree will be as follows:

2.75 pounds of CO_2	$= 2.75 \times .177 =$	.470
2.25 pounds of H_2O	$= 2.25 \times .305 =$	.686
13.00 pounds of N	$= 13.00 \times .174 =$	2.349
18.00		3.505

The temperature of the result will, therefore be

$$\frac{26383}{3.505} = 7801°\ F.$$

By Gay Lussac's law the pressure will then be at the moment of explosion

$$14.7 \times \frac{(459 + 7801)}{(459 + 41)} = 242.844$$

pounds pressure per square inch, and after the contents of the vessel have cooled the pressure will be

$$242.844 \times \frac{(459 + 41)}{(459 + 7801)} = 14.7$$

pounds pressure per square inch.

THOMAS D. SMITH,
Coal Valley, Pa.

Second, J. M. JAMES,
Sioux Falls, S. Dakota.

QUES. 189. We have on hand a ventilating fan that can discharge 120,000 cubic feet of air per minute, with a useful effect of 30 H. P. We are going to sink two rectangular shafts, whose lengths have to be twice their breadths and their areas have to be equal. One of them will be an upcast and the other a downcast for the ventilation, and to prevent a needless waste of energy we wish the shafts to be of such an area that only one-third of the ventilating power, or 10 H. P., shall be necessary to overcome the friction of the shafts. Will you, then, calculate for us the area and the length and breadth required for each shaft?

ANS. $\frac{10 \times 33,000}{120,000} = 2.75$ = pounds pressure used in passing 120,000 cubic feet of air per minute through upcast and downcast shafts. $8 \times 16 = 128$ = assumed area of shafts. $\frac{120,000}{128} = 937.5$ = velocity. Then,

$$\frac{2.75 \times 128}{.0000001 \times 878906.25} = 40,049+ = \text{rubbing}$$

surface, and $\frac{40,049}{48} = 834.375$ = length, or depth of both shafts, and, $\frac{834.375}{2} = 417.5$ = as the depth of each shaft.

Therefore, the area of each shaft is 128 feet, length, 16 feet, breadth, 8 feet and depth 417.5.

La Salle, Ill.

QUES. 190. We have two airways which we will call *A* and *B*, and they are both 2,000 yards in length, and the air is blown through each of them with a difference of potential equal to 2 inches of water gauge. *A*, however, is 10 feet wide and 6 feet high, and *B* is 15 feet wide and 10 feet high, and as we do not require more air to pass through *B* than through *A*, will you find what quantity is passing along *A*, and what should be the area of a regulator in *B* to pass the same quantity as that of *A*; the *vena contracta* being taken at .65, and *k* at .0000001.

ANS.—Quantity of air flowing through *A* =

$$\sqrt{\frac{p\ a}{k\ s}} \times a = \sqrt{\frac{10.4 \times 60}{.0000001 \times 192,000}} \times 60 = \sqrt{\frac{624}{.00192}} \times 60 = 34,200 \text{ cu. ft. per minute.}$$

The quantity of air passing through *B* without a regulator would be

$$\sqrt{\frac{10.4 \times 150}{.0000001 \times 300,000}} \times 150 = \sqrt{\frac{1,560}{.003}} \times 150 =$$

108,165 cu. ft. per minute; but as only 34,200 cu. ft. per minute are to pass through *B*, the difference of potential for the opposite sides of the regulator will be

$$10.4 - \left(\frac{10.4 \times 34,200^2}{108,165^2}\right) = 10.4 - \left(10.4 \times \frac{1}{10} \text{(almost)}\right) = 9.36 \text{ lbs.}$$

The velocity through the regulator will be

$$\sqrt{\frac{9.36 \times 1,800,000}{2,120}} = 89.147 \text{ feet per second or } 5348.82$$

feet per minute, and allowing .65 for the *vena contracta*, the opening of the regulator is

$$\frac{34,200}{5348.82 \times .65} = \frac{34,200}{3466.733} = 9.8368 \text{ square feet.}$$

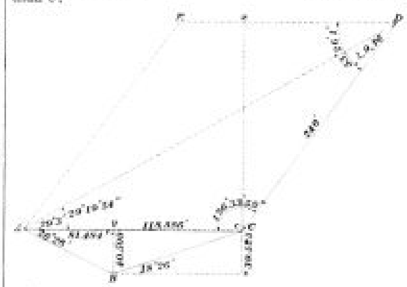
Lucas, Iowa.

Second Prize, DAVID P. BROWN,
Dunbar, Fayette Co., Pa.

QUES. 191. An important vein of iron-stone is outcropping on a hillside, and I will be obliged if you will calculate for me its height above a point we will call *A*. To reach the outcrop, the nearest course is to descend from *A* to *B* and then ascend to *C*, and from *C* ascend the hillside to *D*. Now *D* at the point *A* makes an angle of elevation of 29° 3′. The distance from *A* to *B* is 91 feet, and *B* makes an angle of depression at *A* of 26° 26′. The distance of *C* from *B* is 125 feet, and *C* at the point *B*, makes an angle of elevation of 18° 26′. The distance of *D* from *C* measured up the side of the hill, is 240 feet. What then is the vertical height of *D* above the level of *A*, when the points *A*, *B*, *C*, and *D* all lie in the the same vertical plane?

ANS.—Point *B* is sin. 26° 26′ × 91 = 40.509 ft. lower than *A*. Point *C* is sin. 18° 26′ × 125 = 39.525 ft. higher than *B*.

Point *A* is .984 ft. higher than *C*.



Solving the right angled triangle *c A C*, we have side *cC* = .984 ft.; side *c A* = (81.484 + 118.586) = 200.07 ft.; we find side *AC* substantially the same length as *cA* = 200.07 ft., and the angle *cAC* to be 0° 16′ 54″.

Solving the triangle *ACD*, we have side *AC* = 200.07 ft., side *CD* = 240 ft. and the angle *DAC* = (29° 3′ + 0° 16′ 54″) = 29° 19′ 54″.

To find angle *ADC* = 240 : 200.07 :: .4898639 : .4083628. .4083628 = sin. of 24° 6′ 7″ = angle *ADC*.

Constructing parallelogram *ACDE*, angles *A* and *D* are equal (53° 26′ 1″ each), angles *E* and *C* are also equal (126° 33′ 59″ each), and we find the length of the perpendicular *xC* to be .8031670 × 240 = 192.760 ft.

Deducting *cC*	.984 ft.
xc	= 191.776 ft.

D is therefore 191.776 ft. higher than *A*.

Lucas, Iowa.

Second, J. W. CANTY,
Oskaloosa, Iowa.

QUES. 192. What would occur if the force pumps for feeding a boiler were set at an elevation of 5 feet above the level of the feed water in the heater when the temperature of this water was 212° F.

ANS. A violent pounding, the explanation of which is as follows:

Water heated to about 100° Fahrenheit will begin to boil in a vacuum and produce steam with an increasing pressure as the temperature rises, until 212° is reached, when the steam pressure will equal that of the atmosphere. In a pump a partial vacuum is produced in the water end by the movement of the plunger, into which the water flows by atmospheric pressure. Water when about at 212° in the open air will produce steam on the slightest provocation, such as any reduction in pressure.

To force the water into the pumps 5 ft. above, will require a pressure of 5 × .433, or a little over 2 lbs. on the surface of the feed water; or,—what is just the same—a reduction in pressure in the suction pipe of like amount. If the pump is started and this 2 lbs. of pressure removed, the water will immediately boil and produce steam, and we will pump steam instead of water, or steam and water both. On the return stroke of the plunger the steam will be condensed, and any water that has entered will be met with a blow as if from a steam hammer.

The Colliery Engineer
AND
METAL MINER.

ESTABLISHED 1881, INCORPORATED 1890.

PUBLISHED MONTHLY AT SCRANTON, PA.

WITH WHICH IS COMBINED THE MINING HERALD.

Entered at the Post-Office at Scranton, Pa., as second-class matter.

THOS. J. FOSTER,
RUFUS J. FOSTER, MINING ENGINEER, } EDITORS.

THE COLLIERY ENGINEER COMPANY, PUBLISHERS.

TERMS.

Subscription, (*Postage in the U.S., Canada, or Mexico, prepaid.*) **$2.00 a Year**

TO FOREIGN COUNTRIES IN THE UNIVERSAL POSTAL UNION $2.50.

Remit by P. O. Order, Express Money Order, Bank Check or Draft or Registered Letter.

P. O. Orders.—You can buy a Money Order at your Post-Office, payable at the Scranton Post-Office.

Express Money Orders can be obtained at any office of the American Express Company, the United States Express Company, and the Wells, Fargo & Co.'s Express Company.

Registered Letters.—If a Money-Order Post-Office or an Express Office is not within your reach, your Postmaster will register the letter you wish to send us on payment of eight cents.

We Cannot Be Responsible for money sent in letters in any other way than by one of the four ways mentioned above.

EXPIRATION OF SUBSCRIPTION.

The date after your name on the wrapper of THE COLLIERY ENGINEER AND METAL MINER shows to what time your subscription has been paid.

RENEWALS, ETC.

If you do not want THE COLLIERY ENGINEER AND METAL MINER continued for another year after your subscription has run out, you should notify us by postal card to discontinue it. The courts have decided that subscribers to newspapers who do not order their paper discontinued at the expiration of the time for which it has been paid, are held liable for the payment of their subscriptions up to the date when they order the paper discontinued.

NOTICE OF DISCONTINUANCE.

THE COLLIERY ENGINEER AND METAL MINER is sent to subscribers until an explicit order for its discontinuance is received by us, and all payment of arrearages is made, as required by law. *Papers returned are no notice of discontinuance, as we cannot tell where they are from.*

CHANGE OF ADDRESS.

A Subscriber wishing to have his address changed should be careful to give his *former* as well as his present address; otherwise we cannot find his name on our mailing list.

TO MANUFACTURERS AND DEALERS IN MINE EQUIPMENT AND MINE SUPPLIES.

THE actual paid circulation of THE COLLIERY ENGINEER AND METAL MINER exceeds by fifty per cent. that of any other mining journal. Its columns are devoted exclusively to the publication of first-class articles on mining methods and mining machinery, and consequently its circulation is limited to mining men. It reaches more mine owners and mine officials than any other publication. Its circulation covers every mining field in North America. Its subscribers are at fifteen hundred and seventy-three post-offices in the United States, British Provinces and Mexico. Its editorial staff and force of paid contributors embraces only men who have had extensive practical experience as well as theoretical knowledge. Its mailing list is open for the inspection of advertisers and prospective advertisers. It is unquestionably the best advertising medium in America through which manufacturers of power plants and appliances, mining machinery, and mining supplies may make their business known in every American mining field. A handsome and useful pamphlet on Mine Equipment and Mine Supplies, containing valuable information and statements from many of the leading advertisers in THE COLLIERY ENGINEER AND METAL MINER will be sent free to any manufacturer or dealer in mine equipment or supplies, on application.

COAL DUST EXPLOSIONS IN MINES.

MR. DONALD M. D. STUART, F. G. S. in a lecture delivered at the Technical Schools, Derby, England, on the above subject said: "An experience of about twenty years in collieries where coal dust abounded, where shot firing was general, and gob fires had sometimes prevailed, had, up to the year 1893, led him to the conclusion that coal dust was harmless in non-gaseous mines." Explosions at the Camerton collieries, where for over one hundred years no trace of gas had been found, deepened in his mind the mystery as to the cause of the explosion. A simple calculation showed that the quantity of heat generated in the explosive that was fired was utterly inadequate to produce the results observed after the explosion. It was only after many months' reflection, and some experiments with coal gas, that the difficulties were removed, and he found that when coal-dust yielded up its gases under the action of heat from an explosive, chemical actions were initiated that provided a solution of the observed phenomena. Upon this basis of fact the conclusion became irresistible, that a disastrous explosion, similar to what occurs in gaseous mines, had been produced by coal-dust alone; and there remained no shadow of a doubt in his mind that coal-dust was an explosive agent.

A more recent explosion at Timsbury collieries, also non-gaseous, which he investigated, presented phenomena identical with those which he had observed at Camerton, and confirmed the conclusions at which he had arrived.

He then turned his attention to explosions in gaseous mines, and found that the phenomena in these explosions corresponded with those observed in non-gaseous mines. He expounded his theory that an explosion in a mine was characterized by numerous local explosions, each disturbance being isolated and preceded by a length of mine passage, in which the materials were practically in their normal state, or had not been subjected to violent forces.

Mr. Stuart illustrated his lecture by stereopticon views of the scenes of explosions in several collieries, showing the places where the disasters were originated, and their subsequent development through the workings. Each disaster was traced to its origin, and the developments of the explosions were shown to be characterized by numerous subsidiary explosions, which left their evidence in isolated exhibitions of explosive violence. He explained the nature of the forces in the explosive disturbances, and in the intervening spaces, and the extent and causes of disarrangement of materials in the latter, and with that qualification he remarked that the fields of disaster in the Camerton and Timsbury collieries exhibited the effects of numerous distinct and violent disturbances, in which doors were shattered to fragments, iron work broken and distorted, trams broken and crumpled and their contents scattered abroad; rails torn from their sleepers, timber fractured and knocked down, arches demolished, stone roof ripped in thicknesses up to 3½ feet, and men mutilated, each disturbance being preceded by lengths of mine passage in which the trams were uninjured and their contents undisturbed, the rails were unmoved, the timber unbroken and undisturbed, the arches undamaged, the roof in its natural state, and the men not mutilated. The energies in the disturbances, and the energies in the intervening spaces, therefore exhibited distinct modes of action.

He also reviewed two other notable explosions and showed that the ruin wrought and the extent of the mutilation of the bodies found in different localities proved his ideas.

With this evidence and numerous other facts of the same definite character, Mr. Stuart formulated the theory of intermittent subsidiary explosions, and that the mystery of colliery explosions must disappear, for it was no longer necessary to suppose that there were sudden and incredible outbursts or accumulations of fire-damp at the moment of the disaster. He stated that coal dust, always and everywhere present in the mines, was capable of giving rise to explosions, and of producing the phenomenon of subsidiary local explosions.

In concluding his lecture, he said, "We have now examined disasters in typical gaseous and non-gaseous mines, and have observed, that in their inception, and in their development, they present an identical rationale that demands for its explanation an identical explosive agent; and as coal-dust is the only agent common to both gaseous and non-gaseous mines, it must have been the common source of the gases that produced the calamities to which he had drawn their attention."

Throughout his lecture Mr. Stuart, naturally treated only with explosions in British mines. His conclusions as to "coal-dust, always and everywhere present in mines" does not apply to anthracite coal mines. The dust may be present, and may to a small extent, when present, intensify a gas explosion in an anthracite mine, but it will not originate an explosion or propagate it. The low precentage of volatile hydrocarbons in anthracite coal renders it freer from dust explosions than the various other classes of coal. In fact this feature indirectly proves the coal-dust theory. Some of the anthracite mines of Pennsylvania rank among the most gaseous in the world, and there has never been a gas explosion in one of them that has not been comparatively local in its effect. In both British and American bituminous mines, however, the case has frequently been different. Explosions of small accumulations of gas have frequently been propagated by dust and carried with varying intensity throughout all, or the major portion, of the mine workings. Sudden outbursts of gas, authenticated by positive proof, have occurred in anthracite mines, and have caused disastrous explosions, but the limit of the explosive force was comparatively small. Such outbursts undoubtedly occur in bituminous seams, and are sometimes the origin of explosions, but we are of the firm opinion that the extent of the workings affected, outside of a limited area, depends entirely on the quantity of dust present, and the chemical composition of the coal.

Mr. Stuart's lecture, which was widely published in Great Britain, has drawn out comments from such other eminent British authorities as Messrs. Arnold Lupton, A. L. Steavenson, B. H. Thwaite, J. W. Ronaldson and others.

Mr. Lupton says, in a recent letter to *The Iron and Coal Trades Review*, of London, that "the explosive nature of coal dust was demonstrated thirty years ago by French experimenters, and the fact was proved conclusively by Messrs. W. N. and J. Atkinson, in their work "Explosions in Coal Mines" published in 1886; but notwithstanding this conclusive demonstration, and the equally conclusive and most striking experiments of Mr. Henry Hall, H. M. Inspector of Mines, there still remained sceptics, of whom some where convinced by the Timsbury and Camerton explosions. I think Mr. Stuart is doing a good work in bringing the matter prominently forward. Mr. William Galloway was the leader among English mining engineers; then followed the Messrs. Atkinson; but it is necessary to have a succession of teachers to bring this truth home to the rank and file."

Mr. Lupton discusses the location of the greatest explosive force in an explosion and says: "It does not seem to me that this is necessarily coincident with the position of the greatest evidence of explosive force. These evidences of force seem to me to be produced by a rushing current, and I can conceive it possible that the greatest rush is not necessarily at the place where there is the greatest intensity of heat or of explosive energy. For instance, supposing the explosion to take place at the end of a heading, there could be no rush of air except in one direction, and I think the rush would be greater at some distance from the end of the heading than close to the end. Similarly, if an explosion took place in the middle of a length of roadway, the explosion travelling both ways, it is to me conceivable that at the point of origin there might be a neutral point from which the rush of air would pass in each direction with increasing violence, although the greatest heat and greatest pressure might be at the point of origin, where no signs, or but slight signs, of violence might be observed."

Mr. Steavenson, in discussing Mr. Stuart's lecture is inclined to be sarcastic. In his letter to our London contemporary, he practically coincides with Mr. Stuart's statements, and calls attention to the fact that the latter's conclusions were not original, but that they are the same as other investigators. He cites a number of authorities to prove this, and quotes as follows from the report of the British Commissioners on Accidents in Mines, published in 1886:

"In discussing the manner in which coal-dust operates alone in propagating flame from a blown out shot, Mr. Hilt does not advance any point of novelty, his views being that, as suggested by Faraday and others, the flame furnished by the dust is due in part to the combustion of the coal-dust itself, and in part to that of the gas developed from fine dust particles by their exposure to heat."

While Mr. Steavenson asserts what is an undoubted truth, he can not detract from the credit due Mr. Stuart for his investigations and the publicity he is giving the facts that he demonstrated to his own satisfaction. As we read Mr. Stuart's lecture, we are impressed with the idea that he is a man not satisfied with hearsay evidence or evidence deduced from the investigations of others. He wanted his own, he secured it, and he gives it publicity. Therefore he is entitled to honorable commendation and we regret that an auther of Mr. Steavenson's ability should attempt to detract from his honor by sarcastic references to former investigators who arrived at practically the same conclusion.

Mr. B. H. Thwaite discusses the subject as follows: "The proof that coal-dust disseminated in air is or is not explosive in the absence of marsh or other combustible gas can only be satisfactorily established by a long series of tests with the dust from coals that have varying content proportions of volatile hydrocarbon and varying degrees of physical fineness."

"I believe that, given that coal-dust is sufficiently fine, even if it is pure carbon, or without the least trace hydrocarbon in its constitution, if it is well disseminated throughout the air, and is in explosive proportion to such air, it will certainly be explosive. We have many examples of explosions in flour mills and in the coal bunkers of steamships. It has not been contended that the presence of gaseous combustible associates was the cause of these explosions. If the explosive proportion of carbon coal-dust ratio to the air is low, and this mixture fills long and attenuated roadways in mines, the flame of the explosion will pass along the roadways, but its full explosive energy will not be immediately developed; the explosive action will be in sequential series, and the violence will depend upon the proportion of the suspended carbon ratio to the air in the different parts of the roadway, and upon the character or form or size of the egress for the escape of the explosive flame. In some proportions, as this egress is contracted, the intensity of the explosion will be increased."

"Anyone who has had experience with the working of long flues for the conveyance of combustible gas knows that the explosions occasionally occurring from condensation along the flues act with varying degrees of energy upon the manhole lids, and the action is distinctly sequential."

It will thus be seen that Mr. Thwaite believes that anthracite dust under certain conditions is explosive. There is a possibility of his being correct, but as previously stated, there has never been a coal-dust explosion in an anthracite mine, and some of them are at times so dusty as to make it impossible to see a light ten yards off.

Mr. J. W. Ronaldson, while not disagreeing with Mr. Stuart's theory says:

"I gather that because evidences of force have been found after an explosion to be, not continuous throughout the area affected, but in apparently isolated sections, Mr. Stuart concludes that there must have been a series of explosions, each one isolated from the others. If this is his argument, I cannot accept it as conclusive until satisfied with the proofs in support of his contention."

One of the British Mine Inspectors, in commenting on the lecture, anonymously, in *The Iron and Coal Trades' Review* says:

"There can be no doubt that there are coal-dust explosions, but they require a detonator in the shape of a shot or an explosion of firedamp to start them.

"When once started, it depends upon the dryness of the dust and the amount of air contained in the workings, for immediately an explosion commences, all the supply from the surface is cut off. There are many points needing further examination, such as the quantity of heat evolved and its action in keeping up the flame.

