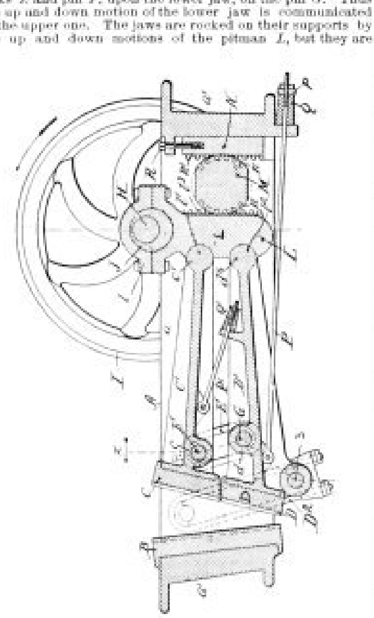
The cutter which is employed in this machine is a tapering spindle E which projects from the sides of the machine as shown, and is armed with numerous small cutting bits. Rotary motion is imparted to it by suitable gearing and an engine of which only the cylinders B are shown. The cutter bar is followed by a cleaning chain K, which removes the chips. The construction of this chain, and the scrapers attached to it is clearly shown in Figs. 10 and 12. The machine is propelled by means of a windlass F, which is rotated by the engine, and a rope F^1 which extends forward to a post F^2. The principal novelty in this machine is in the apparatus for steering. A long steering truck H is attached to the machine by a hinge at 3, and a right and left nut 4. The truck rests on two sharp edged wheels 5, which are made to bite into the floor by means of a large weight R. These wheels are steered by a tiller n^2 which can be secured in any hole in the bar 6. The final and and exact adjustment is made by working the nut 4. When at work, the cutter E tends to force the machine out of the cut, although the rope pulls at an angle tending to hold it in, but it can be held up to its work by setting the steering wheels 5 to lead inwards slightly toward the face of the coal. The angle given to the steering wheels depends upon the hardness of the coal or fire clay composing the floor, and the sharpness of the cutters. It may be varied while running, thus the operator is enabled to make a full depth cut throughout the entire travel of the machine. The forward part of the machine rests on a shoe or sled m^1, which is pivoted to the machine frame at m^2, see Fig. 7. Jacks n, n^1, which are worked by air pressure, serve to steady the machine and maintain a proper inclination of the cutter bar.

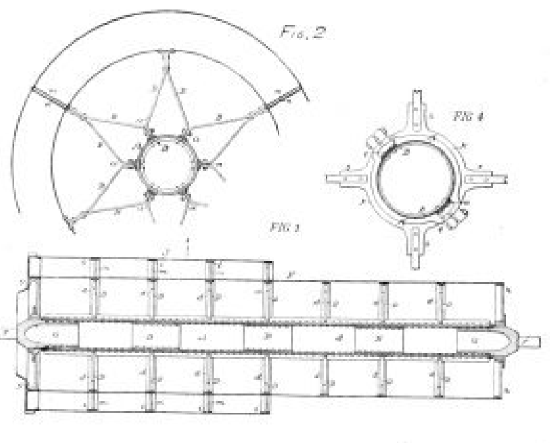
ORE CRUSHER.

No. 548,177. Morton G. Bunnell, Chicago, Ill. *Patented Oct. 22nd*, 1895. This machine has two moving jaws, which are operated simultaneously by the pitman L. The lower jaw D is suspended from the main frame by links D^2 and a pin 3, and is held in engagement with the pitman by the rod P and spring Q. The upper jaw C, is suspended by links E and pin F, upon the lower jaw, on the pin G. Thus the up and down motion of the lower jaw is communicated to the upper one. The jaws are rocked on their supports by the up and down motions of the pitman L, but they are moved forward and back in alternation by its sideways motion. The back of the pitman bar bears on a rolling fulcrum M, which has teeth engaging the pitman and the bearing block N, and moves up and down with it, though to only half the distance. Thus as the pitman is moved sideways by the eccentric J, one jaw is forced slightly forward while the other draws back. By shifting the block N, the bearing point of the fulcrum can be adjusted relatively to the bearings c^1, d^1, of the upper and lower jaws. The peculiar movements given to the jaws by this mechanism, are claimed to be very efficacious for the purpose of crushing stones and ore.



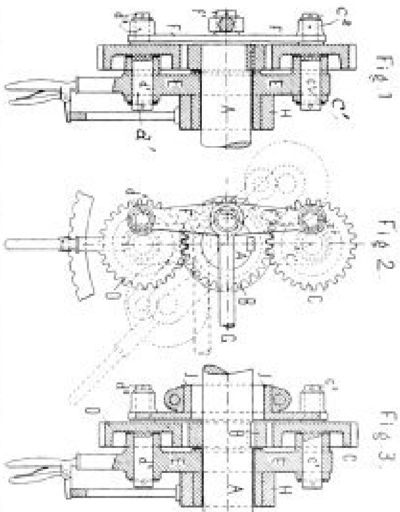
ROTARY SCREEN.

No. 549,365. Edwin H. Jones and Samuel Nicholson, Wilkes-Barre, Pa. *Patented Nov. 5th*, 1895. Fig. 1 is a lengthways section of the screen; Fig. 2 is a partial end view, on a larger scale; and Fig. 4 shows the manner of constructing the spiders. The shaft is made of plates which are rolled up into tubular form, and are joined at their edges by welt strips as in Fig. 4, or by T iron ribs as shown in Fig. 1. The several sections of the shaft are spliced and stiffened by means of internal tubes or thimbles B. In Figs. 1 and 2 a series of T ribs are riveted to the shaft; and the arms, which are made of flat iron, are riveted to these ribs. In Fig. 4 cast-iron spiders are employed, and these are made in halves and are clamped upon the shaft by bolts as shown. In this case the welt strips serve as keys to prevent the spiders from turning on the shaft.



VALVE GEAR.