"In this way there may be an explosion in a non-fiery mine by the dust being ignited at a shot.

"I believe that in all the large explosions quoted by the lecturer coal-dust did perhaps nine-tenths of the damage. It follows that when an explosion happens in a *well-ventilated* colliery, the effect is more serious than in one that is badly ventilated, because there is more pure air for combustion.

"Of course, once establish the fact of a dust explosion, the question follows: Why do we allow explosives to be used in such mines? This is a very large question. The present idea is to have a flameless explosive, and there are parties who profess to have discovered such, but I have not seen them yet."

COAL IN ILLINOIS.

THE Report of the Mine Inspectors in the State of Illinois for 1894 has been received from the Bureau of Industrial Statistics of that state. It contains considerable matter of interest, and valuable tables of statistics.

Briefly summarized the Report shows the total output of all grades of coal for the year 1894 was 17,113,576 tons, a decrease as compared with the production of the year 1893 of 2,835,988 tons. The principal cause of this decrease was a strike. This strike produced the usual collateral consequences of all strikes; namely, a considerable increase in the percentages of fatal and nonfatal accidents. The fatal accidents show an increase of 26% over the average number of the previous twelve years, and the non-fatal accidents show an increase of 30% over the average. The Report ascribes the cause of the increase in the number of accidents to the excessively increased number of men employed and the very large percentage of inexperienced men. Naturally this has considerable to do with increasing the percentage of accidents, but another important factor that has been overlooked in the Report is the condition of the mines succeeding long periods of inactivity. During the times the mines are idle the pillars frequently disintegrate to a large extent and the supporting timbers are very much weakened. When the mine is in active operation these causes of danger are noticed before they have gone very far and measures are taken that check the destruction of the roof supports. When a mine is idle for several months the "stitch in time" is not taken and as a result the workings become more dangerous and remain so until a sufficient length of time has elapsed after the resumption of work to enable all the weak points to be detected and guarded against.

Several curious facts are disclosed by the report. For example, the number of machines in use for coal cutting during the year 1894 was 296, or 14 less than were in use in 1893. Coincident with the disuse of 4½% of the machines there has been a loss 13% in the yield of lump coal, and the reduced yield of lump coal occurs chiefly, but not exclusively in the machine mining districts. Machine mining requires a long face and the long face caused the greatest settlement of strata, and crushing of coal, during the period of the strike. When, on the resumption of work the machines were making a smaller yield of lump coal, the casual observer would imagine they were to blame and not the strike. Quoting from the Report on machine mining we have the following: "Machine mining is now virtually confined to the Fourth and Fifth Districts. Here is disclosed the loss and gain in the tonnage of lump coal for five years. This year's production shows a shrinkage of 2,247,615 tons compared with the year before. The Fourth District shows the largest decrease, the First District is next, the Fifth next, the Second next, the smallest being the Third." Here then we see that the falling off in production of lump is the second greatest in the First District, that is intermediate between the Fourth and Fifth, and that the falling off is neither due to hand or machine mining, but to some other cause such as we have mentioned. The number of accident due to falls of roof and sides is, according to all mining experience, here as elsewhere, above 60% of the total number.

The State makes a fairly good showing for the ventilation of mines as 37% of them are ventilated with fans, and including fans, furnaces and steam jets, 62% have artificial ventilation. It is probable that the other 38% are very small workings.

BOOK REVIEW.

MODERN EXAMINATIONS OF STEAM ENGINEERS.—By W. H. Wakeman. 12 mo. Cloth, 300 pages. Price $2.00. Published by the American Industrial Publishing Co., Bridgeport, Conn. This volume consists of a number of articles published originally in *The Manufacturers' Gazette* of Boston. They are compiled in 53 chapters, each chapter being the same as the article appearing in each issue of the periodical. The author has shown in the preparation of the work that he understands the technicalities of the subject on which he has written, but unfortunately he does not go into sufficient detail to make the book all he intended and claims it to be. It is a good work for practical engineers, firemen, etc., but there is a great deal of it that will be unintelligible to the average man whose early education was neglected. Taken as a whole, the book is well worth the price for which it is sold. Its only fault lies in its covering a wide range in too brief a manner, and in treating too briefly on some subjects which cannot be made clear to a man, unless he has a fair knowledge of elementary physics etc.

REPORT OF BUREAU OF LABOR STATISTICS, STATE OF ILLINOIS, 1894.—This report, compiled by Hon. Geo. A. Schilling, Secretary of the Bureau, contains, first an exhaustive report on taxation, with numerous official tables of statistics etc., to prove and exemplify the text, and an elaborate treatise on the evils of and remedies for abuses in the system of taxation. An appendix contains a statistical review of the coal miners' strike in 1894, together with a consideration of the results of the strike; the decision of the Supreme Court of Illinois on the "Sweat Shop Act;" Mrs. Potter Palmer's address at the opening of the Women's Building, World's Columbian Exposition, and Governor Altgeld's address to the graduates of the University of Illinois, on June 7, 1893.

ANNUAL REPORT OF THE SECRETARY OF MINES, PROVINCE OF VICTORIA, 1894. Price five shillings; published by Robt. S. Brain, Government Printer, Melbourne, Australia. This is one of the British "Blue Books," and as one of great value to the mine manager, or mine owner, is well as to the mining community in general. It contains (1) Special Reports, Descriptions of Machinery, etc.; (2) Operations of Diamond Drills in the Province; (3) Statistics. It is splendidly illustrated, and is worthy of rebinding in something better than the usual blue paper used by the British Government. It will be found of great interest to every mining engineer and mining student, not only for its present worth but as a book of reference for the future.

THE YARDLEY FAULT; AND THE CHALFONT ROCK, SO-CALLED.—By Benjamin Smith Lyman. This is an authors reprint from the Proceedings of the American Philosophical Society. The first is a description and discussion of a striking fault exposed at Yardley Station on the Bound Brook Div. of the P. & R. R., and the second describes and discusses the fault at Chalfont, Bucks county, Pa. Both papers are interesting reading for all interested in geology and the study of faults.

METALLURGICAL AND OTHER FEATURES OF JAPANESE SWORDS.—By the same author. This is a reprint from advance sheets of the *Journal of the Franklin Institute* for January 1896. Mr. Lyman, in this instance deviated from his general scientific papers, and prepared a lecture that was more of a popular nature, and exceedingly interesting to all classes. His long experience in Japan, in the practice of his profession, and his familiarity with Japanese customs and methods, together with his observing nature, specially fits him to describe the peculiarities of that wonderful nation in an intelligent and correct manner.

REPORT ON THE VICTORIAN COAL FIELDS.—By James Stirling, Asst. Govt. Geologist. This is one of the British Governments "Blue Books," and treats of the coal fields in the province of Victoria, Australia. It is illustrated by a colored geological map showing the tertiary, volcanic and mesozoic formations, and by a sheet of cross sections. The price of the work is 2 shillings. It is published by Robt. S. Brain, Govt. Printer, Melbourne, Australia.

YEAR BOOK OF THE SOCIETY OF ENGINEERS, UNIVERSITY OF MINNESOTA. This is an illustrated magazine consisting principally of treatises on engineering subjects, in which mining engineering is represented by two articles, one on Systems of Mining in Minnesota Iron Mines, by Chas. D. Wilkinson, and one descriptive of The Ore Testing Plant at the University of Minnesota.

ESSENTIAL PROPERTIES OF BUILDING STONES.—By H. Foster Bain, Asst. State Geologist, Iowa. This is a pamphlet or author's reprint from one of the State reports.

PERSONALS

Mr. Erskine Ramsey, Superintendent of the Pratt Mines Division of the Tennessee Coal Iron and Railroad Co., has been promoted to the office of Assistant General Manager and Chief Engineer of the company.

Mr. Ramsey has been succeeded as superintendent of the Pratt Mines Division by Mr. P. J. Rogers, warden of the Pratt Mines convict prisons.

Mr. Rogers will retain the post of warden in addition to his new office.

Mr. M. G. Moore, Mining Engineer of the Cambria Iron Co., Johnstown, Pa., called on friends in Scranton during the month. Mr. Moore is an old Scrantonian and is always a welcome visitor to his old home.

Mr. David J. Lloyd, of Pawnee, Ill., has broken the Illinois record in shaft sinking. Last spring he started an air shaft for the Chicago and Virden Coal Co., and completed it to a depth of 323 ft. in ninety days. In June he made a proposition to the people of Pawnee, Ill., that if they would advance him some capital, he would locate with them and sink a shaft for coal. His proposition was accepted. After making all his surface arrangements he started to sink on August 25th, and in 65 days cut Seam No. 6 of the Illinois coal measures at a depth of 315 ft. from the surface.

Mr. Wm. Griffith, Mining Engineer, of Scranton, Pa., is preparing a series of articles on Anthracite coal, for *The Bond Record* of New York. The articles will treat of the subject in a comprehensive and authoritative manner, and will contain much information for investors that will prove of great value. Mr. Griffith's experience, his opportunities to gather the necessary data, and his ability to make sound deductions therefrom, ensure the readers of that excellent financial journal, information that will be well worth reading.

The Columbia Calendar.

The Columbia Pad Calendar for 1896 has made its appearance, representing the eleventh annual issue, and handy and convenient as it has been heretofore, the new issue certainly surpasses any of its predecessors. The cycling fraternity, to say nothing of the general public, has acquired a decidedly friendly feeling for the Columbia Calendar, and its annual advent is looked forward to with interest and pleasure. The new Calendar contains a much better arrangement than in previous years, more space having been allowed for memoranda, while a greater charm has been added by liberal illustration and a unique and convenient grouping of dates calculated to meet the hurried needs of business men. The Calendar can be obtained for five 2-cent stamps by addressing the Calendar Department of the POPE MANUFACTURING COMPANY at Hartford, Conn.

Western Penna. Central Mining Institute.

At the annual meeting of the Western Penna. Central Mining Institute, held at Pittsburg, Pa., on the 26th and 27th ult. the election for officers resulted as follows: Inspector Thos. K. Adams was re-elected President; Mr. Daniel Boden of Carnegie, Vice-President; Messrs. William Seddon of Brownsville and J. C. Kyle of Imperial, Secretaries; Mr. Roger Hartley of Pittsburg, Treasurer; Messrs. August Schaner of Wilkinsburg, T. B. De Arnit of Turtle Creek and Roger Hartley of Pittsburg, Trustees.

THE CAPELL FAN.

Its Efficiency, High Water Gauge Obtained, and Durability at High Periphery Speed.

An interesting and important controversy was recently in progress in the columns of *The Colliery Guardian*, between Messrs Wm. Fairley and G. M. Capell, regarding claims made for the Capell fan. Mr. Fairley takes issue with the following statement published in our London contemporary on Nov. 8th:

"The patentee states that the new fan has been successfully introduced into the deep pits of Germany and Belgium working thin seams, and gauges as high as 11 in. and 12 in. have been obtained with it. Mr. Capell also informs us that the volumetric efficiency of the fan has been largely increased by the new form of construction."

We reproduce Mr. Fairley's criticism and Mr. Capell's answer *verbatim*, merely noting that Mr. Wm. Clifford, of Pittsburg, Pa., American manufacturer of the Capell fan states that "a guarantee of 200,000 cu. ft. at 12'' W. G. means that the fan will produce that volume if the mine will pass it at that water guage. In the cases mentioned by Mr. Capell, the quantities were passed at less than the guaranteed water guages."

To the Editor of the Colliery Guardian.

SIR:—At p. 889 of your last issue it is reported that the new type of fan has recently produced a water-guage of 12 in. It may be well to consider briefly what this amount of pressure represents. This force is equal to that generated by a body revolving at the constant speed of $\sqrt{\frac{12}{.000458}} = 161.86$ ft. per second; in other words, 12 in. of water-guage is the result of a fan running continuously at this tip speed, reckoning the machine to be perfect as regards the production of pressure. Fans, however are not perfect in this respect, and do not usually produce more than one-half of the theoretical pressure, but if it be assumed that this new type of machine has a manometrical efficiency of .8, it will be required to run at a speed equal to the theoretical pressure of $\frac{12}{.8} = 15$ in. water guage, and therefore would have to run at a velocity of $\sqrt{\frac{15}{.000458}} = 180.97$ ft. per second. Amongst the records of scores of observations of the work done by fans, no such speed is to be found, so far as the writer knows. Indeed, he considers himself justified in saying that there is no fan in England running at such a velocity, and that it would not be safe to run any of them at a higher tip-speed than 135 feet per second. Again, if the fan producing 12 in. of water-guage has a manometrical efficiency of only .5 (and many fans now running on English mines are giving less than this) it will be required to run at a tip-speed of about 229 ft. per second.—Yours, &c.,

Shafto House, Chester-le-Street, W. FAIRLEY.
11th November, 1895.

To the Editor of the Colliery Guardian.

SIR:—Your correspondent, Mr. W. Fairley, seems to doubt the possibility of running fans to give 11 in. and 12 in. water-guage, and suggests that 135 ft. per second is the limit of safety. I quite agree with him that this is so with ordinary fans not designed for high speeds. The fan at Pluto Colliery, Westphalia, I designed to give 210,000 cubic feet at 14.7 in. water-guage, calculations being made from a Guibal fan on the mine. I designed a fan, double inlet, 15 ft. x 6 ft. The result shows the fan was above its work:—

Revolutions	270
Water-guage	12.5 inches
Cubic feet per minute	240,000
Horse-power in the air	472
Periphery speed	213 ft. per second.

The first high-guage fan in Germany was at Prosper I. Colliery. I designed this (old style) 12.3 ft. x 6 ft. It gave us:—

Revolutions	323
Water-guage	10.7 inches
Cubic feet	127,000

Since that time I have had numbers of fans running at 8 in., 9 in. and 10 in. water-guage, without difficulty or danger, and all above 135 ft. per second. I have seen accounts of fans by a French maker, 8 ft. 4 in. diameter, giving 30 in. water-guage in steelworks, and running over 300ft. per second, with about 10,000 cubic feet per minute. There is no difficulty in meeting these speeds by proper construction, and I expect in the near future to have mine fans working under 400 mm., say 16 in., pressure. Experience shows it is far less costly to put up an economical engine and a high-pressure fan than to attempt to enlarge the airways in mines working far from the shafts. Facts are stronger than theory. There are the fans working and to be seen, and if theory does not like—why, so much the worse for the theory.

Another mine, General Blumenthal, also in Westphalia, has recently put down my 13 ft. 4 in. double fan. The guarantee was 200,000 cubic feet, at 12 in. water-gauge, and the result was:—

Cubic feet per minute	224,000
Water-guage	11.25 in.

The design of the fan in these high gauges is most important, and I need hardly say I have made a special study of it. The age of wooden blades and cast iron is over for fans. The Siemens-Martin steel has given a new power to all modern ventilators, and high speed is no longer the bugbear it was twenty-five years ago.

Yours, &c.,
Passenham, Stony Stratford, G. M. CAPELL.
November 20, 1895.

To the Editor of the Colliery Guardian.

SIR:—Mr. Capell has the writer's best thanks for his letter of the 20th inst., which appears on page 985 of your last issue. At the outset the writer had the belief that there are no such water-guages as 11 in. or 12 in. in England, because: first, such pressures are always associated with small equivalent orifices; and second, because it would not be safe to run the machines fast enough to generate this pressure; and as yet he cannot get far away from this opinion. So far as the writer knows, the equivalent orifices of the mines of England vary, say, from about 16 to 52 square feet—in rare cases there being some smaller and some larger. The highest water-guage on an English mine which the writer has noticed is recorded on page 223 of the *Transactions* of the North of England Institute of Engineers. In this case the reading was 5 in., the quantity of air 99,000 cubic feet, from which it will be seen that the equivalent orifice was 17.18 square feet, which for an English mine is comparatively small. The comparative smallness of the equivalent orifice is, according to the writer's observation, a characteristic of Continental mines, although in the examples referred to by Mr. Capell they have a comparatively good area. From the data supplied in Mr. Capell's letter, the equivalent orifices of the three cases cited work out to (1) 26.38 square feet for Pluto mine; (2) 15.06 for Prosper I. mine; and (3) 25.92 for General Blumenthal mine. The writer's intention, in his letter of the 11th inst., was to show the high velocity required for twelve inches of water-gauge, which is, in his opinion, unprecedented in English practice. The manometrical efficiency of the fan at Pluto works out to .60; that of the machine at Prosper I. to .53. If Mr. Capell's fan will stand working continuously at the high velocity required for a pressure equal to twelve inches of water, then he is to be congratulated on the success he has achieved.—Yours, &c.,

Shafto House, Chester-le-Street, W. FAIRLEY.

THE CARE OF BOILERS.

Some Important Facts of Vital Importance to Boiler Users.

Through the courtesy of Mr. Albert H. Cary, engineering manager of the Abendroth & Root Co., of New York, we are enabled to give our readers some important facts regarding the use and care of boilers. These facts were brought out by expert testimony in a suit brought by the Phila. Edison Electric Co. against the Abendroth & Root Co., and a counter suit brought by the latter company against the former. It appears that the Abendroth & Root Co. sold the Phila. Co. some 3,500 H. P. of boilers, on four different contracts, each of which followed the other at short intervals. The first suit brought was to recover $34,000 from the Abendroth & Root Co., on the allegation of the Phila. Co. that a series of troubles and finally a fatal accident, were due to bad workmanship, bad material and faulty design in the boilers, and also due to the contractors failing to comply with all the articles agreed upon in their contract. The countersuit brought by the Abendroth & Root Co. was for $6,830.99 due on the contracts and for additional materials furnished.

The Abendroth & Root Co., succeeded in the first place in establishing the fact that they had lived up to every article of their agreement, and had even done more than they agreed to. They also proved that they had used the best material obtainable in the market.

The suit was tried before Judge Wheeler and a jury, in the U. S Court in Brooklyn and a verdict was rendered in favor of the Abendroth & Root Co., for the amount of the countersuit.

In this connection it is interesting to note that the greatest number of breaks occurring in these Edison boilers were reported to be in the item of bolts; and as it is a natural conclusion that the greatest breakage will occur at the weakest point, it was necessary to establish by evidence the fact that these bolts were equal, if not superior, to anything to be found in the market. When these bolts broke, in almost every instance a curious phenomenon occurred. At the point of fracture, the metal, instead of being contracted to a smaller area than that of the bolt itself retained the original size and area, showing no contraction whatever, but breaking sharply and squarely in a similar manner to a pipe-stem. This caused the question to be raised as to whether crystallization had occurred, and to determine this point, many of these bolts were taken to a steam hammer and flattened out cold to less than ¼ of an inch in thickness. In every instance the flattening was done without the slightest show of fracture running up into the body of the bolt, whereas if crystallization had taken place at the point of rupture the metal would necessarily show brittleness and breakage similar to the action of a piece of cast iron similarly treated. Another test applied to many of these bolts was to bend them double when cold so that the two ends met, and this also proved the excellence of the quality of the bolts. In order to show that no effort had been spared to improve the quality of the material used, other bolts made of the best rivet iron, were substituted in the place of the original ones, but all such bolts were fractured in identically the same manner, and a still further trial was made with steel bolts, which were affected with the same results. In order to make this breaking point test still stronger, ⅞'' bolts were substituted for the ¾'' bolts, but with no better results. Beyond this, the shape of the head, and also the shape of the lug which received the head of the bolts, were changed in every conceivable way, but all to no avail, as the fracture of bolts continued in this almost unaccountable manner, whereas fracture in the other parts of the boiler was very infrequent indeed. It follows that no better evidence could be furnished or was needed that good material was used throughout.

It was also proved that the workmanship on the boilers was first class, and that the workmanship and design of the boilers was not at fault was proven by the fact that similar boilers, made under exactly similar circumstances, used in other plants, had never acted in a manner similar to those in question, and it therefore followed that the trouble was due to local causes. It then became necessary for the manufacturers to prove what these conditions were, and this portion of the evidence is of interest to every power user.

It was proved that the accidents were due entirely to the unreasonable handling of boilers by the Phila. Co. It was shown that the boilers were frequently forced far beyond their rated capacity, and this rating was sometimes exceeded as much as 100% and over. It was also shown that unskilled labor was employed, and such employees had instructions to keep steam up to the required pressure, irrespective of any demands that might be made on the boilers, so as to keep the lights going which the Phila. Co. had contracted to supply.

One of the very important matters brought to light in this case, and acknowledged was the use of extremely bad feed-water. It seems that the Phila Co., sunk a well beneath their station, and this was the only water they used to supply their station. This water, as was shown by the analysis presented during the trial, contained not a small amount of sewage, and ran thirty-four grains of impurities to the U. S. gallon, almost eight per cent. of these impurities being proved to be sulphate of lime, while salt existed in appreciable quantities, and also a number of nitrates and ammoniacal salts. This water was what might be called the surface drainage of the City of Philadelphia, and as the city has unfortunately, a very poor sewage system, this drainage amounts to what might be regarded as sewer water which had undergone a certain amount of filtration in the earth down to the imprevious strata along which it ran and finally collected in this well. In order to counteract the bad effects from this water, no small amount of chemicals was used. These were changed at times, and finally the Phila. Co. seemed to settle down on the use of cutch, or what is more properly known in chemistry as Catechu, which contains a considerable quantity of tannic acid. In the storage tank located above the boilers large quantities of caustic soda were also put in the water, making so strong a solution that water dripping from it would take the hair off of the horses that passed beneath it, also inflicted serious burns upon the workmen who were so unfortunate as to catch a sprinkle. The result of the use of this bad feed water was naturally shown in the collection of a large amount of scale in the tubes, varying in thickness from $\frac{1}{16}$ of an inch to one inch, and thereby closing down very materially the area of the tube opening. The chemicals used attacked the metal parts of the boiler and oozed through the joints thus attacked so as to form incrustations, which had at times almost entirely covered the bolts and bends. The incrustation proved so hard that the workmen were obliged to use a hammer and chisel to remove it. This state of affairs caused a rigidity of parts which were designed to be flexible, and it also caused the unnecessary burning out of many of the tubes.

Another very important point established by the evidence was that an excessive forced draft was used in order to drive the boilers to the unreasonable extent to which they were used, and evidence showed that this draft was sufficient at times to support a column of water from three to four inches in height.

Several well-known experts appeared in this case and accounted for the various troubles above enumerated. One of the most interesting points developed was the production of water hammer in the tubes of these boilers, which was explained in the following manner: It is a well known fact that every pipe or tube has a definite capacity of discharge, and when this capacity is reached no more water or steam can be delivered through an opening of such an area; so that in case a larger discharge is required, a larger tube must be used. In driving these boilers to such an excessive extent, in the course of natural circulation the water and steam passed up along the inclined tubes to the front headers and there advanced upward into the overhead steam and water drums from which the steam was delivered to the piping system. When the circulation reached a point equal to the capacity of the tube, of course, no more steam or water could be discharged from that upper end of the tube, but as the heat still continued to be applied around the tube, more steam was generated, and of course the pressure of this steam in the tube forced the steam and water back down the tube until it reached the rear header and here the steam suddenly had a chance to escape upward by the course of the rear headers to the overhead steam and water drums, and the colder feed and circulating water trying to enter the lower end of the tubes from these same rear headers came in contact with the steam thus seeking passage of escape. The result was a sudden condensing of the steam which was followed by a rush of water into the vacuum at an exceedingly high velocity, and this water rushed along the tube at about this same velocity until it reached a bend at the end of the tubes. The result was a very sudden and powerful blow there, practically like that of a cannon ball, which caused the bolts to rupture in the manner above described, breaking them, in fact, so rapidly that a flow of the metal composing them at the point of rupture was impossible.

This flow necessarily would take a certain amoun time. The consequence of this sudden blow was exhibited in the breakage of these bolts without contraction of area at the point of rupture. It was remarked during the course of the trial that it was fortunate that these boilers were composed of small headers covered by small castings known as connecting bends, and that thus the damage done affected merely these small castings, producing the local results instead of rupturing large castings, which would, of course, be attended by far more serious ruptures. Glass models were shown at court which illustrated beautifully the theory thus presented, and in such a manner as to carry conviction to the minds of the Court that this was the true theory of the disastrous occurrences. Other glass models illustrated the irresistible power of the water hammer, the force of which was sufficient to break the tubes, which held the water surrounded by a vacuum.

THE PROGRESS IN MINING.

ABSTRACTS FROM THE PROCEEDINGS OF THE MINING SOCIETIES

And Journals of Europe and America, Illustrating the More Modern Developments in all Branches of the Mining Industry.

Notes on Mining in Portugal.—In a paper recently read before the Mining Institute of Scotland, Mr. Robert Fisher said:

Very little has been done in Portugal in connection with coal mining, not because the country is destitute of coal, but largely on account of the protective policy of the Government, which imposes heavy duties all round, thereby crippling industry and discouraging enterprise. There is little doubt that a systematic and thorough exploration of Portugal would lead to the opening of coal and other mines, to the material benefit of its trade and commerce. There are three distinct coal deposits in Portugal. In the north, near Oporto, anthracite coal of good quality occurs, but it is often so mixed with shale as to render the working difficult. The principal mines are:—St. Pedro da Cora, Passal de Baioco, Covello, and Midors Pegus. The large coal extracted from these mines is used in Oporto in cooking ranges and stoves, and the small coal is made into briquettes for the same purpose. Near Busaco, at Santa Catherina, there are seams of a semi-bituminous coal, but they are not now being worked. Near the town of Batalha, which is situated sixty miles north of Lisbon and twelve miles south of the Oporto and Lisbon railway at Leiria, there is a coal-field extending to 1,200 acres, where the outcrops of several seams of coal have been located, and a few drifts made to prove them towards the dip. Two adit levels, about a mile apart, have been driven into the breast of a range of hills several hundred feet high. No. 1 mine, near Batalha, cross-cutting to the dip, has intersected four coal seams. The first seam lies at an inclination of 49 degs. towards the east, whilst the others are inclined at from 25 degs. to 30 degs. towards the west. The first coal seam, 6 in. in thickness, of good quality, and having hanging and foot walls of hard blue clay, does not appear to form one of a series of stratified beds overlain unconformably by the other beds, but strikes across the strata. Possibly it may be in the line of a dip fault. The other seams have the following sections:—

No. 1 coal seam.	Ft.	in.	No. 2 coal seam.	Ft.	in.	No. 3 coal seam.	Ft.	in.
Marl roof.			Shale roof.					
Coal	0	6	Coal	1	4	Coal	1	0
Shale	1	8	Marl	0	5	Shale	1	0
Coal	1	4	Coal	0	8	Coal	0	8
Shale	1	0	Clay	0	8	Fireclay pavement.		
Coal	0	8	Coal	0	2			
Fireclay pavement.			Fireclay pavement.					

The coal in these seams has the appearance of lignite rather than coal of the Carboniferous measures. The proportion of sulphur and ash is high, and altogether the coal is of little commercial value. Galleries have been driven for a short distance in these seams where the mines intersect them, and there are indications of improvement in thickness and quality towards the dip. No. 2 mine at Alcanada intersects No. 2 seam, into which a dook or dip drift has been driven for a distance of about 90 ft. Another adit mine is being driven at a lower level to intersect the three coal seams and clear the dook of water. In section, inclination and quality these seams are similar to those at Batalha. The small output of the Batalha mines was within the past year, sold at 1,000 reis per cubic metre when the rate of exchange was 5,660 reis per £1. The coal was riddled at the entrance to the mine and the dross carried in baskets on the heads of women to a hand-power washing-machine worked by a woman. Women were paid from 5d. to 6d. per day. The water was directed by means of a dam and mill-race, part of the latter being steep. At this point a woman shovelled the small coal into the current, which carried it into the machine; the washed dross was discharged over the mesh into a basket, which, when full, was emptied into the heap. The dirt was similarly treated; a small shutter fixed at the top of the shoot prevented it from getting out—until discharged when almost filled up to the level of the washed dross. In the vicinity of Porto de Moz, six miles south of Batalha, may be seen a coal seam 3 ft. thick, with sandstone roof and hard fireclay pavement, dipping 25 degs. to the north-east towards the mountain limestone range of hills, at the base of which the coal seam is exposed. Underlying it are beds of laminated blue shale with ironstone balls, limestone beds from 2 ft. to 10 ft. thick, as shown below:—

	Ft.	In.
Sandstone roof.		
Coal	3	0
Clay and ironstone balls	50	0
Limestone	6	0
Shale	7	0
Limestone	2	0
Clays		

The fossils found in connection with the limestone beds comprise corals, shells, and encrinites; but even with their aid it is difficult to determine whether these beds belong to oolitic or carboniferous measures.

The total imports of coal and coke into Portugal in 1892 and 1893, were as follows:—

	1892.		1893.	
	Tons.	Value (£).	Tons.	Value (£).
Coal	603,696	535,527	418,328	367,060
Coke	13,060	10,628	6,342	8,228

The decrease occurring in 1893 is attributable to the strikes in England, and consequent high prices asked for fuel during that time; and the increase in the manufacture of patent fuel in Portugal, partly from coaldust imported from England and partly from Portuguese coal. This fuel is taking the place of English coal to some extent at mills and other factories, and coal from the North of Spain is also being introduced.

Notes on the History of Coal Mining in Scotland.—These notes are copied from the journal of the British Society of Mining Students, and are the work of Mr. Walter H. Mungall, B. Sc.

At an early period in the history of the British coal trade the coal-fields of Scotland seem to have been known and to have received some attention, although there is little documentary evidence of the extent of the operations. Much of the early history of coal mining is associated with the history and deeds of the monks who occupied the various monasteries then established throughout the country, and some of their writings throw a little light on the infancy of the coal trade. Thus, among the earliest legal documents that have been preserved, in which there is reference to this industry, is a Deed of Conveyance from the Earl of Wfnton to the monks of Newtattle, of a piece of land in the neighborhood of Dalkeith, containing a stone quarry and a coal mine. This document, written about the year 1210, is significant of the fact that prior to that date coal mining operations had been carried on in the Lothian coal-field.

About the beginning of the seventeenth century fresh difficulties arose, and the fears that had been entertained half a century earlier seemed now to be almost realized. The supply of coal from parts that were easily accessible was now well nigh exhausted, and to maintain a supply equal to the demand that had arisen, it became necessary to work the coal that lay at greater depths. The new difficulties now to be encountered soon became apparent, and of these, not the least considerable was the difficulty of dealing with the water that was found in greater abundance than formerly. Where the situation of the mine and other local circumstances were favorable, this was overcome by driving level tunnels or adits from the lowest part of the workings across the strata till the surface was reached. Through these tunnels, or "Day Levels" as they were commonly called, the water flowed from the workings and discharged into some river or stream. In the case of mines less favored by local circumstances some mechanical appliance had to be resorted to for unwatering the mines. Probably the earliest form of mechanical contrivance for this purpose was the rag-and-chain pump, which consisted of a column of pipes through which an endless chain, with bunches of rags or other material attached at short distances apart, passed. These somewhat primitive pistons, ascending in the pipes, carried the water before them and it was discharged at the top. Motion was given to these water-raising machines by horses, wind-mills, or water-wheels where they could be applied. An improvement on this form of pump was the Egyptian wheel—a sort of dredger or bucket elevator. One of these wheels was erected by Sir George Bruce when re-opening his some-time abandoned colliery at Culross, near Dunfermline. Sir George, being a man of no mean ability, and having a knowledge of machinery "such like as no man has in these days," his colliery soon became renowned, not merely in the immediate neighborhood, but throughout the district. There were two shafts at the colliery, one on the shore and the other near low water mark, protected from incursions of the sea by an artificial embankment. His water-raising machine, consisting of thirty-six buckets, was placed at the pit on shore, and was actuated by three horses.

About the middle of the seventeenth century the collieries in the neighborhood of Culross were the most important in the district, and in 1663 "considering that several questions and debates do arise betwixt the buyers of Coal and the Customers and Receivers of the Bullion anent the measure of the Chalder" the measure then in use at these collieries was made the standard measure for coal.

The first pumps, apart from Egyptian wheels and earlier contrivances, that were introduced into the pits of Scotland were erected by the then Earl of Mar at his Alloa collieries.

A system of serfdom continued till, in 1775, parliament decreed that no person shall be bound to work in the mines, in any way different from common laborers, and under certain restrictions, liberated the collier from bondage after a given time, but his emancipation was not completed till the restrictions were removed by a further act in 1799. Females and children, however, still continued to find employment in the mines, and it was not till Lord Ashley's famous Bill became law, that the bearing system in Scotland was doomed to extinction, and the labor of young persons became regulated by statute. In carrying coals along the roadways and up the ladders in the shaft, the common load of a woman was from 200 to 240 pounds, while girls and small boys carried single blocks of coal, proportionate to their strength. The coals were carried in wicker creels or baskets fitted to the back and steadied with a strap across the forehead. In reporting on a colliery in Midlothian in 1830 where this system was then in operation the late Matthias Dunn says: "The bearers find their own lights and creels, and are hired at from 10d. to 14d. per day, by such of the hewers as are not fortunate enough to possess wife, sister, or daughter, the necessity of which tends to constant and early intermarriages amongst each other, and is attended with utter want of domestic comfort." To quote from a letter written in 1851 by Robert Brown, factor for the Duke of Hamilton: "Muscular strength in a female, not beauty, was the grand qualification by which she was estimated, and a strong young woman was sure of finding a husband readily. There is an old characteristic Scotch saying 'She's like the collier's daughter, better than she's bonnie,' proving the value put upon the description of female excellence."

The condition of the collier boy at the time of the passing of the Act of 1842 may best be described in the words of Wingate, the collier poet, who at the same time makes an appeal on his behalf.

> He's up at early mornin', howe'er the wind may blaw,
> Lang before the sun comes roun' to chase the stars awa';
> And 'mang a thousand dangers, unkent in sweet daylicht
> He'll toil until the stars again keek through the chilly nicht.
>
> See the poor wee callant 'neath the cauld, clear moon,
> His knees out through his troosers, and his taes out through his shoon;
> Wadin' through the freezin' snaw, thinkin' o'er again
> How happy every wean maun be that's no' a collier wean.
>
> Oh! ye that row in Fortune's lap, his waefu' story hear
> Aft sorrows no' sae deep as his ha'e won a pitying tear;
> And lichter wrangs than he endures your sympathy ha'e won
> Although he is a collier's, mind he's still a Briton's son.
>
> And ye wha mak' and mend our laws, tak pity on the bairn;
> Oh! bring him sooner frae the pit and gi'e him time to learn,
> Sae shall ye lift him frae the mire 'mang which he lang has lain
> And win a blessing frae the heart o' every collier's wean.

From this time onwards the social condition of the collier population has steadily continued to improve; their hours of labor have been shortened, their vocation has been rendered less dangerous, they receive good wages, and have many opportunities for self improvement which were unknown not many years ago. From being in a state of bondage at the beginning of the beginning of the century, the collier has risen to a state of liberty and independence not enjoyed by any other class of workmen. In many cases, especially in the east of Scotland, he occupies his own house, and in some of the thriving mining villages a large proportion of the houses belong to private individuals of the mining class.

Coal Mining at Hanover.—The following is copied from the *Colliery Guardian*:

The coal mining industry of Hanover dates back as far as the fourteenth century. With the exception of the mines in the coal measures of Piesberg, near Osnabruck, the operations are confined to the exploitation of the thin coal seams occurring in the Wealden formation at the north-eastern flanks of the Deister Hills, at the Suntel and at the Loccum Hills, near Rehburg. Notwithstanding the small number of seams and their thinness, the industry has attained considerable importance, and at the present time more than 4,000 miners are employed.

At the Deister mining is carried on partly by the Prussian government and partly by private capitalists. The government mine is the most important. It is worked exclusively by adits. The only workable seam dips 8 to 12 degrees, and has a maximum thickness of 16 to 25 inches. It has been worked for a length of six miles. At the present time there are four adits in use at different levels. The first or Kloster adit was driven in 1853, and encountered the seam at a distance of 4,750 ft. It is used for horse-haulage, the horses hauling twenty wagons, each holding a ton of coal. The output amounts to 200,000 tons annually or about 650 tons per shift. The work of the Kloster adit section is carried on by 1,240 men. The second, or Hohenbostel adit, was driven in 1834 in the north-western portion of the mine. At the present time 220 men are employed in this section, the output being 35,000 tons. At this adit there is a coal-screening and washing plant. The coal is run down an incline at the surface and conveyed by a tramway two miles in length to the loading station at Barsinghausen. The third or Egestorf adit in the south-eastern portion of the mine, has an output of 40,000 tons and employs 230 men. It is in connection with the Egestorf station. The fourth or King William adit is situated furthest to the east and affords access to a mine purchased from Baron Knigge. The daily output is 60 tons, which is used for local consumption; and 150 men are employed.

Besides these, there are numerous older adits which in some cases have to be kept open for draining the workings. A dislocated portion of the seam at the Kloster adit section is worked by a shaft in the Bullerbach Valley, which serves to raise the mineral 102 ft. to the adit, as well as to ventilate the workings. No mechanical ventilation is used, fire-damp fortunately not being met with. The seam is worked longwall, and the mineral is trammed in trucks holding 5 cwt. to the main haulage level, and thence, in the wagons mentioned above, to the surface. The seam is extremely variable in its character. It is rarely quite pure, the partings being frequently so thick as to render it questionable whether the seam is worth working. The sandstone roof is very firm, and consequently but little timbering is required. The amount of coal wrought per man per shift is calculated at 0.56 tons. Altogether 1,850 men are employed, and the annual production is 297,000 tons.

As the working by means of adits must naturally soon came to an end, the sinking of a deep shaft has been begun. The shaft which is 21 by 13 ft., has attained a depth of 400 ft.

The western neighbor of the Government mine is that of the Bantorf Coal Mining Company. Here 500 men are employed, and the annual production is 115,000 tons. From the Antonie winding shaft, levels are driven at a depth of 280 and 500 ft., the seam being worked by the longwall method. The output per miner is 0.75 ton per shift. East of this a small mine is worked by forty-eight men. It was formerly worked on a much larger scale, but the poor quality of the coal and the difficulty of disposing of the output, prevent its development. This is also the case with the Bredenbeck-Steinkrug Colliery, where coal is mined by seventy-five men for supplying Baron Knigge's limekilns.

The Government mines at Osterwald and Nesselberg are of greater importance. Some 220 miners are engaged, and the annual output amounts to 20,000 tons. Three seams are mined, averaging 18 in. to 2 feet. The main shaft is 300 ft. deep, and the longwall system of working is employed. The coal obtained is used chiefly in the sugarworks, glassworks, and brickworks of the vicinity. Near Munder, coal mining was formerly carried on on a large scale, but on account of the distance from the railway the works were abandoned at the beginning of this year.

There is an old colliery at Loccum Abbey, where a 9 in. seam has been worked since the beginning of the century. Notwithstanding the thinness of the seam, the coal realizes a good price, and with fifty miners employed, the leaseholder is able to carry on the work at a profit. The seam dips 3 to 8 degs. southwest.

The Obernkirchen Colliery is owned by the Prussian Government and by the Prince of Schaumburg-Lippe. The seam averages 13 in. in thickness. It is worked even where it is only 9 in. in thickness. The dip is 3 to

7 degs. northeast. The coal is very variable in its character ranging from gas coal to smithy coal. There are thirteen shafts serving for winding, ventilation and pumping, their depths varying from 200 to 600 ft. The longwall system is employed. The output per man per shift is 0·5 ton. The annual production is 240,000 tons, and 1,620 miners are employed. Special attention has to be paid to the ventilation, as large quantities of firedamp are met with. At the colliery there is a coal-washing plant, and a coke oven plant in which 35,000 tons of coal are coked annually yielding 20,000 tons of heavy and 5,000 tons of light coke. For coking there are thirty-two open Meiler ovens, the so-called Schaumburg ovens, in which the heavy coke is produced, and twenty-four closed Smet coke ovens, which yield as a specialty the Schaumburg coke, a very light, spongy, porous coke, much prized in the metallurgy of copper. The coke-works are connected with three of the shafts and with the Hanover-Minden main line by a branch railway of normal gauge.

Turning to the coal of Carboniferous age, we find that the old st seat of coal mining in the province of Hanover is the Piesberg, near Osnabruck. Originally belonging to the Cathedral, the colliery was transferred to the town in 1568, and in 1889 the civic authorities handed it over to the Georg-Marien Ironworks Company. The coal is an excellent anthracite, with a specific gravity of 1·6 to 1·7. There are four seams, with an aggregate thickness of 10 ft. Both pillar-and-stall and longwall methods of working are in use. Up to 1872 mining was carried on by means of adit levels. Now, however, the Stuve shaft in the northern portion of the anticlinal has been sunk to a depth of 700 ft., and the Hase shaft in the south to the depth of 200 ft. The Stuve shaft is equipped with two Woolf pumping engines at the surface and two tandem engines underground. The Hase shaft has an underground compound engine as well as one at the surface. The output, 600 tons daily, is brought to the surface by endless chain haulage along the Hase adit level. At the mouth of the adit there is a new coal-washing plant capable of treating seventy-five tons a day. In addition to the Piesberg anthracite mine, the company also own a small bituminous coal mine at Hilterberg. There are two seams, each 20 in. to 35 in. in thickness, separated by a parting of 5 ft., dip 60 to 70 degs. north. The seams are however, much dislocated by faults. The deepest workings are now 480 ft. below the surface. The coal is a very good gas coal, used exclusively in the gas-producers and in the brick-kilns at the Osnabruck steelworks. The colliery is connected with the Osnabruck-Brackwede Railway by an aerial wire ropeway.