No. 546,720. Kajetan Moscicki, Warsaw, Russia. *Patented Sept. 14th*, 1895. Fig. 2 is a side view of the mechanism; Fig. 1 is a vertical section of the same, and Fig. 3 shows a modification of the device. This mechanism is intended to take the place of the link motion for reversing an engine and for graduating the stroke of the valve to secure an early cut off of the steam. A gear wheel B is keyed to the engine shaft A. Two other gears C and D, which mesh into B, are supported on pins c^2, d^2, by the arm E. This arm can turn on a fixed bearing H, and it can be locked in any desired position by means of the latch and handle shown. Each gear C, D, carries a crank pin c^3, d^3, upon which a bar F, is suspended. The valve rod G, is attached to a pin at the middle of F. As the shaft and gear B revolve, the crank pins c^3, d^3,



and the pin to which the valve rod is attached, revolve in equal circles. In Fig. 3 the pin f' is replaced by an eccentric J, of sufficient size to permit the shaft to pass through it. The pin f', is shown at the left end of its stroke in Fig. 2. Now, when the parts are turned over to the position shown by the dotted lines, the gears C and D, turn on their spindles sufficiently to bring the pin to the lower quarter of its movement; if the arm be turned in the opposite direction, the pin can be moved to the upper quarter position, thus reversing the engine. If the arm is put in any intermediate position, the angular advance of the pin is correspondingly altered, and the motion of the valve, which is attached to it, is modified accordingly. For use on gas engines, which require the valve to be opened but once for each two revolutions, the gears C, D, are made of twice the diameter of B.

The Colliery Engineer

AND

METAL MINER.

VOL. XVI.—NO. 7. SCRANTON, PA., FEBRUARY, 1896. With Which is Combined THE MINING HERALD.

METAL MINING.

Ventilation by Natural Draft and by Assisted Draft.

Importance of Ventilation in Metal Mines Less Than in Collieries, but Too Often Overlooked—Sources of Vitiation of Mine Air—Special Need of Studying and Utilizing Natural Draft—Working Rules and Practical Suggestions for Controlling Air Currents Underground.

Written for THE COLLIERY ENGINEER AND METAL MINER by Albert Williams, Jr., E. M.

The ventilation of metal mines presents by no means the same difficulties as that of gaseous collieries, since as a general rule all that is needed is to supply enough fresh air for the health, comfort and effective work of the men and to remove the dead air vitiated by their respiration, by burning of candles or lamps, and by powder fumes. Usually there is no need for the additional and large volumes which have to be had in coal mines to carry off fire damp, choke damp, etc. Yet it is evident that, so far as it goes, there is always absolute need of sufficient ventilation; while also there are special cases requiring almost as careful attention as in collieries. However to simplify the matter at once, it may be said that it is very seldom indeed that mathematical computations and refined measurements of volumes, velocities and pressures would be called for, and that for all practical purposes the senses may be depended upon as guides. The exceptions requiring close calculation are so few, that for present purposes the student may be referred to treatises on colliery ventilation for data of this order.

The plain and simple rule is to be always sure that there is a liberal surplus of fresh air. It needs no testing apparatus to discover when the supply falls short.

CAUSES OF AIR VITIATION.

Respiration of the Men.—This is an ever-present source of air deterioration—both by the absorption of oxygen and the production of carbonic acid gas, perhaps still more by exhalation of organic gases. In a confined space, as in a small heading, the top of a raise or bottom of a shaft or winze, the lungs of two, four or more actively working miners would soon render the place untenable, unless there were some movement and replacement of air. Figures used as a basis for computing the number of cubic feet required per man in a given time, as in arranging for ventilation of halls, schools and theatres, are wholly useless here, for it is evident that the requirements per man must be indefinitely greater.

Respiration of Draft Animals.—Animal traction is very seldom used in American mines of any sort, and in metal mines only in large tunnels, assumed to be naturally ventilated. If horses and mules were used underground on closed levels they would, of course, make large demands upon the air supply.

Combustion of Candles or Lamps.—The amount of carbonic acid gas produced in this way may be four times as much as that exhaled in breathing. This is seldom realized. But the injurious effect does not appear to be in like proportion, for the oil, tallow, etc., give off only this one gas and no other poisonous products. The substitution of electric incandescent lights in the working places eliminates this trouble, and the question of non-fouling of the air is not the least of the arguments for the use of electric lights in metal mines.

Animal Filth.—There should be strict prohibition against befouling the workings. This is not simply a matter of decency and comfort, but also of hygiene.

Effect of Explosives.—The foul air produced by explosives is a more serious matter, though intermittent. After every blast, a certain time must be allowed for the gases to drift away and be slowly diffused, and this time can be shortened by strong artificial ventilation. So far as possible the shots should be fired at the end of shift, when less time is thus lost; and in some kinds of work, as in advancing a drift in country rock, the shift may just suffice for drilling all the holes, after which they are charged and fired in two blasts. But this convenient arrangement does not hold in stoping and in the majority of operations; so that in an active mine, blasts are being fired somewhere at frequent intervals. Hence special provision must be made or there will be undue loss of time.

Black blasting powder is one of the least objectionable explosives in this respect, but it is very rarely used under ground now. Its fume consists of sulphide and carbonate of potash, with a mixture of gases—carbonic acid, carbonic oxide, nitrogen, sulphureted hydrogen, marsh gas and hydrogen—but the more poisonous gases are in relatively small proportion. Giant powder (dynamite) and the whole family of nitro-glycerine explosives produce a variety of gases, together with the dust of the absorbent. There certainly is a considerable difference in the effect of their fumes, and while the advocates of each of the dozens of kinds of explosives of this class will admit that all the others are deleterious, they claim special inoffensiveness for their own make. The truth is that none are unobjectionable. It makes a great difference, too, whether the high explosives are completely detonated, as to the proportion of the resultant gases, and it has been remarked that a poorly exploded cartridge gives worse fumes, besides being a failure mechanically. What applies to nitro-glycerine explosives (dynamite) applies also to other nitro compounds—nitro-cotton, nitro-benzene, and the long list of new high explosives—though over each of these too there is an unsettled dispute. In American metal mining comparatively few of these explosives are used in any quantity, and the selection is generally determined on other considerations than that of fumes. If, however, the products of combustion of any particular brand are found to be more noxious, or less so, than the average, due weight should certainly be given.

Some persons are much more sensitive than others to the fumes from the high explosives; while there are others who are affected by emanations from the nitro-glycerine, etc., on opening a cartridge to insert the cap. The effects are nausea and dizziness, for which plenty of fresh air is the best remedy.

Mr. C. LeNeve Foster quotes the estimate of Dr. Angus Smith, who finds that "two men working eight hours and using half a pound of candles and 12 ounces of gunpowder, produce 25.4 cubic feet of carbonic acid (at 70°F), 10.3 by breathing, 12.3 by candles, and 2.7 by gunpowder." This is cited here to show that, with a low consumption of candles and powder (and the weights for both are disproportionately small for ordinary working conditions in metal mines), the breathing of the men is not the chief source of air impairment. The substitution of a high explosive for the black powder, as is almost invariably done, does not alter the general bearing of the case, at least not for the better.

The three agencies just referred to—respiration, burning of illuminants, and products evolved in blasting—are usually the only, or the main things to be considered, and all others may be regarded as exceptional. The former are introduced into the mine artificially, in the course of working it; the latter are mainly due to natural causes existing in the mine itself. There are however, still some subsidiary artificial effects, as for example—

Dust.—Metal mines are more likely to be very wet than too dry, but there are some that are very dry. Dust is made by the handling of broken rock and ore, by the shattering effect of the blasts, and in overhead drilling, or all drilling whether by hand or power, when water is not constantly supplied to the holes. This fine sharp dust may be present in thick clouds in confined spaces, and is highly injurious to the lungs, even if not actually poisonous chemically. Its removal is another call upon the ventilating facilities of the mine.

The dust of mines may be actively poisonous, as that found in lead carbonate ores, arsenical and antimonial gold and silver ores, cinnabar, etc.; good ventilation would be a partial, though not alone a complete, preventive against "leading," salivation, etc.

The upper levels of a mine not originally dry may become so, if there is very thorough drainage in the lower levels, and thus dust may be formed in a mine not naturally a dry one.

Vapor From Exhaust Steam.—This is rather an inconvenience than anything more serious. If there is machinery underground run directly by steam, there may be not only the puffs from the exhaust of the non-condensing engines (pumps, baby hoists, etc.) but leakages of steam pipes and connections. A good draft is needed to clear away the clouds of vapor that may be formed.

Decay of Timbers.—This is so rapid in some mines as to have considerable effect upon the purity of the air. It is not only an oxidizing process, with evolution of carbonic acid, but a putrefying one resulting in the emanation of various noxious gases—a dry rot. The stripping of bark from round timbers to be used as supports underground is thought by some to delay this action.

Heat From Underground Steam Engines and Pipes.—This is sometimes so great as to be very oppressive, and is dangerous also as a possible cause of fire. It cannot be avoided altogether, if steam machinery is still to be used underground; but it can be much mitigated by a plentiful flow of cool air from the surface through the heated places.

Among the detriments to the underground air, due to conditions inherent in the mine itself and not brought in artificially, are explosive gases and poisonous emanations from the ground as it is opened out. These, as already stated, occur comparatively rarely, though there are enough cases on record to make a formidable list when they are all brought together. There is also the question of natural temperature, as related to and modified by ventilation.

Explosive Gases.—Marsh gas (the principal constituent of the fire damp of collieries) is the most important of these. It is derived from decomposing carbonaceous matter (not necessarily coal), and may accumulate in the interstices of the rocks, and subsequently in the mine openings, in sufficient quantity to produce an explosion when ignited. It would not ordinarily be expected or provided against, and there have been a few bad explosions caused by it. It has been noticed most frequently in lead mines, in limestone and in black band iron mines (where also there may be seams of coal). Sulphureted, phosphoreted and arseniureted hydrogen, and simple hydrogen form explosive mixtures with the oxygen of the air, but rarely accumulate in sufficient quantity to be dangerous.

Poisonous Gases.—Carbonic acid gas may exist naturally in ground worked for metalliferous ores, and there have been a few notable instances of its presence in considerable quantities. It would be reasonable to expect it to be found in mines of black band iron ore having also coal seams, and it has been so found; but mines of this character are not worked in the United States. It is also found native in some lead and zinc mines, and indeed might occur wherever carbonaceous matter is present and is being completely oxidized, and under certain conditions may be formed by the decomposition of limestone and other carbonates (ores or rocks) by acid waters or heat.

The hydrogen compounds with sulphur, phosphorus, arsenic, etc., are highly poisonous, and cannot be tolerated in any large proportion in the air mixture. They are readily detected by the various disagreeable odors, however. This is also true of sulphurous acid, resulting from decomposition of pyritic minerals.

Nitrogen (negative, not poisonous) and some other gases are occasionally given off in small quantities from rock and ore.

As a mine is opened and drained, and the active oxidizing action of the air comes into play, while the course of chemically charged waters is altered, there is every opportunity for a variety of reactions to occur between the constituents of the ore and rock minerals, the gases and the waters; and it is not extraordinary that sometimes these reactions result in the formation of products injurious to respiration. While the really serious cases are not very frequent, the possibility of trouble is not to be lost sight of.

Natural Underground Temperatures.—Below the shallow depth (a few feet only) where atmospheric and surface changes cease to have influence, there is in the undisturbed rock a gain in temperature with increase in depth. This gain is more or less rapid according to locality and a variety of conditions. It is of no interest here to attempt to average the observations, for the range is so wide that for any particular mine the rate might be very far from any arbitrary average. The older authorities stated the "average" at about 1° F. for every 55 feet of descent. Later observations show the increase to be generally much less rapid, and 1° to 70 feet would now be considered a sharp rise. There are plenty of cases where the advance is only 1° in 100 feet or more; while on the other hand there are some instances in which a considerably faster gain than the formerly assumed average or mean has been noticed. Moreover, the increment is not even constant for the same mine, and it is quite likely that there are spots in which for a space the temperature change is actually reversed, a cooler zone existing below one heated by a lateral and local flow of hot water, since it is well known that rock temperatures are largely affected by those of the percolating waters. An ore-bearing region is not the proper place to discover the law of heat increase with depth, some such regions having stores of residual heat from volcanic eruptions and earth movements, while many others still feel the effects of solfataric action, with frequent hot springs in the neighborhood. Probably metal mines (excepting those of bog and lake formed deposits) as a general thing are in ground that with depth grows hotter than the true normal rate (if there is one) for the earth at large.

The essential point is that the rock is naturally hotter as we go down, and in most very deep mines (say from 2,000 to 4,000 feet) this increased heat is a great drawback. Ultimately it will put a limit to all mining, apart from the lesser mechanical difficulties. At present it is safe to look forward to working at a depth of at least 6,000 feet, probably more, so far as heat is concerned, in the cooler districts. Men have already mined with a rock and water temperature of 150°, provided the fresh air supply was abundant. In extreme cases the intake pipes have been discharged through ice water. [Consolidated Virginia (Nevada) used $15,000 worth of ice in one year.]

It is found that though, after reaching a certain depth in sinking, the rock at the bottom of the mine is always hot and growing hotter, the upper levels after being opened and properly connected by means of winzes, and a copious volume of fresh air constantly passed through, become cooler. The cooling effect of the air upon the rock is slow, as there is so large a store of heat, rock so poor a conductor, and only the small exposed surface to act upon. It is possible to have a lower level cooler than an upper one in time, by giving it better ventilation, as can be managed by suitable arrangements.