In addition to bituminous coal, brown coal is largely mined in the province of Hanover. It is mostly referred to the lower Eocene period. At Delliehausen, in the Sollinger Forest, four seams occur of one to four yards thickness, associated with fireclay and quartz-sand, which is used for glass manufacture. The brown coal is wrought partly by mining and partly by quarrying; altogether 200 men are employed. The greater portion of the output is made into briquettes. In 1894 the mine produced 60,000 tons of brown coal, the amount of briquettes manufactured being 13,000 tons. At Duderode three seams of Miocene brown coal are worked. The top one is 5 to 8 yards thick, the second 2 ft. to 2 yards thick, and the bottom one 15 to 18 yards. While the material of the two upper seams is earthy and poor, the third contains a large proportion of lignite and bitumen. As brought from the mine, the brown coal contains 47 to 51 per cent. of moisture. The dry coal contains 48 per cent. of combustible gas. Safety lamps have consequently to be used in the workings. The output in 1894, with eighty miners employed, was 8,400 tons.

Atmospheric Pressure as Affecting Mine Explosions.—*Colliery Explosions and the Barometer.*—The members of the South Wales Colliery Officials' Association have been considering, at some of their recent meetings, the influences of meteorological changes upon colliery operations, and particularly the connection, if any, between fluctuations of atmospheric pressure and firedamp explosions. Opinion on the latter question, says the *Newcastle Chronicle*, has undergone many changes during the past few years. It was originally believed that escapes of gas were most likely to occur when the barometer had fallen suddenly to a low level. Experience has, however, shown that many colliery explosions, perhaps the majority, have occurred when the barometer is high, and conditions are what the meteorologists call anticyclonic. This has led some experts to the conclusion that fluctuations of atmospheric pressure have nothing to do with the causation of colliery explosions. But when we remember the important part which coal dust is now admitted to play in these disasters, that dust is most dangerous when dry, and that the air of an anticyclone is usually very dry, it is evident that dusty mines may be most dangerous in anticyclonic conditions, and the rise of the barometer to an abnormally high level may convey a useful warning. Yet anticyclonic airs are not invariably dry, nor, when they are, need they necessarily affect the atmosphere of a pit; for they may become more or less damp in the course of their journey to the workings. The question is not one upon which those who have studied it would care to dogmatize. But, on the whole, it seems probable that there is some connection between barometric variations and colliery explosions; that this connection is indirect rather than direct; and that it is due not so much to the hygrometric state of the atmosphere as to the production of earth tremors by the removal of weight from the earth's crust, or the reverse. The late Mr. R. A. Proctor, the astronomer, some years ago calculated the weight removed from or imposed upon a certain area of land during the rise or fall of the mercury by an inch. The figures were rather startling. Miners are well advised to study the bearings of meteorological changes upon their calling, but they would render the investigation of greater value if they were to make it include a systematic observation of the minor earthquakes which are constantly taking place. It may not be generally known that a movement is on foot to secure reliable records of British earth tremors by a band of volunteer observers, just as a similar band of observers furnish reliable data concerning the rainfall. The leader of the movement is Mr. Charles Davison, 373 Gillott Road, Birmingham. If those interested in the matter will communicate with him, he will, we are sure, gladly send copies of his hints for observing an earthquake.

Inflammable Gases in Quarries.—From the French *Annales des Mines*, we copy the following:

M. Oppermann, Ingenieur-en-Chef des Mines, has for several years noticed sudden disengagements of inflammable gas in the underground quarries of fire-clay at Bollene; but he states that this phenomenon, very rare and irregular, only occurs in the neighborhood of old workings, incompletely gobbed, while it always denotes the proximity of cavities in which the gas accumulates under pressure. When these cavities are broken into by driving, the gas escapes, and forms, with the air, a mixture which explodes in contact with flame, and often causes serious accidents. Similar facts have been described by M. Humbert in connection with the clay pits of Vanves and Malakoff, in the French department of the Seine, and also by M. Roberti-Lintermans in connection with the underground quarries of plastic clay in Belgium. The gases thus disengaged are hydro-carbons, among which *formene* or *methane* predominate. As regards the origin of these substances, it is observed that fire-clay does not contain organic matters, the decomposition of which can generate such gases, which, moreover, do not issue from great depths, as the compact clay mass is but little permeable. It is true that seams of lignite are found in the beds of white sand which separate the clay strata; but this lignite is too poor to disengage hydro-carbons. The fact that the gas always proceeds from old workings, in which there exist timber supports, had been noticed, and it was concluded that the gas is generated by decomposition of the wood. It has long been known that cellulose, which enters largely into the composition of wood, is susceptible of fermentation, and under the influence of *bacillus amylobacter* it decomposes, while giving off carbonic acid, formene and a residuum rich in carbon. As a rule, all vegetable matter left in contact with water undergoes a series of transformations which lead to the production of hydro-carbons. M. Leon and M. Leproux, ingenieurs des mines, have noticed, in many colliery of the Loire basin, disengagements of inflammable gas, caused by the fermentation of timber, which has remained under water for a long time, when the mines have been drowned, and this in collieries where the seams worked never give off fire-damp. M. Ledin recorded numerous similar cases which occurred in metalliferous mines, observing that if collieries have only been seriously troubled with fire-damp in recent times, this fact must be attributed to their development not being so ancient as that of salt and metalliferous mines.

Electricity in Mines.—The following is taken from the *Electrical Engineer*: The advantages inherent in the electric explosion of mining charges will be generally recognized. It permits of an absolutely simultaneous explosion of several charges, which is always desirable from the point of view of the destructive effect produced, and at the same time it avoids the loss of time brought about by consecutive discharges, particularly when they have to take place in badly-ventilated workings, from which the smoke and gases produced by the explosion can only be cleared out very slowly. Besides, there is no danger from miss-fires, and the workings can be immediately approached without fear of the delayed explosion, which is always a possibility with powder fuses. Moreover, there need be no danger from fire-damp, or from the act of firing the fuse. All these reasons, M. P. F. Chalon, writing in *L'Electricien* of October 5, thinks, will favor the use of electric fuses. Unfortunately, however, they are very expensive. In France, wire fuses cost 300 fr. a thousand, and the discharging apparatus comes to 400 fr. or 500 fr. High-tension or spark-dischargers are a little more economical, but it is not easy to determine previous to the explosion whether they are in perfect order, and it is necessary that the insulation of the conductors should be absolutely perfect. M. Chalon then goes on to describe a cheap American discharger, which he strongly recomends for adoption in fiery workings in French collieries. The discharger consists essentially of a magneto-electric machine driven by a rack and pinion, so that the action is very much like that of a garden hand-pump, an intermediate gear being provided to give the necessary speed. A discharger of sufficient size to produce twenty or thirty simultaneous explosions weighs 13 kilogs. (about 28 lb.), including the strong wooden case. It is designed to work with fulminate detonators up to a distance of about 500 yards. It is tested by connecting up to the terminals a small specially constructed incandescent lamp. A separate apparatus is required to test the fuses and line. A current is sent through the line, not strong enough to heat the wires of the fuses, but sufficient to ring an electric bell if the circuit is in good order and complete. An arrangement is provided for adjusting the current to the number of fuses in circuit.

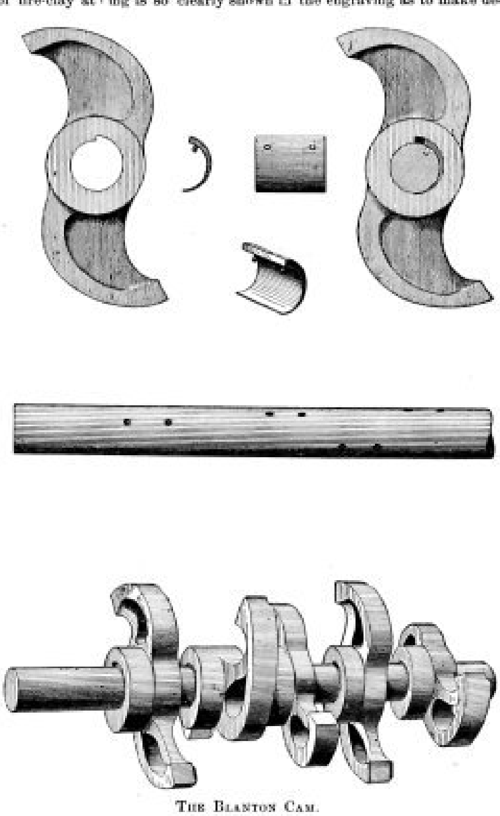
The Blanton Cam for Stamp Mills.

A device recently introduced by Frazer & Chalmers of Chicago, by which the changing of cams on stamp mills is greatly facilitated is illustrated in the accompanying engravings.

The difficulty of removing worn out cams from shafts when the cams have been secured in the ordinary way is too well known to mill men to be dilated on here, and it was to avoid this trouble that the cam and fastening herewith illustrated, known from its inventor, as the Blanton, was devised.

The construction and operation of this cam and fastening is so clearly shown in the engraving as to make de-



THE BLANTON CAM.

tailed description superfluous. It is the work of but a few minutes to remove or renew any cam and such can be easily done without taking the shaft to a machine shop.

The expense of refitting mills with these stamps is comparatively slight. A slight "backing" of the cam on the eccentric-shaped wedge and the cam is easily removed. Messrs. Frazer & Chalmers have had a large demand for these cams both on new stamp mills and for refitting old ones, and their use bids fair to become general.

Cableways on Chicago Drainage Canal.

The Chicago Main Drainage Canal is to-day probably the most interesting engineering work being carried on in the world, and is an interesting exposition for contractors machinery. The visitor to this canal is at once impressed by the great number of travelling cableways. As built by the Lidgerwood Manufacturing Co. of New York, they are to be found on nearly all the rock sections on the canal. On section two, McArthur Bros. use two cableways; on section three, the Des Plaines Cons. Co. use four; on section four, McArthur Bros. use two; on section five, the Qualley Cons. Co. use two; on section six, Mason, Locher & Williamson use four; on section seven, Locher, Harder & Williamson one; on section eight, Mason and King three and Locher, Harder & Williamson two. The only reason why about ten more cableways were not installed on this work was because the travelling cableway was not perfected in time. It is a fact that cannot be controverted however, that since the travelling cableway demonstrated its present capacity no other hoisting and conveying machine was sold on the canal. One cableway was used on the river diversion work, and is now no longer used, however the balance, nineteen can be seen in daily operation, in fact working night and day. The travelling cableway is capable of handling 600 cubic yards of rock in place per day of ten hours, and any capacity short of that is due to the difficulty of loading the skips.

A Creditable Publication.

The "Record Almanac" issued by *The Wilkes-Barre* (Penna.) *Record* is one of the most complete annuals we have ever seen. It is a complete encyclopedia of Luzerne County's history, politics, societies, sports, etc., etc., for the year 1895. Its mining statistics are very completely, yet concisely stated. It reflects great credit on Messrs. Johnson & Powell, the publishers.

EASY LESSONS ON MINING.

This Department contains articles to assist ambitious Miners to educate themselves, and obtain Certificates of Competency as Mine Foremen, or to become Mine Superintendents.

The articles are written to be understood by the unlearned and the learned alike. Plain language is used, no obscure terms are employed, and each subject treated, is made as clear and easy to understand as possible.

Further: The Questions asked at the different Examinations for Mine Foremen and Mine Inspectors, are printed and answered.

☞ The Series of Articles "Geology of Coal," "Chemistry of Mining," "Mining Methods" and "Mining Machinery" was commenced in the issue of March 1894. Back numbers can be obtained at twenty-five cents per single copy, $1.00 for six copies, and $2.00 for twelve copies.

MINING MACHINERY.

Recapitulation of the Principles of Action of the Centrifugal Fan.—The Varying Density of Air.—To Find the Volume of Air Entering a Fan.—The Balance of Mine Resistance.—One Ventilating Machine for One Stream—Advancing Curvatures of Blades.

98. Recapitulation of the Principles of Action of the Centrifugal Fan.—It is important that we should review the conclusions we have arrived at concerning the mode of action of the centrifugal fan, for this enables us to introduce such illustrations as will manifest to the eye and the mind of the reader that the deductions of our previous lessons were based on invariable law. For example, in the lesson given in the last October issue, it was shown that a stream of air in common with that of other fluids is never set in motion by tension, but by compression and therefore the direction of the stream is always into a region of depression. Now the statement just made is capable of the most satisfactory manifestation; and in support of this conclusion we introduce Fig. 135, and here it is seen that water is in the course of being upraised or really pumped by centrifugal force. The mode of construction and and the principle of action of the apparatus shown by the figure is as follows: A hollow horizontal shaft at S, is connected by a handle H, for rotating the arrangement, and between the supports a tube branching from the hollow shaft extends to C; the object of this branch pipe is to generate by its rotation the required centrifugal force, and when this pipe rotates radial fashion in a vertical plane it is the exact analogue of the blade of the fan. The hollow shaft S is connected with the fixed upright pipe or tail column PP by a gland G, to make a water tight joint and allow for the rotation of S. At the bottom of the "stand pipe" PP, a faucet is shown just over the surface of the water in the tank V. To start this centrifugal pump, the radial pipe C is set in a vertical position with its open end upward and the trap valve or faucet is closed, when water is poured into C until the radial tube, the hollow shaft and the stand pipe are filled, then the faucet is opened, and at the same instant the radial pipe is rotated by the handle H. At this same time water will be discharged out of the open end as seen at C, and will thus continue the outflow until the tank V is emptied. Now arises the all important question: how does the water rise in the stand pipe PP to a considerable elevation above the surface level of the feed water in V? the answer is clear and conclusive because fluids cannot be moved by tension like solids, but by compression; and this being so, it follows that there must be a depression in the region of the junction of the radial tub C, with the hollow shaft S, for otherwise the water could not rise from the water level in V, up the stand pipe PP to the elevation of the hollow shaft S.

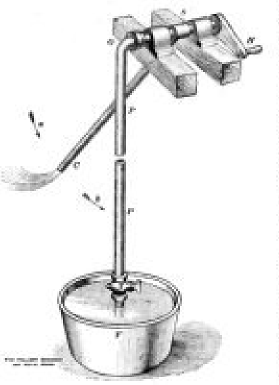


FIG. 135.

To understand the matter clearly, let us assume some values to reason with. First, then, let the pressure of the atmosphere be taken at a column of 34 feet of water. Second, let the elevation of S above the water level in V, be equal to 16 feet; and third, let the resistance due to the flow be equal to 5 feet of head, then $16 + 5 = 21$ the amount of the difference in pressure required between that of the atmosphere and that at the junction of C with S. For the depression at the junction must be $34 - 21 = 13$ feet, or if the pressure of the atmosphere is equal to that of a vertical column of water 34 feet high, the pressure at the junction cannot be more than that due to a vertical column 13 feet high, consequently we here establish the conclusion previously arrived at, that air cannot enter a fan until a depression or a reduction of pressure has taken place in the air between the fan blades in the region of the orifice of entry. In addition we learn that the velocities of fans must vary for the same quantity, as the square roots of the heights or resistances, and that the same fan can be made to pump different quantities or volumes of air with the same water gauge when the mine resistances per unit volume are different. For example, with a depression of 21 feet of water column we obtain say, a discharge of water out of our tube C, of 20 gallons per minute at an elevation say, of 21 feet, but at an elevation of 7 feet and with a depression still of 21 feet we would obtain $\sqrt{\frac{21}{7}} = \sqrt{3} =$ 1.732 or $1.732 \times 20 = 34.64$. Now if we obtain different quantities with the same motive pressure, we can by the figure before us discover the cause of the apparent anomaly.

There is another matter of first importance that claims our attention while this figure is under notice, and that is, the velocities of fluids into depressions, and here let us make it quite clear that fluids, apart from gravitation and inertia, are only moved by a superior pressure into a depression. We may then after having realized this truth practically, apply it in a few examples that will now engage our attention; as for example: Air is found to be blowing into a depression, where the pressure is two pounds per square foot below the pressure of the atmosphere, what then is the velocity of the wind? By the well known law, the velocities of air currents vary as the square roots of the pressures, or the converse, the pressures setting air currents in motion vary as the squares of the velocities. Now if we know the square of the velocity of air into a vacuum, and the pressure per square foot of the atmosphere. The atmospheric pressure would be to any other pressure, as the square of the velocity of air into a vacuum is to the square of the velocity of the air sought for by the proportion. Now the square of the velocity of air into a vacuum is 1,800,000, in feet per second and the pressure of the atmosphere is 2,120 pounds on the square foot, then 2,120 : 2 :: 1,800,000 to 1,698 +, that is to say the velocity of an air current subject to a pressure of two pounds per square foot, if the density of the air moved was the same as that of the normal atmosphere, would be $\sqrt{1{,}698} =$ 41.2 feet per second, and should the density be half that of the normal atmosphere, then the square of the velocity would be 3,499, or the velocity would be 58 feet per second. It will be seen that the mass of air at 58 feet per second and at half the normal density, is much less than the mass at 41.2 feet per second, and of full density as $\frac{58}{2} \div 41.2 = .7$ or as 1 is to .7; and it is for this reason that $2{,}130 + M^2$ was taken as the denominator of the fraction in the formula given in a former lesson; and while we are engaged in this inquiry, let us introduce an example of the use of the formula we have referred to. Then let T be the pressure calculated from the fan blades at a given velocity, and let M be the mine resistance, and let the case be that of an exhaust fan, then $\frac{(T - M) \times 1{,}800{,}000}{(2130 + M^2)}$ is equal to the square of the velocity of the air into or out of the fan, for let T equal 13 pounds, and let M the mine resistance in pounds per square foot equal 10 pounds, then $\frac{(13 - 10) \times 1{,}800{,}000}{(2130 + 10^2)} = 2421.52$. The velocity then is $\sqrt{2421.52} = 49.2$ feet per second. As a further illustration of the facts just cited Fig. 136 is given.

99. The Varying Density of Air.—To furnish a graphic idea of the different densities of the air within a fan, let M and M on the opposite blades represent the density of the air on entering the fan, which would be according to Boyle's law and the M just given $\frac{(2120 - 10)}{2120} = .9952$. At D and D the point of maximum depression is reached, and at A and A, the normal pressure of the atmosphere is attained, and at P and P the pressure of discharge is attained, or $2130 + T - M = 2130 + 3$, and the density therefore is $\frac{(2130 + 3)}{2130} = 1.0014$, or we may state the case as follows:

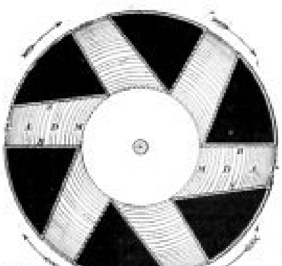

FIG. 136.

Density of the in flowing air .9952.

Density of the air at discharge 1.0014.

100. To Find the Volume of Air Entering a Fan.—In the case just noticed it will be seen that the velocity of the air entering a fan is greater than it is on leaving a fan, because the mass of air entering a fan, is never more or less, than the mass leaving it, and it follows that the velocity will be inversely as the density; hence the velocity on entering the fan will be in the proportion of 1.0014 and the velocity on leaving the fan will be in the proportion of .9952. And the mass per cubic foot entering the fan may be proportionate to 1 and that leaving the fan will therefore be 1.00623 or

Mass entering the fan $1 \times 1.0014 = 1.0014$.
Mass leaving the fan $1.00623 \times .9952 = 1.0014$.

It will be remembered that we referred to the *vena contracta*, and said that before it could be taken say at .62 due allowance must be made for any obstructions that would constrict the ports either at entrance or discharge, and we have introduced fig. 137, to draw attention again to these important matters.

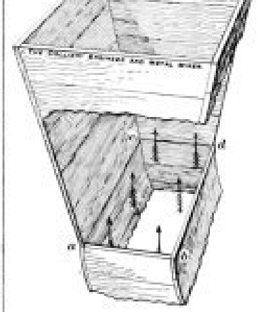

FIG. 137.

Calculations for velocities and quantities must always be made for the smallest orifice, whether it be located near the entrance or discharge of the fan. In this case the rectangular orifice a, b, c, d is supposed to have the smallest area, and is therefore taken, and to ward off any misunderstanding about how the quantities are calculated let us suppose the velocity is 41 feet per second and that the orifice gives a clear section of $6 \times 8 = 48$ square feet and taking the *vena contracta* at .62 the quantity passing through this orifice in cubic feet per minute, must be $48 \times .62 \times 41 \times 60 =$ 73209.6. The true measure of what a fan does is clearly indicated then by the processes given at first and now repeated.