For immediate purposes, however, what concerns the miner is not so much the temperature of the rock and water, as the coolness, freshness and volume of the circulating air. After starting a level it is out of the question to wait for it to cool off before advancing and fully developing it. Later, it is so much the better that a main gangway, possibly to be used for several years, is becoming cooler. At the moment, what is wanted is effective ventilation.

The increasing heat of deep mines has another relation to ventilation. With the mine connections in suitable shape, this heat acts like that of an artificial furnace in causing an upward current, and therefore a corresponding downward intake to replace it. Whether or not there is artificial ventilation besides, this is of great importance.

The temperature of shallow mines, if not raised artificially, is cooler in summer than that of the surface, and warmer than the surface in cold weather. Usually it is only at considerable depth that the rock temperature is hotter than that of the surface all the year round. As in the mountain regions (where the greater number of metal mines are) there is a marked change in surface temperature from day to night, it often happens that there may be a daily alternation in relative surface and underground temperatures in mines of small depth. These facts have a controlling influence upon natural ventilation, and an important bearing upon artificial ventilation.

NATURAL VENTILATION.

In the great majority of metal mines this is the sole reliance. It is usually sufficient, and in very small mines is often allowed to take care of itself, although the adoption of simple and cheap arrangements for controlling natural currents would greatly improve conditions. As the workings are extended, the connections made for development of ground or convenience of handling ore, waste and water serve also for ventilating; but if these connections are planned with a view to the most effective ventilation as well as for the other purposes, the result is much better, and there is generally but little additional expense. In mines having a plant of surface machinery for hoisting and pumping, power drills driven by compressed air are commonly used, except in the few cases where the ground is mostly "picking," and then the exhaust from the drills usually suffices for ample ventilation. Even when starting a mine in hard rock, without knowing in advance to what extent the workings are to be carried, a small compressor plant is sometimes set up, so that driving by air drills may expedite development.

But if natural ventilation is of more importance to the metal miner than to the collier, it is also requisite for the former to understand it thoroughly and pay more attention to it, so that it will operate to the best advantage. It is always desirable to avoid putting in fans or blowers and their connecting pipes unless this becomes absolutely imperative; and this is all the more true in the case of a mine which has no other machinery.

General Principles.—The theory of natural ventilation is simplicity itself.

1. Air heated above the temperature of the atmosphere at a given level has a tendency to rise, because expanded and therefore lighter. Cooler air sinks, for the opposite reason.

2. Diffusion is the tendency of two or more gases of different densities, but originally of like temperatures, to become uniformly admixed without regard to the difference in weight.

3. Convection is the tendency of currents of different temperatures to seek an equilibrium, and in the circulation thus produced an approach to uniformity of temperature within a closed space.

The first principle explains the movement of main trunk currents in a mine. Diffusion and convection together explain why powder smoke and foul air, in the absence of appreciable ventilating currents, slowly become diluted through the mine air, so that, while the whole body of air is deteriorated, that at the place where the blast was fired or the foul air produced becomes in time diluted enough to be respirable.

Simple Tests.—The direction of air currents, not otherwise perceptible, in horizontal workings may be ascertained by observing the flame of a candle held very steadily and not breathed upon. In a drift the candle should first be placed on the floor (to test the lower current), and then held or fixed near the roof (to test the upper current).

The velocity of a current can be found by burning a pinch of powder at one point, a second observer at, say, 100 feet away, timing the interval required for the odor to reach him. If there is any current worth considering, the time will be less than that required for mere diffusion. The time required for the fumes from a blast to reach a given point also gives indications.

The following are some common and simple cases of natural ventilation:

Unconnected Workings.—It might be thought that here is no chance for ventilation. But so small are the differences in conditions required to set up a current that wherever work is going on the air is never absolutely dead.

At the heading of a tunnel the air is heated by the burning of candles and the animal heat of the men. This air rises to the roof, drawing in cooler air at the bottom to replace it, and if the tunnel is not too long there will be a gentle outward flow along the roof to the tunnel mouth, and an inward flow along the floor. This for a certain distance may suffice. When a shot is fired the hot gases from the blast have a similar, but intensified effect, as may be seen by noticing that the smoke follows the roof outward. If, however, the up-grade of the tunnel places the heading too far above the mouth, this movement is checked or altogether stopped, and the air at the face becomes permanently bad, requiring artificial or assisted ventilation.

Similar conditions hold as to inclines.

In a vertical shaft the dripping of water down the sides may cause downward exterior currents, with a compensating upcast centrally, or there may be a difference between one side and another.

Single Tunnel Connected with Single Shaft.—If the air at or near the junction is warmer than the exterior atmosphere, it will rise through the shaft, making it an upcast, and cooler air will enter the tunnel to replace it. If the depth and horizontal distance are moderate the course of the air may be reversed by the weather, by season, or change from day to night. When the air in the mine is cooler than that of the exterior atmosphere, as on a hot summer day, the shaft becomes a downcast.

Two Tunnels Connected by a Winze.—If the air within the mine is warmer than without, the inflow will be through the lower tunnel, up the winze, and out of the upper tunnel. If cooler, the reverse.

With more than one connecting winze, the general course will be the same, but the air (following the direction of the least resistance) will favor one winze rather than the other or others, even sometimes to the extent of rendering the latter practically useless for ventilation.

If there are several tunnels at different levels, with several connecting winzes, the same general principle holds good; but of course the circulation will not be uniform throughout, the air again taking the easiest course.

Straightness and smoothness of course have a selective effect upon air currents, as against crookedness and irregularity. If the temperature differences are very slight they may be offset in this way.

Two Shafts Connected by One or More Levels.—Which shaft will be the downcast and which the upcast will depend on the relative weights of the respective columns of air they contain. The problem is somewhat complicated by having three elements to be balanced against each other: (1) relation of mine air temperature to exterior temperature, plus or minus; (2 and 3) depth of each shaft. Where these differences are slight, it is not easy to predict which way the current will go, and it may fluctuate. When a current is once set up it has a tendency to continue in the same direction; and, if reversed, to go on in the new direction. Thus after a fire in a mine opened by two shafts and connecting levels, the current was permanently reversed. In this case the conditions were so nearly balanced that the accidental change could not be overcome. The direction may also vary with change of season, sometimes from day to night even, or according to the wind.

Evidently, other things being equal, the lighter column will be a rising one, or (what is the same thing) the heavier will fall. If the mouths of the two shafts are at considerably different altitudes, the case resembles that of a mine with one tunnel connecting with one shaft; that is, if the interior air is hotter than the outer atmosphere, it will rise through the taller shaft, making that the upcast, and *vice versa*. Yet, although the elementary principles of ventilation are so simple, the influence of small counter-acting conditions (to which no numerical factor can be assigned) often produces unexpected and puzzling results. Thus the engineer who has planned connections with a view to having the shaft in which the men are hoisted and lowered the downcast, and the other (the "air" shaft) the upcast, may be disappointed in his calculations, unless the differences in conditions are so marked as to be unmistakable. This does not argue ignorance of the laws of physics, or signify that there is any mystery about the principles, but only that in a problem of much delicacy the necessary data are not obtainable with precision. This difficulty, instead of discouraging the projector, should stimulate him to make the most careful observations and inferences before planning new connections for ventilation.

In most instances it does not make very much difference which way the current moves, provided the volume and velocity are sufficient. It is desirable, however, if possible, that a working shaft should be a downcast, so that the men entering and leaving the mine may have fresh air, while an idle shaft may be the upcast for removal of vitiated and heated air and vapor. It is also desirable that the fresh outer air should be led as directly as possible to the working places, leaving the mine air to find its way out through unused workings.

Some large metal mines have several shafts or tunnels connected on many levels. To direct the currents to the best advantage it may then become necessary to resort to some of the expedients explained beyond or introduce artificial ventilation, for with a multiplicity of passages the currents are very prone to short circuiting.

Disturbing Influences.—The wind has already been mentioned. It will readily be understood that a high wind striking in at the mouth of a tunnel, or deflected by a hillside or buildings down a shaft, may cause the mine air current to be reversed, like the draft of a smoky chimney under similar circumstances.

Unusual heat from underground steam pipes and engines, the combustion of illuminants, the heated gases of blasts, and animal heat, cause local disturbances of temperature which generally assist ventilation (so far as mere circulation is concerned), though in rare cases it is conceivable that they may retard it, while of course they impair the quality of the air.

The movement of cages, cars, pump rods, balance bobs, etc., and of rock in chutes, also has on the whole a beneficial effect, though a stationary cage or car may temporarily block circulation.

"ASSISTED" NATURAL VENTILATION.

There are several ways in which natural ventilation may be accelerated and properly distributed, without much expense or trouble, to meet moderate requirements not calling for the setting of special blowing or suction plant. The most obvious is to separate counter currents or moving air from dead air, thus giving them a clear passage instead of letting them be retarded and become mixed with air that actively or passively opposes them.

Sollars.—These are horizontal partitions in drifts and along main galleries, by which the heated air from the working face is led out to the tunnel mouth or discharged into an upcast shaft. They are made of lagging or boards, and are placed rather close to the roof. They assist the air movement, but have great offsetting disadvantages, so that they are very seldom used in metal mines: (1) In order to allow head room in the gallery, the excavation must be a foot or so higher than it would otherwise be, at considerable expense for labor, explosives and for the additional length of props; (2) they are awkward to set up and to advance; and (3) the introduction of any woodwork besides that actually needed as timber supports, and especially woodwork of this light and inflammable character in such an exposed position, is to be avoided on account of the danger of fire. The wood has every opportunity for drying out and would become ignited on small provocation.

There are also bottom sollars, along the floor of a gallery. If constructed for the sake of ventilation alone they would be equally objectionable; but when a water drain is cut in the floor and planked over, it would be well enough to allow a little extra space for the passage of air—which, however, would usually have to contend with an opposing water flow and thus move sluggishly.

Brattices—Are vertical partitions extending along and near one side of a gallery, or (if the latter is very wide) through the center, cutting it then into two roadways, one an intake and the other an outlet air passage. They are made of boards, brattice cloth or old canvas, and to prevent the canvas or cloth from rotting it is tarred. This makes another very dangerous fire risk, added to which is the large amount of extra space required. Brattices are not in favor in metal mines.

Wooden Air Boxes, in continuous lengths are sometimes used, and are much preferable to sollars and brattices. They are roughly made and do not need to be anything like air-tight. The usual practice is to place them in one of the upper corners of a gallery, or, more rarely, in the water drain. They add to the fire risk, but less so than sollars.

Metal Pipes of thin sheet iron, old tinned roofing iron, etc., are much better. They can be round or rectangular in section.

Large Canvas Hose.—A cheap air conductor can be extemporized with old canvas or any cheap fabric. The objection to both metal pipes and canvas hose is that, with natural ventilation alone, their cross section is too small to carry a sufficient volume of air, unless the natural draft is unusually strong. The canvas pipes have the advantage of being very readily moved about as required; and both the wooden boxes and metallic pipes can be placed and removed with little trouble also.

Air Doors.—These are very seldom seen in metal mines, though there are many situations where they would be of great assistance, as where the current short-circuits and refuses to pass through the working places, taking the easier cut. Air doors may be made of boards or planks, fitting close to a frame or the timber supports, hinged, and self-closing. A simpler arrangement is to hang a loose sheet of canvas (of the same size as the gallery section) to a cap or a special scantling. Passing cars then push under it, after which it falls back into position.

LINED SHAFT COMPARTMENTS.

Unless there is special reason otherwise, the two, three and four-compartment shafts of metal mines are left with open frames between the compartments. This is for safety in the case of cage accidents of some kinds, and for convenience in getting at the pump compartment from a hoisting one. But, if advisable, the compartments may be partitioned off by lining (with boards or planks, usually set vertically with butt joints), so that a single shaft may serve both as an upcast and a downcast—though by no means so well as two separate shafts. Air doors would generally be needed at stations and especially at the bottom level.

Chimneys.—If an air shaft (upcast) does not draw well, and it would not interfere with any other use to be made of the shaft, a cheap chimney of some sort can be built or placed on its collar and carried up to the necessary height, which need not be very much.

Housed Shafts.—When the hoisting and pumping machinery are placed in a house built to cover the shaft, head frame, sheaves, etc., (as is the custom at Western mines, on account, mainly, of the severe winters), the mine ventilation should not be overlooked. If the shaft is an upcast, over it should be an open, but hooded, belfry or cupola-like structure, to allow free escape of mine air and vapor. If a downcast, the air admitted should be fresh and free from the dust made in the surface handling of ore and waste.

Windsails.—Fresh air may be forced to the bottom of shafts of moderate depth, by setting up a funnel-shaped canvas ventilator, which can be turned to face the wind, and connecting it with the shaft bottom by means of a large canvass hose or any sort of pipe that is large enough. This is a simple and convenient make-shift for use while sinking uncovered shafts to 100 or 200 feet in depth.