101. The Balance of Mine Resistance.—We have great pleasure in introducing Fig. 138, because it makes quite clear and satisfactory a matter that was calculated to excite surprise and even doubt about the accuracy of the conclusion arrived at in a former lesson, when we stated that two, ten, or a hundred, or any number of fans would all have to run at nearly the same speed as one fan to exhaust the same quantity of air and no more than that obtained with the single fan; and in support of this conclusion the figure furnishes unmistakable evidence. Before water can be raised by centrifugal force out of the tank T, four centrifugal pumps in this case A, B, C and D must each and all run at a speed the same as that of a single pump to produce a depression into which the atmospheric pressure on the surface of the water at W can lift the column into the depression made. Now this depression can only be made in one or any number of fans by a fixed amount of exhaustion that is due to an equivalent amount of centrifugal force, and this force is due to a velocity that cannot be substituted by a lesser one, for if the column from W to A or B, or C, or D is equal to 21 feet, then for the water to rise to that elevation, they must all make the same amount of depression; that is, they must all lower the atmospheric equivalent from 34 to 13 feet; or let us suppose that A has made a depression of 21 feet of head or a depression to 13 feet of pressure, then the centrifugal pumps B, C and D, would receive no water from the rising main, or they would be useless until they were run at the same velocity as A. Here then we see that an increased number of fans would reduce very little the peripheral velocity of any

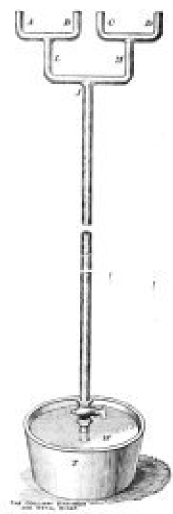

FIG. 138.

number of fans while the resistance remained the same as that due to one fan.

102. One Ventilating Machine, for One Stream.—The figure under consideration teaches another great lesson; namely, that there should only be one fan, for one ventilating current, or there should never be more than one fan exhausting out of the same drift, for if there is more than one set to exhaust the same stream of air, they introduce a high resistance that arises from an unpreventable cause, and let us try to discover its nature and character. In the first place let us notice that it is impossible to set up two fans exactly alike and under the same conditions of approach and discharge; and it is still more impossible to erect two steam engines with their valves so made and arranged, that the clearance, and the cut off, and the release will be identical in the two cases, but as we assume that each fan is worked separately with its distinctive engine, we cannot, so run the engines as to sychronize their movements so that the beginnings and endings of the strokes shall be coincident; the result is, we would find a high resistance, arising from an intermittent action developed by two causes, first, the instability of mechanical equilibrium; and second, the variations in the power due to the varying tangential force on the crank pins of the respective engines. It is singular and yet true, that in mechanics, we can only get uniform time out of varying velocities, and this is even true of the clock, for the pendulum or the spring, only regulate the escapement by acceleration and retardation.

In celestial mechanics the orbits of all the planets are elliptical, and the result is the body accelerates in going into perihelion, and retards in going to aphelion, and it is so with the comets and all other wanderers in space, the winds that blow are intermittent, the noise of water escaping from a faucet is the result of intermittent motion along the line of equilibrium, and how much more will this occur with two or more fans? Let us suppose that the pump *A* for a moment accelerates, then at that moment it will make a greater depression than *B* and will cause the inert water to run in its direction, but when *A* gets more water it will do more work, and if *A* gets more work, it will run at a less velocity, and while *B* gets less work, it will run at a higher velocity, and at that moment it will make a greater depression, and the result will be the water will leave *A* and run to *B*, and so on with the others in succession. We can, therefore, see that two or more fans running together will provide work for themselves, by developing an increased resistance out of the action and reaction due to intermittent motion.

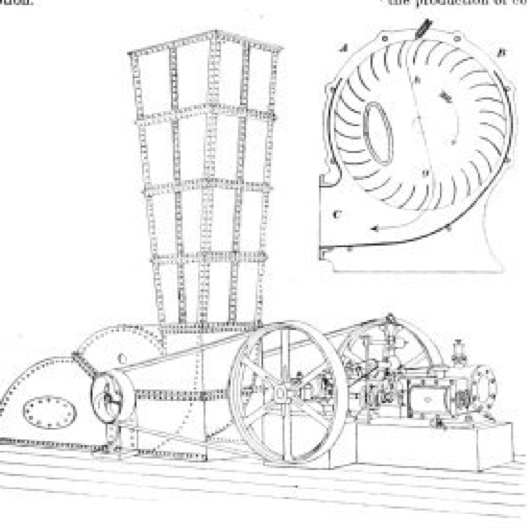

Fig. 139.

103. Advancing Curvatures of Blades.—Fig. 139 is an illustration of what is called the "Mortier Diametral Fan" and we only introduce it here to recapitulate what was shown in reference to the retreating curvature of fan blades, for this fan fully sustains all our conclusions, as it will be seen that the curvature is the reverse of retreating and is actually advancing as shown by the arrow on the *B* side of the long arrow *g*, *h*. This fan does not take in air at a concentric central orifice but strange to say it takes in air through one segment of the periphery as from *A* to *B*, and discharges it through another segment that is open into the evasey chimney as at *C*. The makers of this fan claim that its principle of action is independent of centrifugal force, and we are sorry to say that we think they are mistaken because the particles thrown off the revolving blades as by *g* are not only subject to centrifugal force, but that in a multiplied degree. They claim that the course of the particles passing through the fan is along the trajectory *h*, *g*, or the arrow *h*, *g*. These conclusions may be right or wrong but with that we decline to treat, for our present purpose is to show that if straight radial blades were a cause of loss of mechanical efficiency, how much greater should be the loss due to blades having an advancing curvature, and yet along the lines of what we claim and teach they get, as we expect, good results without unusual resistance.

This fan finally sets aside the claims of the retreating curvatures of fan blades, and sustains the conclusions we have arrived at in the former lesson.

This fan is made to intake air by scooping it in, and taking advantage of its inertia, and this is done on the *A B* side. The inflowing stream enters at an angle of 20 degrees with the mean tangent of the segment, and the air is undoubtedly discharged by a centrifugal force that is increased by acceleration along the blades that are curved in advance. In our next lesson will be introduced a number of examples worked out to elucidate the principles of the action of the centrifugal fan.

(To be continued.)

MINING METHODS.

Air Coursing in Relation to Haulage.—How the Cars Produce Coal Dust.

79. Air Coursing in Relation to Haulage.—It is now a decided principle in coal mining that haulage should not be carried on in the return airways, and therefore, mines are planned and the roads are made in conformity with this rule.

Haulage in a return airway introduces a greatly magnified danger, because the air on these roads is always charged in a greater or lesser degree with fine coal dust in suspension and marsh gas, and observation and experience, and well attested experiments have established the fact, that air charged with these very inflammable substances is always either in a dangerous condition, or in a state of partial saturation.

The presence of these two combustible bodies in the air of such a haulage road is due to two causes, and one of them is normal, or it is peculiar to it; for the object of ventilation is to gather up and carry off in the return air the gas produced by the coal, or that given off from fissures either in the working places or in the roof, sides or floor of the roads, or the broken cover or underlying rocks of the gobs. The other dangerous body in the return air is not only not normal, but arbitrary, and it is therefore dispensable, or in other words it is a self imposed danger.

80. How the Cars Produce Coal Dust.—No practical miner can fail to notice that fast running cars produce more coal dust than slow moving ones, and granting that this is true, we at once realize a great fact, namely, that fast running should not take place in a return airway. It is true that we cannot in level seams, or those of small pitch, avoid hauling cars from the working face in return air, because the fresh air of the last room, is the return air of a former one, but this is not in any sense a main haulage, but a local one where the cars are hauled singly at a low rate of speed. The question now arises: How does the rate of speed affect the production of coal dust? and the answer is decisive, for the dust scattered on a given length of the road is inversely as the time, or directly as the speed; that is to say, if the speed of a train of cars is doubled, the volume of fine coal delivered into the air will be doubled, and we might conclude that this statement had about it the "air" of a finality, but this is not so, for the writer knew a case where an explosion occurred during the running in of an empty train, on which rode a man carrying a flaming torch light.

Now, in a case like this we can only arrive at one conclusion, and that is that the inflammable contents of the air were raised by the whisk of the train of cars running in a confined gallery of relatively small area, or that the dormant dust had been lifted by the rapidly whirling wind eddies developed at the front and rear and along the sides of train, and as we have seen in such a case, the bright air becomes densely clouded with easily suspended flocculent particles, that contain so little matter, that the shell of air that envelops them contains sufficient oxygen for their combustion.

We see, then, that the saturation of the air with coal dust arises from two mechanical and correlated agencies; first, the dust arising from the loaded cars, and second, the dust raised with the whisk of the train; and the conjoint effect of these two causes is startling in its magnitude, for the amount of the saturation of air with flocculent dust varies as the squares plus the velocities of the cars. As we have just stated, the prime source of the dust varies directly as the velocities of the cars, and this we can discover by noticing that the shaking effect set up by the rocking and vibrating of the cars varies as the squares of the haulage velocities, and at first sight this fact presents the phase of a contradiction, but on further investigation it is found that, though the volume of dust given off per second is quadrupled when the velocity is doubled, the time of running the course is inversely as the velocity, or the train runs the journey in half the time, and, therefore, the volume of dust scattered in the air and on the floor and sides of the airway per journey is directly as the velocities, because $\frac{v^2}{v} = v$. We have just referred to dust brought in and scattered in the airway, but the greatest source of danger arises from the dust that is raised by the whisk of the fast running train, because the power of the wind to sweep up and raise the dust varies as the squares of the velocities, and, therefore, the sum of the causes of floating dust due to a train of loaded cars is equal to $v_1^2 + v_2$. Observe, then, that the dust in the air due to a loaded train varies as $v_1^2 + v_2$, and the dust due to an empty train varies as v^2.

With the facts just cited before us, we learn now that the running of cars in mines should be as little practiced as possible in the return airways, and further, the upraised dust is more to be dreaded than the dust given off by the coals in the cars, and, therefore, it is important that the roads from the working face to the main haulage should be kept as free from dust as possible.

To correctly establish our meaning concerning the haulage on dusty roads and especially on return roads connecting the rooms in flat workings with the main roads, we introduce Fig. 121. It will be seen at a glance

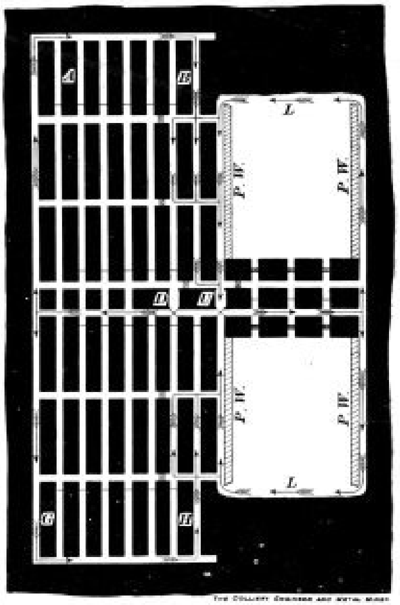

Fig. 121.

by a practical miner that the ventilation and local haulage are both bad and it often occurs that more attention is given to the development of a novel system of working than to the collateral particulars that may affect the mode of obtaining the coal favorably or unfavorably.

In this case we introduce a novel system of *part longwall* in which gob packs are made if sufficient top rock falls for that purpose and side pack walls are built as *P W*, *P W* on the right hand side of the figure. The object of these two pack walls should be to do duty as brattice. On the left side of the longwall gob are two pack walls also *P W* and *P W*; their intended use is to so break the cover as to prevent it breaking over the first line of pillars. Now this "part longwall" is often convenient and successful where top rock is not available for making roads through the gob, and therefore the roads are

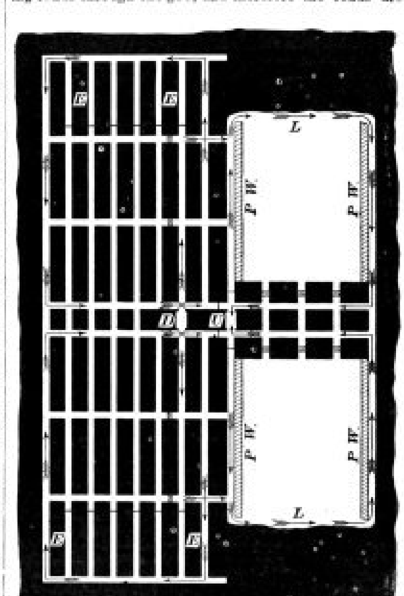

Fig. 122.

made secure with pillar walls and are used for ventilation and haulage, but here the haulage is done in return air when it could be otherwise, and therefore the only excuse possible in a case like this is to suppose that the pitch of the seam is across the map from the pillar to the longwall workings or from *A* to *B* or from *G* to *H*. In that case the ventilation of the longwall face at *L* or *L*, would be the best possible for the removal of the gas from the face and the gob, but before this longwall with coal gates or roads was commenced the forewinning of the district should have been done by advancing the pillar roads down the pitch, or by commencing the longwall workings on the west instead of the east side of the pillar roads,assuming for the sake of explanation that the top of the map is north.

Where the seam is quite level, however, the "part longwall" can be worked and ventilated on correct principles as illustrated by Fig 122. *E E* at the top of the map and *E E* at the bottom indicate that the seam is not pitching.

The cars now run in fresh air and besides, the main haulage roads are directly in line with the hoisting shaft. The advantages of the last plan are so evident that no arguments further than those that come from practical experience are required and yet when the two illustrations are set side by side, we can see how mistakes can be made, and further we can see the importance of considering how we should ventilate as well as work a field of coal before we put any plan into practical effect.

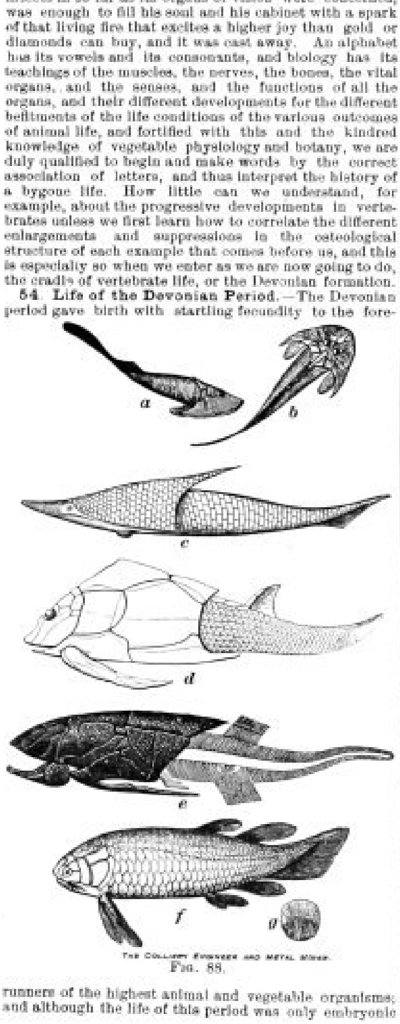
GEOLOGY OF COAL.

The Alphabet of Life.—Life of the Devonian Period.

53. **The Alphabet of Life.**—No man can ever succeed in making the study of the science of geology pleasing to his own feelings, and useful in his profession, unless he first studies and learns the first principles of the science of biology. You might with as much propriety call a maker of jingling purposeless rhymes a poet, as call a man a geologist who has collected fossils to fill a cabinet, and knows nothing more about them than the greek names he has written on their labels. The science of biology furnishes the alphabet out of which we are able to spell the words that reveal the environment of the life of every organism, animal and vegetable, that once lived and is now only represented by its fossil cast in stone. As a proof that the study of geology requires a qualifying fitness from a knowledge of biology, the writer remembers a case where a collector of fossils showed him some examples of trilobites, and pushing one of them to a side as he considered it worthless, he remarked, "you may have that one if you choose, as I have plenty better ones." Now, the castaway specimen was worth many times more than all he had, because it was stamped with the insignia of its rank among sentient beings, and this was no less than a perfect print of the facets of its compound eyes.

Why! To be able to associate this crustacean with insects in so far as its organs of vision were concerned, was enough to fill his soul and his cabinet with a spark of that living fire that excites a higher joy than gold or diamonds can buy, and it was cast away. An alphabet has its vowels and its consonants, and biology has its teachings of the muscles, the nerves, the bones, the vital organs, and the senses, and the functions of all the organs, and their different developments for the different befitments of the life conditions of the various outcomes of animal life, and fortified with this and the kindred knowledge of vegetable physiology and botany, we are duly qualified to begin and make words by the correct association of letters, and thus interpret the history of a bygone life. How little can we understand, for example, about the progressive developments in vertebrates unless we first learn how to correlate the different enlargements and suppressions in the osteological structure of each example that comes before us, and this is especially so when we enter as we are now going to do, the cradle of vertebrate life, or the Devonian formation.

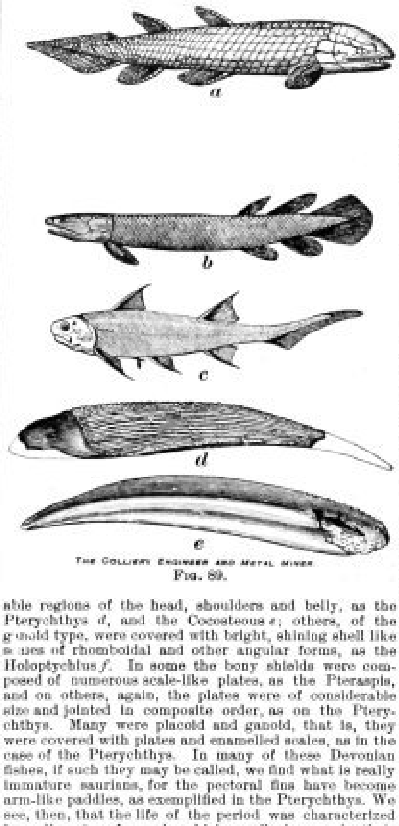
54. **Life of the Devonian Period.**—The Devonian period gave birth with startling fecundity to the fore-



THE COLLIERY ENGINEER AND METAL MINER.
FIG. 88.

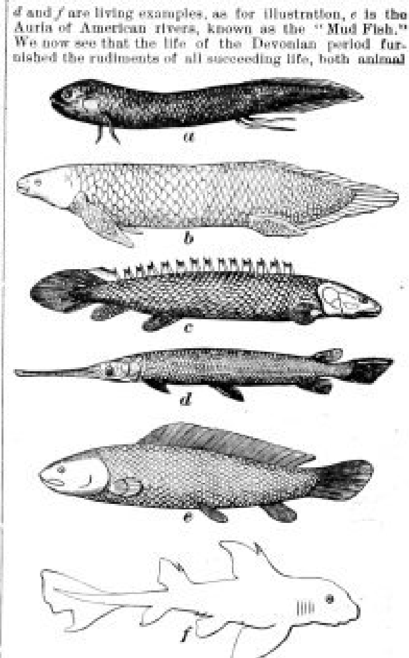
runners of the highest animal and vegetable organisms; and although the life of this period was only embryonic in the two kingdoms, it was remarkably coincident with a greater fitness for life on land and in the sea, for now great land masses had emerged and still left large areas under very shallow waters wherein immature saurians found a congenial environment. The struggle for existence must have been fierce and severe among creatures whose organs of locomotion were rudimentary and ill adapted for offense, and therefore their organs for defence were of a very formidable character, and the result was many of the fishes of the period that were slow swimmers and otherwise inert, were protected, as seen in Fig. 88, with plates of armor and shields to protect them from the assaults of their predaceous enemies. This was the age of ganoid and placoid fishes that swarmed in these early seas, and out of their differentiating cartilages have come the rudiments of the organs of the latest and highest life forms that now sport in the seas. It was the age that matured the vertebral column, and the peculiar organs of locomotion, the pectoral and ventral fins, or paddles of propulsion that were extended by processes hinged on to the vertebral column of these primitive fishes. In nothing is the unity of structural relationship so manifest as in the skeleton of an animal; for if it is viewed apart from all types it is found to be homologous, and the only differences found all along the differentiating line of vertebral organisms, are in the extensions and suppressions of individual bones. Truly then we may claim that the Devonian period was the cradle of the higher life now on the earth.