Bailing Foul Air.—As in well digging, it is occasionally possible to partially get rid of the heavy bad air (charged with CO_2) which may collect in the sump and near the bottom of a small shaft, by bailing it out. This can be done, in an imperfect but practicable way, by extemporizing a dipping apparatus in the shape of an inverted umbrella, lowering it down gently and raising slowly, repeating the operation a number of times.

The Exhaust from Air Drills.—This is the most important agency for ventilating mines short of putting special machinery for the purpose. Indeed, where many power drills run by compressed air are in use, they do away with the necessity for blowers and fans, except in very extreme cases.

Although the drill pipe is so small, it carries a great deal of air (as measured by its expanded volume at atmospheric pressure.) The delivery at the drills is 70 lbs. or so, and when released and expanding the exhaust has the additional great advantage of largely reducing the temperature, which is ordinarily too high at the working face. This air is delivered precisely at the place where most needed, and a better effect is produced than by any suction fan arrangement. Again, there is no shifting of ventilating pipes, boxes, etc., as the work progresses. All of these points are of high importance, especially when driving very long galleries.

ADVANTAGES AND DISADVANTAGES OF NATURAL VENTILATION.

Wherever it is practicable to get along without the use of blowing or suction machinery the metal miner will inevitably do so.

Natural ventilation has these advantages: (1) It costs nothing, after the connections are once made; (2) it takes care of itself, for the most part. And it has these disadvantages: (1) It is often insufficient; (2) it is not always reliable, fluctuating with the weather, the time of day, the wind, and artificial disturbing causes; (3) while it costs nothing for maintenance, it may require a considerable initial outlay in making connections or sinking (or raising) air shafts which would not be otherwise needed. As against this latter point, it may be remarked that most of the work in developing fits in with that done to gain air connections, and *vice versa.*

All metal mines are started on the basis of natural ventilation. When that becomes unsatisfactory, the various "assisting" expedients come into play. Finally, if there is no other course, the management will have to turn to means of artificial ventilation. (These will be considered under a separate heading.)

(To be continued.)

THE GARLOCK PACKING CO., of Palmyra, N. Y., with branch offices in the cities of New York, Boston, Chicago, Philadelphia, Pittsburg, Omaha, St. Paul and Rome, Ga., report that their business for the year 1895 was the most prosperous in the history of the company. Their Sectional Ring, Elastic Ring, Spiral and Special Water Packings are not only holding their own but are becoming more popular year after year and are coming into general favor with engineers of all sections of the country. Their new Water Proof Hydraulic Packing is especially adapted for high pressure pumps, hydraulic machines and pumping stations. They have recently placed in the market a high pressure packing intended for high pressure work on locomotive, stationary and marine engines, which is designed and made to insure long services. Engineers who are unfamiliar with the products of the Garlock Packing Co., and are using cheap, inferior packings, would do well to investigate. Samples, catalogues, and prices can be obtained by addressing the nearest office.

COAL MINING IN WASHINGTON.

The Coal Resources of the State and Their Stage of Development.

A Paper Read at a Meeting of the Washington State Immigration Assocation, by Mr. T. B. Corey, Late Superintendent of the Oregon Improvement Co.'s Mines.

In writing an article on this subject, I find that the time given me is so limited that I shall be compelled to draw largely from a former paper written by myself and published some three years ago in the *Illinois Mining Institute Journal.* It would be a very difficult task to go into a detailed statement of the various coals found in this State, owing to the diversified condition of the coal beds; in fact, I doubt very much if there is any state in the Union where there is such a variety of coal. There has already been found coal from the lowest grade of lignite to the highest grade of anthracite. As yet, the coal industry of this state is only in its infancy. Hardly a month passes but what new discoveries are made, and some of them considered valuable. Most of the discoveries so far have been made by accident rather than by any preconceived plan of prospecting.

Commencing at the western portion of the state, the veins as exposed show hardly anything but woody matter; but, as we go east to the Cascade mountains, the coal increases in richness until we find a very good quality of anthracite.

It is also true as we approach the Cascades the strata are more irregular, in fact, in the bituminous districts there seems to be no regularity whatever, but the strata being more or less broken up with anticlinals and synclinals. East of the mountains the veins run a great deal more regularly and the angle of the dip is not so great.

Commencing at the northwestern part of the state, there are three or four seams of high grade bituminous coal and a few lignite seams. The coal measures are all underlain with clay schists and metamorphic slates, and this fact shows that they are in an upheaval; the coal measures, consequently, are in a very disturbed condition. The coal does not run regularly, but what is known as "pockety"; that is, the seams pinch to nothing or thicken to abnormal size. The seam nearest the schists, which is sometimes only two or three feet from them, is richest in carbon and lowest in moisture, the higher ones gradually losing carbon as they recede from the schists, and those on the Skagit river yield a coke equal to any made in the United States.

This coal district is in the region of Skagit river, Lake Whatcom and Nooksack river and extends almost to the Canadian line. The dips are from 50 degrees to vertical. Around Lake Whatcom to the northwest, Skagit river, southwest, and at Nooksack river the dip is very changeable, although in general terms it may be said to be north or south, depending on which slope of the great anticlinal and synclinal folds the seams are exposed. The area of this section is about 300 square miles. The coal around Hamilton, on the Skagit river, is very rich in carbon. There are four distinct seams, dipping at an angle of about 45 degrees. There are also here large seams of iron ore which are exposed to view on the Skagit river. For miles south of this there are strong indications of coal, and some very good veins have already been discovered. Around Hamilton the coal seams are more regular than in any part of the field in the northwestern part of the state. At Jennings, which is west of Hamilton, are two or more seams of coal. Quite a number of coke ovens have been erected, about one-third of the output being made into coke, and an excellent coke it makes, too, which, as I have before stated, is equal to any in the United States. This coke, being so near the iron ore, will be accessible for smelting iron. The coal veins run from thirty feet to one foot in thickness and dip at various angles. North and west of Jennings is the Blue Canyon coal mine, which is located on the eastern shore of Lake Whatcom. The vein varies from twenty feet to one foot, and has not the coking qualities of the Skagit coal, but is a good gas coal; it dips northwest 30 degrees. The seam rests on the clay slates, which are soft and swell, causing considerable trouble in mining.