Most of the Devonian fishes were placoid and ganoid. The placo-ganoids were shielded with defensive plates of armor, and these were of the most curious shapes. For example, some formed a kind of hat or hood for the head; in other cases a large bone formed a hood and neck collar; in other cases, again, a pair of plates, oreven a single one, formed a hood and mantle, as in the case of the Cephalaspis, *a* and *b*, Fig. 88, others, again, had the mantle without the hood, as in the case of the Pteraspis at *c*. Others, again, were armor plated in the vulner-



THE COLLIERY ENGINEER AND METAL MINER.
FIG. 89.

able regions of the head, shoulders and belly, as the Pterychthys *d*, and the Coccosteous *e*; others, of the ganoid type, were covered with bright, shining shell like scales of rhomboidal and other angular forms, as the Holoptychius *f*. In some the bony shields were composed of numerous scale-like plates, as the Pteraspis, and on others, again, the plates were of considerable size and jointed in composite order, as on the Pterychthys. Many were placoid and ganoid, that is, they were covered with plates and enamelled scales, as in the case of the Pterychthys. In many of these Devonian fishes, if such they may be called, we find what is really immature saurians, for the pectoral fins have become arm-like paddles, as exemplified in the Pterychthys. We see, then, that the life of the period was characterized by rudimentary forms in which small changes in their environment would at once develop extensions and suppressions in the cartilages of their immatureosteological structures. Fig. 89. The compensations in nature are very remarkable and the armor plated fishes were no exception to the rule, for all of them were slow and sluggish, and we are justified in this conclusion by three sources of evidence. The first is mechanical, for creatures so heavily weighted in the region of the head could not turn swiftly or swim quickly; therefore, their movements would be languid, and, again, nature never provides a means of defense for a creature that can act offensively, and in the third case, the ganoids that have continued from the Devonian period until now, as for example, the sturgeon and several others, found in the rivers of South America and Africa, are all sluggish in their movements. The lazy sturgeon is the scavenger that lies on the floors of the rivers catching what the stream brings to his mouth. The figure before us still further exhibits the peculiarities of the singular divergent forms of the period and furnishes examples of the spines of some of the gigantic placoids that flourished in these primitive seas, as the Osteolepus *a*, the Glyptolemus *b*, the Diplacanthus *c*, and the remarkable spines *d* and *e*. By Fig. 90 we are able to contrast the ganoids of the past and present, for *a*, the Lepidosiren, and *b*, *c*, *d* and *f* are living examples, as for illustration, *e* is the Auria of American rivers, known as the "Mud Fish." We now see that the life of the Devonian period furnished the rudiments of all succeeding life, both animal



THE COLLIERY ENGINEER AND METAL MINER.
FIG. 90.

and vegetable, and perhaps no other formation or life period has furnished so good an illustration of the reason why certain groups of the rocks have specific names, according to the characteristics of the organisms that flourished during their deposition.

[TO BE CONTINUED.]

CHEMISTRY OF MINING.

What Will be the Future Miner's Lamp.—Electric Lamps in Mines.—Velocity Testing of Safety-Lamps.

79. **What will be the future Miner's Lamp.**—We cannot undertake to say what will or will not be the future of the miner's lamp, for in these days the march of progress in science and mechanics is so rapid that what appears to us unassailable to-day is totally untenable to-morrow, and the greatest changes come without the warning of a prophet. A very short time ago we were told that the chemist had succeeded in liquifying air and now we find that the mechanic has succeeded in making liquid air a mechantable article for the worlds wants as a substitute for ice.

What effects us however, in the lamp question is this, liquid air only contains 30 per cent. of nitrogen and consequently 70 per cent. of oxygen by weight; for during the compression of the gases nearly 89 per cent. of the nitrogen in the air is set free as insoluble in the oxygen. The liquid air then consists of nearly pure oxygen and a little more than a pint or one pound of it would suffice to burn 4 ounces of oil, but the light would be so brilliant that 2 ounces of oil would be sufficient per shift to maintain a good light with the aid of half a pint of liquid air. Now such a lamp could be made to have no other connection with the external air, than by a funnel for the discharge of the inert gases produced by combustion, for the oil and the liquid air would be contained in close vessels completely isolated from the external air and the consequences would be the gauze cylinder could be dispensed with and the miner would be absolutely safe with his lamp in an explosive mixture.

Such a lamp may be tried, and it may be found to fail, for just as much was expected of the miner's portable electric lamp and up to now it has not displaced the safety oil-lamp, and perhaps never will.

80. **Electric Lamps in Mines.**—There are two distinct classes of electric lamps used in and about mines.

First. The magneto-electric current lights.

Second. The battery current lights.

The magneto-electric current lights are divisible into two kinds.

First. The arc, or fire stream lamps.

Second. The incandescent lamps having a glowing filament in a vacuum in a glass shell.

The battery current lamps are divisible into two distinct varieties.

First. Those having in the case of the lamp a primary battery of chemical cells, to supply the current for the light in a portable lamp.

Second. Those having in the case of the lamp, a secondary or storage battery to supply the current for a portable lamp.

All the varieties of electric lamps, further come under two heads, and these are *fixed* and *portable*. With the fixed lamps we have very little concern, as they are used more for efficiency and economy, than for safety, and it is, therefore, only with the portable lamps that we are interested as they have been introduced as a means of safety in mines.

The draw backs to portable electric lamps may be classed under five heads.

First. They can only be recharged and kept in working order by skilled men.

Second. They are costly at first and expensive in maintenance.

Third. They cannot be used to indicate the presence of fire-damp.

Fourth. They are too heavy to carry in the hand.

Fifth. They give a relative small light for the prime cost, and that of future maintenance.

To realize correctly the value of the facts enumerated you only need to contrast the first, with the latest examples of the miners electric lamp; for all the makers are now aiming at the production of a lamp that will be free from the faults we have noticed. One thing, however remains that cannot be otherwise and that is a portable lamp, must always be a battery lamp, and this means that to obtain a good light, you must have a heavy lamp.

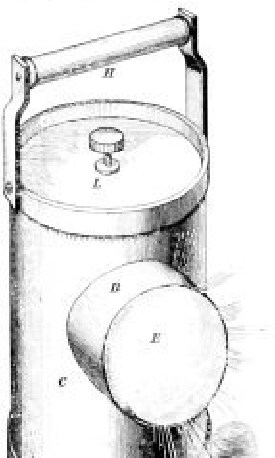


FIG. 119.

FIG. 119 is an illustration of the Bulls-eye lamp with a primary battery. Now as we have just indicated, it is impossible to obtain with a primary battery of small cell's that can be contained in the case of a portable lamp, a high voltage and a small resistance, without at the same time introducing a high chemical potential with the resulting corrosive action in the cells, and therefore an economical light under the circumstances is impossible and the result of this is, we see that a very small filament or very small lamp is used, and it is expected that by this means a light will be obtained that will rival the oil flame of an ordinary lamp, and thus solve the problem of electric illumination. Now it so happens that a few intense beams of light that illumine a small circular area and leave all outside of that field of view intensely dark, baffle the human eye, and jeopardize the miners life. This may seem a strong assertion but the conclusion can be established by proof. The iris of the eye or the curtain that gives the characteristic color of blue or grey eyes, contracts and diminishes the pupil in a bright light, the result is blindness in a subdued light, and what makes the matter worse is the fact that the iris or curtain is not subject to volition or the power of the will, but is under the control of reflex action, or it is only made to contract or dilate in obedience to the stimulus of light. All miners know that they have to find their "pit eyes" on entering the mine from a cage in a vertical shaft. With a slope it is somewhat different as they leave the light by slow gradations of change. The small bright bundle of rays of light is then a source of danger, and a much weaker light more widely diffused is a source of increased safety, as the miner is never safe unless he can see the floor, and the roof and the sides, without much handling of his lamp. At C we have the case, E is the bull's eye, and L is a contact maker or breaker for shutting the current off or on. This lamp is actuated by a primary battery and only casts a bright beam of light in one direction. Fig. 120, is an example of an up and all round light sustained with a current of high voltage from a storage battery, and the vacuum glass is seen to be protected in a cage of strong wire. This lamp gives a powerful light and but for its weight and cost would no doubt be a success. The uses of the different parts of this lamp are as follows: B is the chamber containing the storage battery, CC are the cage bars for protecting the glass shell of the lamp, and LL are the terminals of the carbon filament.

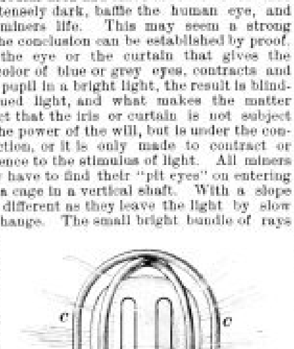

FIG. 120.

81. Velocity Testing of Safety Lamps.—Lamps are tested with the view of finding at what velocity they will pass the flame and explode. In the past the "explosive mixture" was prepared without regarding the difference between a simply explosive mixture, and a true *maximum* explosive mixture, or one in which one volume of marsh gas was mixed with exactly 9.5 volumes of pure air.

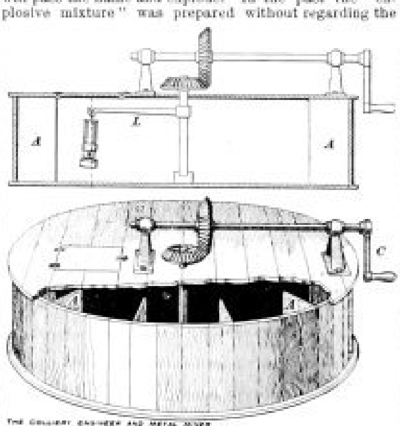

FIG. 121.

No tests with safety lamps are, however, of any value unless the mixture in which they are tested is of determinate and standard proportions, and therefore it is of all things most important that the volumes of air and gas should be correctly measured for the test. The mechanical arrangement illustrated in the Fig. 121, is a tester, and perhaps is the oldest or most primitive one in use, and therefore is not one of the best, but it answers our purpose best for illustration and explanation. Here, then an upright shaft with a crown wheel on its upper end, and an arm keyed on just below the cover at L, is made to turn by the handle C, and revolve the lamp that is hanging on the end of the lever L. To prevent the rotation of the air within the case, arresting blades A A, etc., are fixed within the shell of the cylinder. Now it is not necessary to say more about the apparatus, as its mode of action is evident at sight, but the length of the circle in which the lamp turns, and the number of turns per minute have to be found, so that the velocity of the lamp in feet per second may be determined, and this having been done, all lamps may be tested in a uniform velocity, and yet the velocity per second at which any lamp will explode in a unit of time, can from the time of the uniform velocity be determined, as the times are inversely as the squares of the velocities. For example, the Davy lamp "fires" in one second, when the velocity of the explosive mixture is at the rate of 6 feet per second and at a velocity of 4 feet per second the time, therefore, is $\frac{6^2 \times 1}{4^2} = 2.25$ sec.

That is, to say a lamp that fires in one second, at a velocity of 6 feet per second, will fire in 2.25 seconds at a velocity of 4 feet per second. Or the velocity per second at which any lamp will fire, can be found if the velocity per second at which it has fired, and the time are given; because if the velocity is multiplied by the square root of the time, we find the velocity for one unit of time as in the case before us is $\sqrt{2.25} \times 4 = 6$ feet per second, the velocity at which a Davy lamp fires in one second of time.

We see then that the velocities increase or decrease the time; for example, a velocity of 12 feet per second will cause a Davy lamp to explode in one quarter of a second, as $\frac{6^2}{12^2} = \frac{1}{4}$.

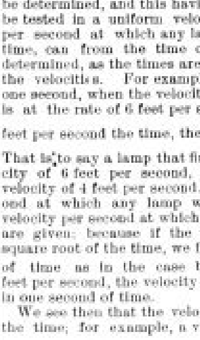

FIG. 122.

Fig. 122, is an illustration of a Davy lamp, and it is interesting to observe the entry of the fresh air, as shown by the *sagitta* or arrows at d and d, the exit of the inert air as at e and e, and f and f, and at the top of the cap at g.

The only protection provided against the passage of the flame in this lamp is the gauze cylinder; and, therefore, when the lamp is exposed to an air current moving at a high velocity, the displacement of the dead air and the entry of mine air that may be charged with gas, takes place also at a high velocity, with the result that the lamp becomes full of flame, the gauze becomes heated to redness and the passage of the flame through the gauze follows.

Such a lamp as this has a small motive column for obtaining a supply of fresh air or effecting the discharge of the foul air from the lamp, and, therefore, a draught may increase the ingress and egress many times and convert the interior of the lamp into a veritable furnace. This lamp in its original form is now a thing of the past, and it is chiefly used now in a can with a glass pane for the passage of light. The can is a screen that prevents the rapid entry of gas-charged air, and thus secures the safety of the lamp. At T is seen the oil fountain, and at F, the bottom ring in the lamp frame, that is seen to be screwed onto the top of the fountain. The wick is shown passing up the wick pipe, and a slit is shown in this pipe at B, for the entry of the pricker's point A, to adjust the length of the wick and the flame.

82. Safety Lamp Dimensions.—Fig. 123. The writer remembers seeing some lamps at the Blantire Colliery in Scotland, at which an explosive mixture was fired. They were rude copies of the Davy lamp and consisted of a large gauze cylinder with a conical cap. The lamps for the "hewers" consisted of a gauze cover 7 inches high and four inches in diameter, with a rude, vulgar looking hook riveted onto one side of the gauze, and this cover and hook was fitted onto a ruder oil well, and, altogether, such a lamp could be little, if any, better than a naked light, but this example of a safety lamp taught a lesson, and that was that the cubical contents of a gauze cylinder are an important matter in the construction of a safety lamp, for in the first place, the volume of mine air entering such a lamp in a draught will be proportionate to the surface area, and as the explosive force of gas that fires in such a lamp, will be in the proportion of the cubical contents, we cannot wonder at the risk and danger that such a large lamp engenders. To enable the reader to realize the magnitude of the danger, let us look at A in the figure and contrast it with E, and the instinctive feeling set up by a glance makes you feel that an explosive mixture in A, if ignited, would pour into the meshes of the gauze such a flood of flame that the wire would at once become hot and allow the fiery stream to pass on unobstructed; whereas, in E the volume of flame would be small in proportion to the surface area of the gauze, and, therefore, a lamp with the small gauze cylinder would secure greater safety and protection. It is easy to see, then, that the relative safety of every gauze in the series A, B, C, D and E is inversely proportionate to their size.

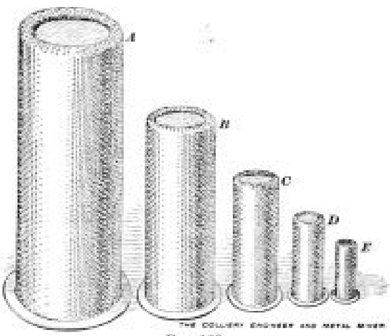

FIG. 123.

(TO BE CONTINUED.)

MISCELLANEOUS.

FLORIDA PEARL FISHING.

A writer in the *N. Y. Sun* thus describes his experience on a fishing trip with two Florida pearl fishers:

The Pickles are a collection of rocky islets lying out beyond the outermost keys, with the shoal water of the reefs on one side and the deep channel of the Straits on the other; and to reach them it was necessary to cross Florida Bay, and run across the outer reefs—a sail of some hours.

"Off the Pickles you can have the water about any depth you want," the diver said, "say from 30 feet to 250. The bottom comes in ledges, and a man can go down thirty or forty feet to a ledge and step off that right into thirty or forty fathoms. Conchs are plenty there, because the ordinary fishermen don't care much to go down after them."

"We're none too soon," he said, when the sharpie, with sails lowered, lay outside the Pickles. "The nearer the sun is overhead the better for this deep-water work. Not much use trying it on a dark day or after the sun has gone down. You'll not see any bottom here," he went on, turning to the stranger, "not even with the sun overhead."

The water was as clear as in nearer the keys, but on account of its great depth nothing could be seen below but a mass of deep green. Hawley produced a great coil of rope from a locker under the stern seat, rope slightly thicker than a clothesline, and carefully made one end fast around a huge piece of coral rock that lay on the boat's bottom amidships. This rock was as big as five or six full-grown heads and had been useful throughout the voyage for ballast. But a deep notch chiselled all the way around it in the centre, and the tying of the rope around this notch, showed that it served another purpose. When one end of the rope was secured to the stone, the other end was made fast to an iron ring in the sharpie's bow. The diver then slung an old coffee sack over his shoulders, after the fashion of a pair of saddlebags, having a slit in both sides, and a stone in each end to keep them from floating up.

"Now you'd better sit here on the starboard thwart to balance me," he said to the stranger; and when this was done he lifted the big stone to the opposite thwart and threw off his hat.

The stone apparently weighed in the neighborhood of a hundred pounds, and balancing it neatly on the narrow ledge, he climbed over the side into the water and rested there holding on to the thwart with one hand and keeping the stone in place with the other.

"Keep that line clear," he ordered, but before there was time for a reply the stone toppled over into the water, and stone and diver disappeared together.

The line paid out with some rapidity, but not so fast as might have been supposed, for it was evident from the manner of the taking off that the stone was merely a sinker to carry the diver to the distant bottom. After a long interval the line ceased to run out, but more than half of it was still left in the coil.

"Will he give the signal when he's ready to be drawn up?" the stranger asked.

"Drawn up!" the skipper exclaimed; "he'll not need any drawing up. When he's ready to come he has only to let go of the stone, and he'll shoot up like a flash. It's no trouble to come up; the only difficulty is about getting down. I don't know just how deep the water is here, but if it's more than fifty feet a man would have hard work to get down without weights."

While the skipper was speaking the diver's head appeared at the surface ten or fifteen feet away, and he immediately struck out for the boat.

"You fellows draw up the stone while I unload," he said, resting with his hand on the side of the boat. "I may as well get a load while I'm about it."

"How deep did you go?" the stranger asked, while the diver took conch after conch from his bag and dropped them into the boat—twenty-two in all.

"It's about 15 fathoms here, 90 feet," he replied, "and it gives a man a buzzing in the head, but that soon goes off. This is one of the best conch beds along the whole coast, I could fill the boat in no time."

The stone was up at the surface by this time, and with a look at the wet line to see that it was properly coiled, he disappeared again. The period of submersion each time was estimated at about three minutes; and after the third descent he climbed in over the stern and the stone was taken on board.

"That will do for to-day," he said, "for we have a long sail yet before supper. I could show you some conchs from deeper water than this, but this shows you how the work is done. Sharks?" he repeated in answer to a question; "Humbug! I never think about them, and I guess they never think about me, so we have no trouble."

Darkness fell before the sharpie reached Shell Key, and the conchs were piled up on the beach to wait till morning. The diver was too old a hand at the business to have any great curiosity about his find. There might be a fortune in pearls lying there on the beach, but he slept unconcernedly on his coconut mat till time came for the midnight smoke.

When the seventy conchs were opened and examined in the morning, they gave up one little yellowish pearl, that he said would be worth about eight shillings in Nassau. It was no larger than a small pea, and imperfect; and it came from one of the gnarled conchs of Blackwater Sound.

"It's all right," said the diver, "I've done many a day's work for less than that."

THE WORLD'S HOLIDAYS.

Thanksgiving Day comes nearer even than the Fourth of July to being a legal national holiday, for altogether the Fourth of July is celebrated in some parts of the country where Thanksgiving Day is neglected, the President's proclamation gives to the latter a sort of official character that the former has not obtained. It is not for the Federal Government to tell the people of the United States when they shall quit business and take to pleasure. It is a matter for the States to establish legal holidays. The President in his Thanksgiving proclamation merely recommends that the people, neglecting their ordinary vocations, observe the day with proper ceremony.

As a matter of fact, the people of the United States work harder and have fewer holidays than any other people in the world. This is not especially a characteristic of democracies, however, for the Australian colonies, which are hardly less democratic in their local government than the United States, keep more holidays than any other country in the world. All the important sporting events, whether cricketing or racing, are made the excuse for a general holiday.

The usages as to holidays, legal and otherwise, in the several States of the Union greatly vary. Louisiana seems to have more holidays than any other State. It observes Jan. 8, the anniversary of the battle of New Orleans; Mardi Gras, on the eve of Lent; Feb. 22, Washington's Birthday; March 4, firemen's anniversary (in New Orleans), Good Friday, July 4, Labor Day in November and not September, as in most States, Christmas Day and New Year's Day.

Lee's birthday, Jan. 19, is a holiday in Georgia, North Carolina, and Virginia. Lincoln's birthday, Feb. 12, is a holiday in Illinois.

Texas makes Feb 2, the anniversary of her independence, a holiday, and also April 21, the anniversary of the battle of San Jacinto.

Alabama and Georgia have a memorial day, or Decoration Day, on April 26, and North Carolina on May 10. North Carolina also celebrates, ten days later, the anniversary of the Mecklenberg Declaration of Independence. Florida celebrates Jefferson Davis's birthday, June 3. Utah keeps Pioneers' Day on July 24. California keeps Admission Day on Sept. 9, and Nevada on Oct. 31. South Carolina keeps not only Christmas Day, but Dec. 26 and 27 as well. This, doubtless, is a relic of slavery times, when in many parts of the South the negroes kept the whole week between Christmas and New Year's, when little or no work is done. It is was a sort of truce of God for the slave, who for the week lived as a free man and made merry.

Arbor Day is observed in a constantly increasing number of States, and the Saturday half holiday is gradually extending from State to State, though it is not strictly observed anywhere.