The company operating at this place has expended large sums of money in erecting bunkers and building a large boat to transfer railroad cars across the lake, at the foot of the mountain, to a railroad which carries the coal to New Whatcom. From thence it is conveyed to the coast towns by ships. New Whatcom is located on Bellingham bay. Near this bay the first coal in this state was discovered and mined for the Hudson Bay Company's steamers some forty years ago. The vein is from ten to twelve feet in thickness, and is found in the upper measures of the Cretaceous; it is a lignite, and is not underlain by metamorphic slates. It dips to the northwest. On the west side of Lake Whatcom there are several small seams of coal, but not in sufficient quantities to make them workable. South of this is Chuckanut bay, where the coal measures crop out for miles, showing an enormous thickness, but no veins as yet have been discovered which are considered to be of any value. The measures end abruptly in the northwest corner of Skagit county. Going north of New Whatcom the country is flat, and consequently no exposures are to be seen. The coal on the Nooksack river is all high grade, but the seams are thin. The productive part of this field is nearly all on the eastern range, or nearest to the mountains. All through almost the entire northwestern part of Skagit county the country is very mountainous and broken, and is densely covered with timber, fir, cedar and hemlock—the finest in the world.

Farther west, near Port Townsend, coal measures are to be seen, and several small seams of coal, but as yet nothing to justify starting a plant.

In Snohomish county there have been several veins discovered, but from the best information I have, no developments have been made to justify an opinion as to their worth.

Next is King county, which is the largest and most developed coal field in the state. There are two classes of coal in this county, one a high grade of lignite, which has an area of about 120 square miles; the other a bituminous, which covers about 300 square miles. They no doubt belong to the Cretaceous epoch, the lignites being in the upper, and the bituminous being in the lower, the bituminous coal lying in closer proximity to igneous agencies, which by their heat and pressure have driven off volatile gases and moisture, resulting in a higher grade of coal. For this reason the quality of bituminous coal is improved as it approaches the mountains, and is often of strong coking quality, but the regularity of the seam is destroyed. The lignites of this county must not be confounded with the lignites of the Tertiaries found farther to the south, from which they differ as materially as oak does from cottonwood for heating purposes. These lignites have great heating qualities, while those of the Tertiaries are not much better than "brown coal." The general dip of the lignite seams is apparently to the north, then again a little west of north, while in the bituminous district there seems to be no regularity whatever; but the strata are more or less broken up with anticlinals and synclinals, and in this part of the field, as they run into or approach the mountains, they become very much distorted; but the coal becomes much richer (in some cases almost coke), yet so broken as to almost discourage any one from attempting to utilize it. No better place in the state of Washington can be found where the measures are so exposed as to show the peculiarities of contracted strata than in section 8, township 21, range 7 east, Green river canyon. At one point the seam is seen emerging from the river and rising into the exposed side of the river bank, then it turns over again and disappears in the river in the opposite direction, all in a distance of a little over 100 feet. At the point where it turns over, in the fissures at the top of the seam and by the squeezed and contracted condition of the bottom, can be distinctly seen the crushing it has been subjected to.

Nearly the whole of King county is covered with drift carried down by glaciers from the Cascade mountains during the glacial epoch of the Quarternary period, which has in some instances covered the ground to a depth of 300 feet. Thus, were it not for the rivers and watercourses, bed-rock would seldom be seen.

In journeying closer to the mountains the eruptive rocks become plentiful and the coal measures gradually disappear, only to be seen again in small, isolated, barren patches.

The mines at Durham and Kangley are on the eastern edge of this field.

At Issaquah (formerly Gilman) there are five seams of coal, varying in thickness from three feet to eight feet between walls, dipping at an angle of about 35°. This coal is a lignite. The mine is forty-two miles from Seattle by rail and fifteen miles in a direct line.

Newcastle is four miles west of Issaquah; is a new mine, the old one having been abandoned. There are here four lignite veins, which are being worked, averaging about five feet in thickness. Dips to the north about 40°.

Renton, about five miles southwest, is working one vein (lignite) about seven feet in thickness, dipping 12° east. This mine has just been started after a shut-down of some years. There is also another mine just being started at this place, but as yet coal has not been reached.

Cedar mountain, which is some six miles east of Renton, has just been reopened, after lying idle for three years. There is here a twelve-foot vein of lignite coal.

At the next town east of this, which is Maple Valley, the Danville Coal Company has begun development work on a six-foot vein, which bids fair to become a good mine.

At Black Diamond, still further south and east, there are three workable bituminous veins, respectively five, six and seven feet in thickness.

There is also a new slope being sunk to a first-class vein of coal.

Three miles south of this on Green river is located the Denny mine. It is a six-foot vein, and is used exclusively by the Denny Clay Company at Seattle.

Next we come to Franklin, also located on Green river, where there are three mines, one having just been opened. They have a three and a six-foot vein of bituminous coal, which are being worked. There is also here a forty-foot vein, which is worked to a small extent.

The Black Diamond and Franklin coal is an excellent steam coal, most of it finding a market in San Francisco.

Beyond this are Kangley, Cokedale, Alta and Durham, at which places there are six or seven veins of coal ranging in thickness from three to ten feet; the last three places named are not working at present. There has been more development work done at Kangley than at any of these places. It has the longest slope in Western Washington, and is about 1,500 feet in length.

Scattered all along from one mile south of Palmer to as far north as Grand Ridge are dozens of holes and tunnels, on some of which considerable work has been done, especially so on those at Sherwoods, Raging Creek and Niblock.

East of Franklin about three miles, on the Northern Pacific railroad, are the American, Eureka and Navy mines. The American has from four to five feet of bituminous coal, which they are working, and also two or three veins on which some prospecting has been done. The Eureka has about the same number of veins. The Navy mine has four or five workable veins, which will average about four feet in thickness. These mines have made considerable improvement during the last three or four years.

In Pierce county we find a field small in area, not over 100 square miles, but rich in the number and thickness of its seams. The coal is of an excellent quality, of which the numerous mines situated in the belt ship large quantities to San Francisco and the cities of Puget Sound, besides the great amount made into coke at Wilkeson, which is shipped as far east as Helena, Mont. This field commences at Burnett and extends in a due south line to the Nisqually river, a distance of about twenty-six miles. It is known as the Wilkeson coal field. A portion of this district is broken up by dykes. There are nine or ten workable seams, dipping from 35° to perpendicular.

Commencing at the southern end of the county, the coal is exposed, overlooking the valley of the Nisqually river. From this point north to Wilkeson it is an unbroken wilderness. The coal crops out from the flanks of the steep mountain side, dipping usually to the east at heavy angles. The ground is covered with a magnificent growth of pine, fir and cedar trees. Over all stands Mount Rainier, 14,444 feet high, and about twelve miles distant.