Great Britain really has no public holiday that corresponds to the Fourth of July. There is no day when Britons of every political party and faction come together and celebrate in hearty accord a national event. Christmas is not even a legal holiday in England, though it is in Scotland. It is, of course, celebrated throughout the kingdom, but it was made a statutory holiday in Scotland, because otherwise the strong Puritan spirit prevailing there would have brought about a neglect of the observance. In London the Saturday half holiday is as much observed as Sunday. The Bank Holiday act, passed at the instance of Sir John Lubbock in 1871, made four legal holidays, Easter Monday, Whit Monday, the first Monday in August, and Dec. 26. In Scotland the legal holidays are New Year's Day, the first Monday in May, the first Monday in August, and Christmas Day. Christmas Day and Good Friday are holy days, but not legal holidays, in England. On these days all the theatres are compelled to close. New Year's Day is the great holiday in Scotland. It is much more widely observed than Christmas Day, while New Year's Day is not observed at all in England. Guy Fawkes's Day, Nov. 5, is kept after a fashion in England, but it is not a day that Catholics care to remember, since it recalls a time when they were hated and suspected. The French observe New Year's Day, Jour de l'an, in great pomp. The glory of that day has faded in New York, and New Year's calls are about extinct, except that in some of the old American quarters over on the west side, in some of the long ago fashionable streets, the day is still remembered. The people keep open houses, eggnog and other drinks are provided, and there are callers all day long.

The Queen's birthday, which is totally neglected in Great Britain and Ireland, is observed with great enthusiasm in most of the colonies, especially in Canada. It is to the colonial Briton a rallying day that comes nearer the Fourth of July than any other in the year. The Canadians also have an annual Thanksgiving Day, generally a week earlier than ours.

Scotchmen of all classes rally on St. Andrew's Day, and this is really a very important day in the English colonies, for Scotchmen have in large part made the colonies of Great Britain, and they are strong, the world over, wherever the British flag flies. St. Andrew's Day is celebrated in China, in Malaysia, all over India, in South Africa, in Australia, in Canada, and in a hundred insignificant islands and small settlements. Burns's birthday is another Scotch holiday, though, of course, not a legal one. It is celebrated wherever Scotchmen are. St. Patrick's Day and Orange Day are familiar to all sorts of people wherever the warring factions of Irishmen are found. The Welsh celebrate St. David's Day at home and abroad.

Englishmen in India keep not only their own but also the native holidays. There is Holi, a carnival of license, when the natives go about striking each other with bags of red powder, and their white garments are dusted as with red pepper. There is Dipwali, the feast of lanterns, celebrated in gorgeous fashion not only all over India, but in China and Japan, a beautiful and, to the stranger, marvellous holiday. There is Dasera, when all the animals are decorated with flowers, and masters are expected to give presents to their servants in recognition of the holiday. This corresponds to Boxing Day in Great Britain, Dec. 26, when postmen, street sweepers, servants, and employees of every class expect presents. Nearly every country has such a gift-exacting day.

The Saturday half holiday is one that has existed in fact for a long time in various parts of the United States. For many years it has been the practice of working people on the Eastern Shore of Maryland to quit work at noon on Saturday and to spend the rest of the day fishing, hunting, or carousing. That is the day when the country negroes come to the villages; indeed, when all country folks visit the town. It is sometimes called Public Day, being the day when country folks drive to town to make their purchases. The village stores keep open later on Saturday night than any other night in the week, and every considerable village becomes a sort of business and social exchange. There is a disposition in New York city to extend the Saturday half holiday through the whole year, and many self-employing men quit work at noon on Saturday the year round, in order to make excursions into the country that shall last over Sunday. Whit Monday is a holiday among Southern negroes. They commonly call it "Whistling Monday." In those Southern States largely settled by Catholics or Episcopalians the colored people still celebrate feast days and fast days. The old New England Fast Day seems to be dying out.—*N. Y. Sun.*

ALONG THE YUKON RIVER.

On account of the rich gold finds which have been discovered in Alaska and the resulting boundary dispute which is threatened, much interest has been excited. Most people, however, who have not made a study of the subject have a very vague idea of the nature extent and value of the region. Mr. C. A. Weare, treasurer of a company trading in that region in an article in the *Chicago Inter-Ocean*, thus describes the Yukon River and some of the neighboring regions.

"The Yukon River is navigable for about 1,800 miles for steamboats. It has five outlets, and yet, as I have intimated, no direct, practicable channel to the ocean has been discovered heretofore, its mouth at this season of the year being, for about forty miles, filled with bars and islands. For some 600 or 800 miles up the river the water is very deep, and would be navigable by middle-sized ocean steamers if there were any way to get in over the sand bars at the mouth. The river averages from one mile to ten miles wide for 800 miles, and above that it averages about one and a half miles wide for the next 800 miles. The waters of the Yukon drain a country in extent as large as the United States east of the Mississippi River. The country is mountainous, but the mountains are not very high. They have evidently been ground off by the glacier period in these canyons. The valleys are filled in with these washings from the mountains, and it is in these canyons and valleys that the gold dust is found, along the sides of these hills and mountains. It is found everywhere along the Yukon River and in the sands of the river. It is estimated that about $2,000,000 to $3,000,000 of gold dust has been taken out of the Yukon River in the past five or seven years, but a record of it does not appear in the public record, for the reason that the miners bring it out, as a rule, go to the first assay office and pass it through and sell it, without mentioning where it is from, and the Yukon never gets the credit for it. Usually the country, where the mine or assay office is situated, is the country that gets credit for the production of that gold. I mention this because it looks to a person who is interested in that country that the United States Government is not fully alive to the situation and to the magnitude and value of the country that we own there. The Canadian Government is fully alive to the situation, and has already placed officers, among whom is a magistrate, with a mounted police force numbering twenty-two men, to look after the people of the Canadian Government in the Yukon country. The dividing line between the British country and the United States on the Yukon is a little southeast from the Arctic circle, so that a good deal of the valuable gold country lies not only in the United States, but in the British Northwest.

"I look for a great future when the country is opened. Of course, it is now very new and crude, and the kind of people who are needed to develop it are sturdy miners who have some money to take with them, so that in case they do not happen to get a good 'prospect' immediately, they will have something on which to depend. It won't do for the ordinary run of humanity to go into that country without money.

"The country produces gold and furs in quantity. We brought down our usual collection of the latter, such as bear skin, marten, sable, silver fox, cross fox, and red fox, beaver, otter, mink, lynx, and on the coast quite a quantity of hair seals are taken, this being too far north for the fur seal.

"Another matter which should be of great interest to the people of the United States is the opportunity offered for the fishing industry along not only both sides of the Aleutian Peninsula, with its myriad islands, but the entire western and northwestern coast of Alaska, from Norton Sound to the mouths of the Yukon and the Koskoquin. There are fishing banks, both of cod and halibut, extending through the entire district mentioned, and all the rivers running into these different islands and coasts at the proper season of the year are full of salmon. The natives of the Yukon country consume salmon as their principal diet, and upon it even feed their dogs. Their dogs are their beasts of burden. They do their travelling in the winter, over the snow or ice; they dress in skins; in fact are Eskimo. The Indians of the northern Arctic coast and the lower Yukon River are short, fat, sturdy people, good natured, and usually honest, while the Indians of the Yukon River are more genuinely Indians—short, slight in build an active, hardy race, and yet from the nature of their food—mostly fish, with some game, of course, are a species of Eskimo.

"It would be greatly to the advantage of the United States Government that more interest be taken in that country, and that a proper survey be made of that great river and its mouth, as also of the proper line between the British Northwest and our Alaska."

DOCTOR OF MACHINERY.

Among the multitudinous trades and professions there are many which are entirely unknown, even by name, to the general public. One of the least known and most interesting is that of the expert in machinery. The work of a machinery specialist is far higher than that of a skilled engineer, and many years of experience and special training are necessary to fit the expert for his duties. There are only about half a dozen of these men in the country, one in every large city. When anything goes wrong with a machinery plant of whatever nature, the cause of which the engineer in charge, frequently the builder of the engines, cannot discover, the machinery doctor is called in. Every chief engineer of a big plant may be called a specialist so far as the machinery under his charge is concerned, but the specialist in machinery is an expert in engines of every description.

Though he has never seen the engine before, he rapidly diagnoses the case and prescribes a remedy, just as a doctor does for a sick patient. The instrument most used by him is a dentophone, which consists of a thin steel rod about a foot long, which he holds between his teeth and applies to the head of the cylinder. To the practiced ear of the expert every sound transmitted from the cylinder tells a story. The working of the piston in the cylinder, and, indeed, of the whole engine, can be heard distinctly in this manner by anybody, but it takes an expert to tell just what those sounds mean.

In the case of a mysterious knocking which was heard in the cylinder of the big driving engine in a large spinning factory not long ago, an expert was called in to determine the cause. Every method had been tried to discover where the trouble was, but without avail. Bearings were examined, the cylinder was taken apart, and every part well oiled, all to no purpose. When the expert came he traced the mysterious knocking from the cylinder, along the piston rod, crank shaft, and through the main shaft, away off among the looms, where one of the looms was found to be the cause of the trouble.

Often an expert's services are required in the case of synchronizing looms. If all the looms in a big spinning factory happen to beat together, as sometimes happens, the vibration is strong enough to bring the building down. For the same reason soldiers always break step when going over a suspension bridge, for otherwise the measured tramp of the many feet all striking the ground at the same time would seriously endanger the structure. The power of sound is also enormous when exerted in a particular way. Every substance in nature has a keynote, and when a sound of the same pitch is caused near it a considerable amount of vibration is produced. When the great tubular bridge was being built across the Menai Straits, which divide England from the island of Anglesea, a traveling violinist nearly caused the collapse of the whole structure. He happened, while playing, to hold for a considerable time a note which chanced to be the keynote of the huge bridge structure. The sound echoed along the vast tube and re-echoed with ever-increasing force until the whole bridge vibrated as if an earthquake were taking place. The bridge engineer, who was near by, instantly divined the cause, and stopped the playing of the violinist.

Part of the business of the machinery doctor consists in so arranging the distribution of looms and other machinery that their working will not endanger the stability of the factory. Defects in a boiler can also be instantly determined by the practiced ear of the specialist. A plate in the boiler is selected which is known to be in good condition, and he takes mental note of the pitch of the sound made when the plate is struck with a hammer. All the other plates are struck in the same way, and any one which does not ring true and conform to the correct pitch is examined and replaced. A case is on record where a machinery specialist was crossing the ocean and detected crystallization in the center of the shaft, thereby averting what might have been a serious accident in midocean. Measures were taken to strengthen the shaft to the place where the quick ear of the expert detected weakness, and when the vessel was docked his suspicions proved correct.

Few men, even with the most exhaustive training, can become experts at this business, as it requires a marvelous quickness of ear and delicate perception of sound with which few men are blessed. Technical knowledge is of little avail of itself, and a fine engineer might be a poor machinery doctor, just as a great musician might make an indifferent piano tuner. Whenever a big mill is erected, a specialist is always consulted as to the placing of the machinery, and his fee is generally well worth the expense and trouble which an injudicious distribution of machines may cause.—*N. Y. Tribune.*

AMBERGRIS.

What is ambergris? In the "Arabian Nights" we are told of Eastern beauties whose cheeks were marked with moles like bits of ambergris, and in the story of the sixth voyage of 'Sinbad the Sailor" we read in the description of the place where the voyagers were wrecked. "Here is also a fountain of pitch and bitumen that runs into the sea, which the fishes swallow and then vomit it up again, turned into ambergris!" That antique author, Robert Boyle, considered it to be of vegetable production and similar to yellow amber; thus it received its name, amber-gris—gray amber.

This and other even more plausible theories are but indeed fallacies that puzzled savants have set forth when they were at a loss to account for its origin. It is now ascertained beyond a doubt to be generated by the large-headed sperm whale and is the result of a diseased state of the animal. The victim of this rare malady may possibly throw off the morbific substance, or finally die of the ailment. The disease is located in the intestinal canal, and some savants suppose it to be caused by a biliary irritation. After a deep study on the subject several modern scientists have agreed that the disorder is akin to to that now fashionable human peril, appendicitis, intensified and prolonged in this great mammal, yet that dread ailment that has but lately been understood by the surgeons and medical men of the world.

It is known that the ambergris whale feeds upon the cuttlefish. This creature is armed in its head with a sharp-pointed curved black horn resembling a bird's beak, much like that of a parrot, only the lower mandible is the larger. This is found—as it is too indestructible to be digested—in many specimens of ambergris, and may oftentimes aid in establishing a seated disease. It may be considered, though, to be but the primary cause of irritation, as much of the finest ambergris is entirely free from the tough little horns. Such is the effect in the whale of the magnified—and tremendously magnified—illness which, when established in our own comparatively puny organism, causes an instant and fatal collapse unless quickly and heroically attacked by the skill of the surgeon. The habits of the great water mammals, however, tend to prolong life, and their resisting power against the insidious destroyer is eloquent of their tenacious hold on existence.

To the conservative whale fisher of New Bedford or Provincetown, the discovery of ambergris is as unexpected and as longed for as the sheeny splendor of the pearl that gladdens the pearl fisher. Almost awe-stricken are the sailors when the cry of "ambergris" is uttered. This is the happy event of a lifetime. The substance is carefully taken from the bowels of the whale and is packed in casks if it is in liquid form, or in sacks if it is dry enough.

It is then brought direct to Boston, where it is appraised by the head of the largest wholesale drug firm in the city. This young man has no enviable task before him in ascertaining the value of the article. He has to examine the fetid mass, which is sometimes in a rank liquid state, sometimes of the consistency of soft putty, and again a chalklike substance. That which is more like putty usually is to be relied on for making the best market ambergris, and gradually, as it dries, the only curing process it undergoes, the unwholesome dark shade turns to a soft squirrel gray. The substance lightens in weight, developing a fascinating odor almost indescribable, like the blending of new-mown hay, the damp woody fragrance of a fern copse, and the faintest possible perfume of the violet.

And to what use is ambergris put? It is an indispensable article with fine perfumers, as it is used to give permanency and lasting qualities to very fleeting scents. It is a curious fact that the keynote or basis of "nosegays" or "bouquets," as handkerchief odors are called, is not, as one might suppose, the attar of garden flowers, neither the penetrating balsams. These are indispensable, but are not the groundwork. That basis is always one of the four animal odors, *i. e.*, ambergris; musk, obtained from small musk deer of Asia; civet, from the civet cat of India, and castor, a secretion of the castor beaver, and now almost obsolete in the perfume trade. The pure and separate tincture of any one of these odors is too intense and powerful to be tolerated. Like all substances of these kinds, it must undergo a slow decomposition, till the remainders possesses very little volatility. Even then they contain a virtue which clings pertinaciously to woven fabrics, and not being soluble in weak alkaline lyes, are still to be detected in the material, after passing through the severest lavatory ordeal. They are, therefore, of great value to the perfumer, and are the foundation in almost every formula.

The price of ambergris varies from $5 per ounce to as high as $30 for the finer qualities. It is told that as much as 150 lbs. was found in one whale by a lucky crew and the prize was worth $60,000; and among the whale fishers the possibility of such a find is dreamed of in the same way as the drawing of the grand prize in the lottery or the finding of Captain Kidd's gold is thought of by other people.—*St Louis Globe Democrat.*

LIQUID AIR IN COMMERCE.

An interesting illustration of the rapidity with which purely scientific discoveries frequently become the starting point of new industries is furnished by the case of liquid air. It is no long time since liquid air was produced for the first time in quantities great enough to admit of its application for purposes of research; yet steps are already being taken to treat liquid air as an article of commerce, and to turn it out upon a large scale. As in most cases of the kind, laboratory methods require modification to suit the needs of wholesale production. Patents are being taken out for machinery which, though constructed upon the principles of that used for purposes of research, will attain the desired end with greater directness and with the omission of several intermediate steps. The necessary reduction of temperature to the critical point of air has hitherto been effected by the successive employment of liquefied gases boiling at lower and lower points on the scale. But the final decrement of heat has been won by the cooling effect due to the rapid evaporation of the product itself. The new apparatus dispenses with the use of these intermediate cooling agents, and relies entirely upon initial compression by powerful engines and subsequent partial expansion of the compressed air under carefully regulated conditions. Most people probably have seen at one time or another the familiar lecture-room experiment of forcing a piston suddenly down a cylinder, and showing the ignition of a scrap of touch-paper by the heat thus produced. If while the compression is maintained the cylinder and its contained air be cooled to the original temperature, then, on suddenly withdrawing the piston and allowing the air to regain its original volume, there will be a fall of temperature corresponding to the rise on compression. If now the cooled air could be used to reduce the temperature of a second quantity of air before expansion, it is evident that, starting from a lower point than the first batch, the second would on expansion reach a lower point. This is the principle of the new liquid air apparatus. A powerful engine compresses air, which is cooled as far as possible by ordinary refrigerating methods, and passed into a spirally coiled pipe, over 100 yards long. This pipe is enclosed in a second spiral. By means of a throttle valve at the end of the inner spiral a certain proportion of the compressed air is allowed to expand in the space between it and the outer pipe. Thus the stream of compressed air from the pump is cooled by that portion which has been allowed to expand, and arrives at the throttle valve in a colder state than the portion that preceded it. Consequently it reaches a still lower temperature on expansion, cooling yet more powerfully the advancing stream in the inner tube. By carrying this cumulative cooling effect sufficiently far, the circulating air is at last brought down to its critical point and liquefies, after which a continuous stream of liquid air is merely a question of engine power. It is impossible without the aid of diagrams to explain clearly how the continuity of the process is maintained, but the cycle of operations can be readily apprehended. There is compression, expansion in a closed chamber, and utilization of the cold thus produced to repeat the cycle from a lower initial temperature. The inventor, Herr Linde, who is a man of great experience in refrigerating machinery and methods, believes that a large demand will shortly arise for this most powerful of all refrigerators. In the meantime his apparatus produces with the greatest ease a substance for which there is already a large industrial demand—oxygen gas. During the process just described the air becomes steadily richer in oxygen until that gas forms some 70 per cent. of the product. This relatively pure oxygen is sufficiently good for certain purposes, and it may be further purified from nitrogen if desired. The price of oxygen gas thus obtained compares favorably in respect of cost with that produced by the methods now in use. It would have been gratifying to have been able to announce that this commercial application of recent scientific ideas, so closely associated with the Royal Institution, had been made in England. But, unfortunately, in this, as in so many other cases, it has been "made in Germany," where there is at present far more alertness and a far higher standard of technical knowledge than among ourselves. It is obvious from what has been said that this process is an affair of engineering far more than of chemistry. This remark applies to many of the most important and lucrative manufacturing processes of the day, and, unhappily, engineering, chemistry, or chemical engineering, is just one of the things in which the Germans are conspicuously superior.—*The London Times.*

UNDERGROUND WATER

"Stories about a great subterranean lake or sea beneath Nebraska, Kansas and a part of Indian Territory are going the rounds of the press," said Robert T. Hill of the United States geological survey. "They are accompanied by details relating to the bottomless ponds occupying areas where patches of land have sunk and disappeared. Other reported phenomena, supposed to be in the same connection, are roaring wells in which water ebbs and flows.

"Such tales become current periodically. So far as the wells are concerned, they are based on fact. I, myself, have seen a number of wells in which the water rose and fell at intervals. This is not an uncommon phenomenon in parts of the West. It has a relation to changes of the barometer. When the barometer is high, the pressure of the atmosphere being greater, the water in such wells and springs stands at a low level. On the other hand, when the mercury in the glass is low, the diminished pressure permits the water to rise. The surface level varies from day to night, for the same reason.

"There are many phenomena connected with Western wells and springs which are calculated to excite the attention of the observer from the East. They are puzzling sometimes even to a scientific student. I have never seen a well that roared, but I know of no reason why such a thing may not happen. There are wells from which currents of air come up. Stories are told of magnetic wells, in the neighborhood of which the needle of the compass is affected. I never saw one, and no facts appear to support this peculiar yarn. Water is the most common substance in the world, and there is nothing about which so much humbug exists.

"The most remarkable well I have ever seen was on the old battlefield of Stone River in Tennessee. A man digging for water struck an underground stream. He made the hole big enough to hold a water wheel. The stream ran the wheel and pumped water up to the owner's house. Underground streams, of course, are common enough. They are frequent in the limestone region of Texas, in the gypsum region of New Mexico, in the Appalachian region, and in the limestone region of Iowa and Missouri. The very fact that these streams are flowing shows that they are seeking a base level, and hence it is useless to try and tap them by artesian wells, because the water will not rise.

"There is no such thing in the world as an underground lake or sea. Nevertheless, such lakes have been created frequently by the imagination of hopeful settlers in the West. The truth in this matter was established years ago by the Government engineers who, under the direction of Col. Nettleton, journeyed across the great plains of Kansas and Nebraska. They sounded every well they could find, studying the underground water. Of the fact that there was no underground sheet of water they made certain. The wells were like any other wells, the water coming from saturated rocks below the level of surface evaporation."—*Pittsbury Commercial Gazette.*

REVERSAL IN INVENTION.

Mr. Edward P. Thompson, in an article in the Journal of the Franklin Institute, entitled "Reversal in Invention," points out a simple fact that may be of the greatest use to future inventors, as it certainly would have been to inventors in the past. He reminds us that a large number of important devices may be sorted out into pairs, one of each pair being what he calls a "reversal" of the other. Thus, the dynamo, which transforms mechanical into electric energy, on being reversed becomes the motor, which changes electric energy back again into the mechanical form. Now if this principle of reversal had only been recognized long ago, each of those pairs of inventions would have required but a single inventive act, instead of two entirely independent ones. Both the invention and its reversal would have been devised at once, instead of by different persons going through different trains of thought at widely different periods. We quote a few of Mr. Thompson's illustrations of these "reversed" inventions:

"At the time the microscope was invented the principle of reversal could have been applied by reasoning that, if a distant large object could be made to appear nearer, could not a near object be made to appear larger? Had this idea been created, the mechanical execution could have been carried out by experiments with lenses of different convexities, concavities and numbers.

"A reversal of the telephone, which causes distant sounds to appear near, would be a microphone, but the present instrument is improperly named, as it does not enlarge, but simply creates a sound. When first invented its wonderful power was spoken of as making the walking of a fly sound like thunder, but this is false, because the fly jarred loose carbon electric contacts, thereby causing great fluctuations of current and violent action of the receiving telephone. . . . .

"The present air brake system is now recognizable as a reversal of the early type, but a long time passed before the change took place. The principle had not been used as a kind of tool, and, therefore, the idea of the new brake did not come by demand of the mind, but by a combination of circumstances, that is to say, accidentally. The two systems of brake referred to are perhaps already conjectured by the reader, the first operating to stop a train by the positive action of compressed air against the wheels through the medium of the usual brake shoes, and the second by the negative action of compressed air, which normally holds the shoes away from the wheels in opposition to a spring. The advantages of the second way are apparent as soon as compared as to their main object, safety; for, by the former the train cannot be stopped in the case of leak or a disordered pump, while with the latter the train stands still as soon as the air leaks out or the pumps refuse to work. . . . .

"The mental process of investigating this subject makes the principle so simple that it is a wonder that inventions existed so long before their opposite phases were thought of. Electricity furnishes several examples besides the dynamo motor example, where the principle was not applied by a predetermined act. The old form of burglar alarm had an open circuit, and the process of opening the window closed the circuit and rang a bell. The reversal of this is a normally closed circuit. The opening of the window breaks the circuit and the bell rings. The idea once gained, and the advantages are apparent, for an alarm is given if the burglar cuts the wire. . . . .

"The storage battery, although condemned for railway traction, is still one of the valuable inventions of the day, and is an exact reversal of the galvanic battery. The reversal is disclosed by stating that the operation of the primary or galvanic battery consisted in placing metal plates into a solution of salt or acid, and carrying off the electric current by a wire. The reverse of this consists in starting with an electric current, after the battery is partly exhausted, and passing the current through the solution in order to restore the chemicals to their original composition, ready to give off current as before the charging."

SLEEP.

Elizabeth Cady Stanton in an article describing her manner of living thus speaks of her ability to sleep and its healthful effects. "Someone, knowing my genius for sleep, says, 'You cannot be in health and sleep as you do on the slightest provocation.' "This, too, is an ancestral tendency. My grandfather made Sunday a day of rest. After feeding his cattle and taking a bird's eye view of his farm, he slept until dinner, and after a frugal repast, again until tea, and as soon as the sun went down he retired and slept all night. My father, conforming rather more to the demands of a progressive civilization, solaced himself with a few short naps; both at church and at home. He has been known, in our old Scotch Presbyterian church, to sleep standing all through the long prayer, and on a few occasions to maintain the perpendicular after all the congregation were seated, much to his own mortification and the amusement of his children. Yet as a judge and a lawyer he was always awake to the interests of his clients and the sophistries of the advocates in his court. He was the oldest judge that ever sat on a bench in this country, resigning at the age of eighty-four. When as a child I was disappointed in any anticipated pleasure, punished, or suffered injustice, I hurried to my room and went to sleep.

"In the palmy days of Theodore Parker's popularity, I attended his ministrations regularly. As it involved a long walk, and I reached his place of worship very tired, I made it a rule to sleep through all the preliminary services that I might be wide awake for the sermon, a friend near by arousing me at the right moment. Just so in going to a ball, party or dinner, I felt a short nap was an important factor in my toilet, as nothing could make me so attractive as the color and look of repose that follows sleep. No rouge or stimulus equal to it. If from no higher motive than vanity, I say to all girls in society, sleep. Cosmetics, laces and flowers cannot conceal a weary jaded look, nor a chronic condition of dissatisfaction. I have emphasized this point because most people seem to think that sleep is disreputable, that there is great virtue in being forever on the watch tower. This is one doctrine in the gospel of health that I have preached to nervous men and women in all my travels from Maine to Texas.

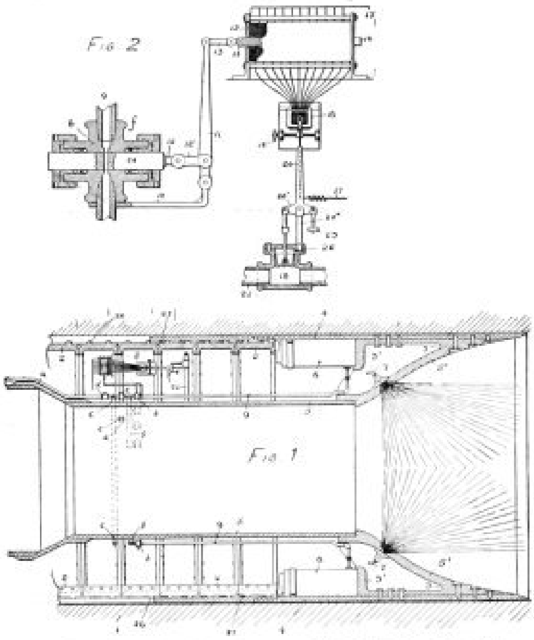
"Occasionally you will meet a crotchety man or woman who has some theory about early rising, and not satisfied to get up themselves to see the sun rise, they will waken a whole household, pulling young children out of their nests, making them cross all day. The insane asylums are full of people whose sweet morning slumbers have been rudely broken by some ignorant theorist. One of the most pitiful sights I recall in my Western travels was a breakfast table surrounded by children under ten years of age, eating bacon and buckwheat cakes by candle-light, the thin, nervous, tired mother during the day utilizing the time she had stolen from sleep in hemming half a dozen yards of ruffling for a pillow-sham. Seeing her continually yawning and stretching, I said, 'Why do you not lie down and take a nap?' 'Ah,' she replied, 'I have too much to do to waste an hour in sleeping.' "Why not dispense with the pillow shams and refresh the woman in view of her comparative importance in domestic life? is a question anyone of common sense would put to a mother under such circumstances."—*The Journal of Hygiene.*

WALKING BACKWARD CURE FOR HEADACHE.

An apostle of physical culture says that an excellent and never failing cure for nervous headache is the simple act of walking backward. Ten minutes is as long as is usually necessary to promenade. It sometimes, however, requires more than ten minutes to walk at all, if one is very "nervous" But it is not understood that it is necessary to walk a chalk-line. Any kind of walking will do, provided it is backward. It is well to get in a long, narrow room, where the windows are high, and walk very slowly, placing first the ball of the foot on the floor, and then the heel. Besides curing the headache, this exercise promotes a graceful carriage. A half hour's walk backward every day will do wonders toward producing a graceful gait.—*Medical Record.*

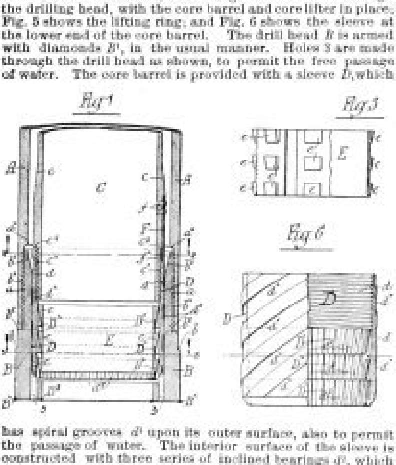
SHAFT SINKING APPARATUS.

No. 549,586. RICHARD P. ROTHWELL, NEW YORK, N. Y. *Patented Nov. 12th*, 1895. Fig. 1 is a lengthways section through the apparatus; and Fig. 2 is a detail of the governing apparatus, on a larger scale. In sinking shafts or driving tunnels in soft or wet ground, great difficulty is found in keeping the hole straight. When the head is forced forward it is apt to encounter softer earth on one side than on the other, and thus be deflected out of proper alignment. The apparatus here shown, is designed to govern the hydraulic jacks which force the head forward. Each jack 6, is supplied with pressure water through a pipe 9, and all these pipes are connected to a belt pipe c, by valves f. The mechanism of these valves, and the means of controlling them is shown in Fig. 2. The supply of water to any one jack, is varied by moving the balanced plunger 24. The valve lever is operated by an iron rod 14 which moves through a series of magnetic coils 15. The terminals of these coils are brought together in a switch board 16, and electric connections are made by means of a switch lever 20. A pipe 21, which extends around the inside of the head, is filled with mercury. Each switch lever is operated by the rise and fall of the mercury in a cell below the plunger 18, to which it is coupled. If the head 5 tilts out of plumb, or out of alignment, the pressure in the mercury cells varies accordingly. The shaft linings 2 are put in place, in sections, at the same time that the soft earth is being removed through the central tube 5, the space between the tubes 4 and 5 being sufficient to permit the workmen to operate. Several water jets 7 are arranged at convenient points, by which water may be projected with more or less force upon the earth in front of the head, to loosen it and assist its removal.



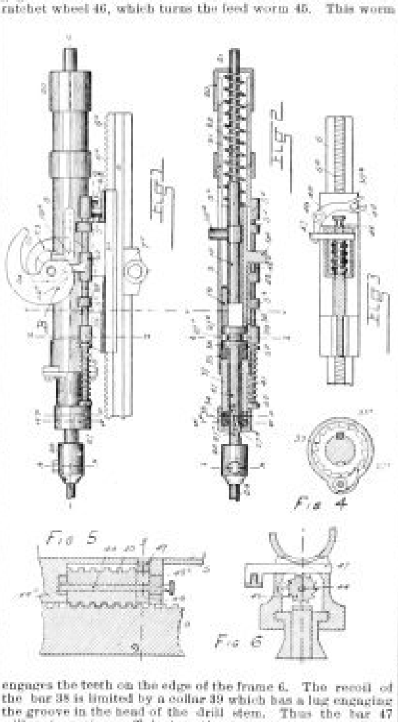
ROCK CORE DRILL.

No. 548,607. J. F. DUGGAN AND M. C. BULLOCK, CHICAGO, ILL. *Patented Oct. 22nd*, 1895. Fig. 1 is a section through the drilling head, with the core barrel and core lifter in place; Fig. 5 shows the lifting ring; and Fig. 6 shows the sleeve at the lower end of the core barrel. The drill head *B* is armed with diamonds B^1, in the usual manner. Holes 3 are made through the drill head as shown, to permit the free passage of water. The core barrel is provided with a sleeve *D*, which has spiral grooves d^1 upon its outer surface, also to permit the passage of water. The interior surface of the sleeve is constructed with three series of inclined bearings d^2, which engage corresponding bearings *e* upon the exterior surface of the ring *E*. This ring is split at one side, so as to contract easily, and is smooth upon its inside surface, so that a large surface is provided with which to grip the core. By making the bearings in three series, a sufficient amount of contraction of the ring is secured with a small upward movement of the core barrel *C* upon the gripping ring. The provisions made for the passage of water between the parts, adapt the drill to all varieties of work.



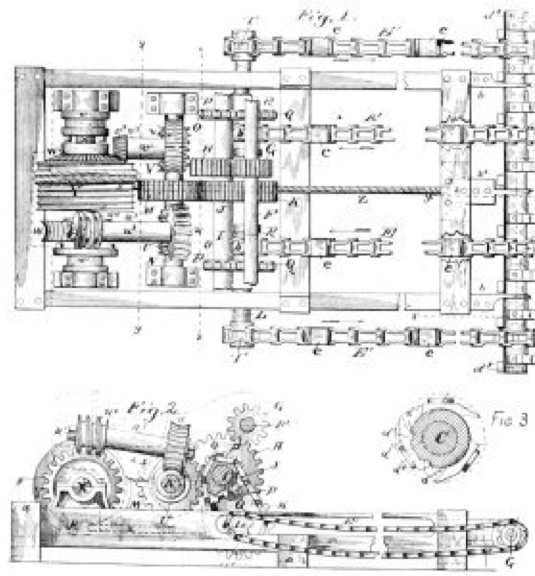
ROCK DRILL.

No. 548,324. HORACE B. MCCABE, LAKEWOOD, COLO. *Patented Oct. 22nd*, 1895. Fig. 1 is a side view of the machine; Fig. 2 is a section of the same; Fig. 3 is a partial view of the under side of the cylinder; Fig. 4. is a cross section at the line *W W* in Fig. 1; Fig. 5 is an enlarged section through the feed worm; and Fig. 6 is a cross section through the same on the line 9. This drill is worked by hand power, by means of a crank, which rotates the two cams 23 and 24. These cams engage the pins 18¹ and 19¹, which are attached to the hammer bars 18 and 19. The bar 19 is tubular, and the solid bar 18 plays inside of it. A spring 22 propels the hammer 19, and the bar 18 is thrown by the spring 21. The cap 20 can be adjusted, to vary the tension of the springs. The drill is held in the chuck 28. The stem 27 has two feathers, one spiral and one straight, which engage a pair of ratchets 33 and 34. The spiral feather operates to turn the drill stem at each forward movement. The feed is operated by the small cam *B* on the crank shaft, which moves the rod 38 by means of the finger 42. A pin 38¹ on the back end of the rod engages a lever 48 and works a tooth bar 47 across a small ratchet wheel 46, which turns the feed worm 45. This worm engages the teeth on the edge of the frame 6. The recoil of the bar 38 is limited by a collar 39 which has a lug engaging the groove in the head of the drill stem. Thus the bar 47 will not receive sufficient motion to engage a new tooth on the ratchet feed wheel, and turn it, until the drill stem has advanced within its casing nearly to its forward limit. The feed worm is supported on an eccentric spindle, and by turning the knob shown in Fig. 5, it can be lifted clear of the rack teeth, so that the drill may be freely drawn back.



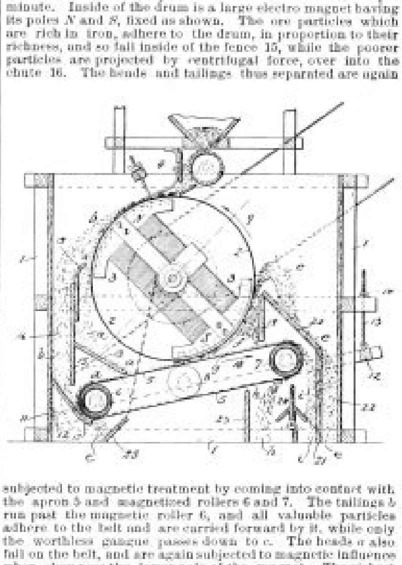
MINING MACHINE.

No. 548,760. BENJAMIN A. LEGG, COLUMBUS, O. *Patented Oct. 29th*, 1895. Fig. 1 is a top view of the machine; Fig. 2 is a side view of the same, and Fig. 3 is a section of the cutter bar. The chief novelty in this machine is in the cutter bar. The cutters are bolted to the outside of the cutter bar, as shown in Fig. 3. The bar is tubular and is made in four sections, which turn upon a fixed spindle *C*. This spindle is firmly held in three brackets b, b¹. Each section of the cutter bar is driven by an independent chain, the two middle sections revolving toward the left, and the outer ones toward the right. Thus, half of the cutters tend to lift the front end of the machine, and the others tend equally to depress it, consequently the machine is free from any tendency to "climb" or "dive." Each chain is armed with about four cutters, which make way in the coal for it. The outer chains are driven by the shaft *L*, which is geared to the engine shaft *F*, by means of the wheels *K*, *J*, *H* and *G*. The inner chains are driven by means of sprocket wheels *S*, which turn loosely on the shaft *L*, and are rotated by means of chains *P*, and sprockets *O*, on the shaft *I*. The machine is fed forward and back by means of a wire rope which engages the drum *Y*, and is fastened to each end of the stationary frame *A*. This drum is keyed to the shaft *X*, which is turned by means of the clutches *w*, *w*¹. One of these clutches can engage the worm wheel *W*, which is turned slowly by the worm *u*², shaft *u*¹, small worm wheel *u* and worm *U*. To reverse the feed and draw out quickly, the clutch *w*, is made to engage the bevel gear *W*′, which is driven by the pinion *v*¹, worm gear *v* and worm *V*. By making the rope a little slack, it will slip on the drum, when the cutters encounter anything unusually hard, and thus save the machine from breakage.



MAGNETIC ORE CONCENTRATOR.

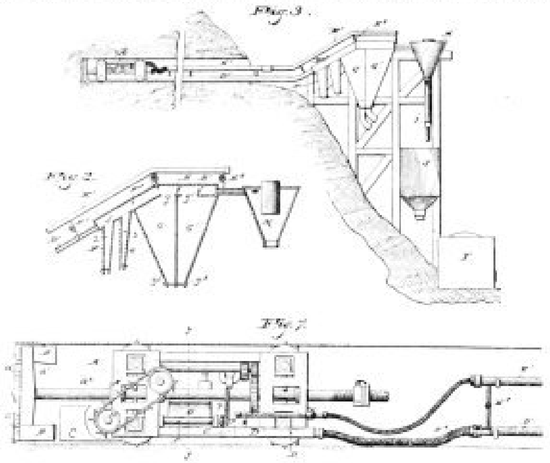
No. 548,176. CHARLES G. BUCHANAN, BROOKLYN, N. Y. *Patented Oct. 22nd*, 1895. The pulverized ore is fed through suitable feeding devices at 4, onto an iron drum 2, which revolves with a surface speed of about five hundred feet per minute. Inside of the drum is a large electro magnet having its poles *N* and *S*, fixed as shown. The ore particles which are rich in iron, adhere to the drum, in proportion to their richness, and so fall inside of the fence 15, while the poorer particles are projected by centrifugal force, over into the chute 16. The heads and tailings thus separated are again subjected to magnetic treatment by coming into contact with the apron 5 and magnetized rollers 6 and 7. The tailings *b* run past the magnetic roller 6, and all valuable particles adhere to the belt and are carried forward by it, while only the worthless gangue passes down to *c*. The heads *a* also fall on the belt, and are again subjected to magnetic influence when they pass the lower pole of the magnet. The richest particles adhere to the drum and are thrown upward over the fence 20, and pass away into the chute 22. The medium stuff strikes the plate 19 and falls back on the belt. The final separation is made by the magnetic roller 7, and the middlings



are delivered at h. The belt and rollers are mounted on a hinged frame, which permits the belt to be adjusted more or less closely to the drum 2 to suit varying qualities of ore. It is claimed that ordinary magnetites can be concentrated by this machine to sixty-eight per cent.

METHOD OF MINING COAL.

No. 550,031. Edward S. McKinlay, Denver, Colo. *Patented Nov. 19th*, 1895. Fig. 3 is a side elevation of the apparatus, showing the general arrangement; Fig. 2 is a detail of the separators; and Fig. 7 is a side view of the coal cutting machine. The machine employed is an ordinary "header" or tunneling machine, and it removes the coal in small pieces, as chips and dust. The cutter head is provided with two plates B, which scoop up all of the borings into the pan C. All of the large lumps are picked up by the conveyor N, and are thrown into crushing rolls P, which reduce them to fineness. The engines which drive the machine are driven by compressed air, and the exhaust is used with suitable jet nozzles to blow the fine coal, etc., into the end of a tube D, which is connected by a flexible pipe D^2, to a stationary delivery pipe D^3. At intervals along this pipe jets of compressed air are introduced by means of pipes E^1, from the air main E^1. The jets are pointed forward, so as to drive the pulverized coal toward the point of delivery. When the destination is reached the pipe D^3, is enlarged, as at F^1, in Fig. 2, and the stuff is shot upward over the mouths of the pockets 2 and 3. A separation of the good coal from the accompanying slate, etc., occurs at this point, because the coal being lightest flies over the pockets, while the heavier impurities which move more sluggishly drop into them. The coal is intercepted by the screens H, H^1, and is caught in the pockets G, G^1. The dust passes on into the dust catcher M. The coal passes by suitable pipes into the receiver J, from which it is fed into the coke ovens I. Slack coal, that is the material produced by this apparatus, is preferred by many manufacturers of coke, to lump coal, in fact they usually grind or pulverize their lump coal to a similar condition. This apparatus pulverizes the coal in getting it.



LONG WALL MINING MACHINE.

No. 545,168. Jonas L. Mitchell, Chicago, Ill. *Patented Aug. 27th*, 1895. Fig. 1 is a top view of the machine; Fig. 7 is a cross section at the rear of the engine cylinders; Fig. 10 shows the construction of the cleaning chain; and Fig. 12 shows one of the scrapers which are attached to the chain.