At the northern end of this field several of the branches of the Northern Pacific railroad have been built up to the mines at Carbonado, Wilkeson, Burnett, Pittsburg and Acme. Carbonado shows great signs of disturbance, but the seams are so numerous and aggregate so great a thickness of coal that large outputs can easily be kept up. This is the largest producing mine in the county, if not in the state.

At Wilkeson there are two mines opened on the opposite sides of the anticlinal fold. The Wilkeson coal is used as a standard by the United States government in making comparisons of coal in this western country.

At Burnett, which is four miles farther north, at which place the South Prairie Coal Company is operating, there are two or more workable seams, dipping to the west. This coal is of great value, producing about 10,000 cubic feet of gas per ton, and is used extensively at all the Pacific coast cities for making gas.

At Pittsburg and Acme, which are farther east from Burnett and situated on the same creek, considerable work has been done. I think it can be said beyond a doubt that the Burnett seams are the same as those at Wilkeson and Carbonado. The veins vary in thickness from three to nine feet.

We now come to Lewis county. Its coal fields are divided about as follows: Anthracite, 72 square miles; bituminous, 216 square miles; and lignite, 180 square miles. In the western portion of this county the lignite veins appear dipping at an angle of about 10°. Very little as yet is known about the lignite seams. One opening has been made at Bucoda, three at Centralia and one at Chehalis. Nothing south of this has been discovered worth mentioning. As we go east we find a rich bituminous field of coal, as yet undeveloped, owing to lack of transportation. This is no doubt a continuation of the Wilkeson coal field, and the coal is considered equally as good. There are quite a number of veins exposed, varying from two to fifteen feet between walls. This coal makes excellent coke.

Still farther east is the anthracite field, but not developed for previously mentioned reason, lack of transportation. These deposits are very much mixed, and it is at this time a difficult matter to place any estimate as to their utility; but there will, no doubt, at some future time be considerable coal produced in this section of Lewis county.

In Cowlitz county, which is south of Lewis county, there are two small mines in operation, one at Castle Rock and the other at Kelso, both mining lignite coal.

Crossing the Cascades into Kittitas county, we come to Roslyn, where the Northern Pacific Company's mines are located. Here over a quarter of a million tons are mined annually, and they could produce half a million if demanded. This vein is about five feet in thickness and dips from 8 to 17 degrees south; it is a splendid steam coal and used mostly by the railroads. There are three mines at this place, and there is also one, perhaps two, small mines adjoining this field. At Cle-Elum there is a mine which is working a seam overlaying the Roslyn, and is about four and a half feet in thickness. To my knowledge all the coal discovered east of the Cascade mountains is in this county, and comprises an area of about 300 square miles.

So it is seen that the combined coal fields of the State of Washington cover an area of 1,650 square miles as far as is at present known. At the rate of the present consumption this will not be consumed for several hundred years.

There are at present only thirty-two mines in operation, giving employment to about 5,000 men, and they could give employment to more, as there is a scarcity of miners at the present time.

The Blue Canyon, Fairhaven, Black Diamond, Franklin, Kangley, Navy, South Prairie and Roslyn coal has all been tested by the United States navy, and on the whole has proved to be satisfactory.

All Washington coal is brought into competition with that of England, Australia and Vancouver Island, and compares very favorably, and were it not from the fact that this foreign coal is to a great extent brought over as ballast (consequently landed on our shores very cheap) and the low tariff, it would not be long before Washington would supply the whole Western country.

There never has been a geological survey made of this state, consequently, many errors may have slipped into this article, but on the whole I think it to be correct. It would be a life's task to arrive at the true geological formations of the state. The mountainous country, the heavy timber and undergrowth, the wash of superficial deposits, completely cover up the strata, making it a herculean undertaking. This being the condition, the mineral wealth of Washington has only begun to be discovered.

There can be no doubt that the time is fast approaching when Washington will be the greatest state in the Union for its various and vast mineral resources.

WIRE ROPE HAULAGE.

Necessity of Proper Study of Conditions in Deciding on Type.

Avoidance of Friction Necessary to Secure Most Satisfactory and Economical Results.

(By T. E. Hughes, M. E.)

(Read Before Ohio Institute of Mining Engineers.)

An interchange of ideas on a practical subject of this kind is bound to result in the common good, and if this paper does not prove an exception to the rule, it will have accomplished the purpose for which it was written.

For underground haulage there are to-day (generally speaking) three systems in operation in the bituminous coal regions of this country. 1st. The tail rope system; 2nd. The endless rope, and 3rd. The electric system. Each system has its good points as well as its weak ones, and no engineer or coal operator should let any influences have a bearing upon which method he will adopt other than those produced by the conditions as he finds them at his particular plant.

A general rule to be observed by all as to the manner of operation, would be one of the worst things to meet with in coal mining. Let me right here quote literally from an article read before the mining engineers of Western Pennsylvania, as follows: "It is very essential in deciding which system of mechanical haulage is best adapted to any particular mine, to carefully consider all the conditions to be contended with."

This vital point, which confirms my remark at the out-start, covers the true secret of a successful haulage system, be its manner of operation what it may. Hence, you will see that any remarks of the author of this paper will have to be considered in a general way, produced by observation of various plants working under very dissimilar conditions, and the suggestions being of a general nature and not applicable to any particular plant until first the conditions of said plant have been carefully studied out.

Generally speaking, a tail rope system produces more satisfactory results than an endless rope system. First, we can use a tail rope system in single gangways by carrying the tail rope between the tracks, alongside the track, or overhead. An endless system (generally speaking) calls for a double gangway, to produce economic results; *i. e.*, the carrying in of empty cars at the same time the loaded ones are being taken out. This is the first reason why the writer would advocate (where the plant admits of so doing) the use of a tail rope system.

The next reason (and it cannot be considered too carefully) is the main objectionable feature of the endless system, *i. e.*, friction. Friction, reduced down to mechanical results, means nothing more or less than wear and tear at points of contact; and if said friction or wear and tear must produce the moving or grasping the load we propose carrying, it certainly means wear and tear of something, or at some point.

There are several methods of fastening to or attaching the loaded train of cars to the endless rope, one being two pulleys mounted on a small truck, each nearly touching each other at the face when out of service, the shafts carrying these two pulleys being connected together by a right and left hand screw. When said screw is revolved it widens the distance between the pulleys, and the endless rope being passed around said pulleys, becomes taut, friction accrues, and eventually *by friction* the rope takes a permanent grip on the pulleys, and the train is moved.

Another system, and one more commonly used, is to mount on a small truck a device working on the principle of a vise operated by a screw. Thus, by the closing of the jaws, makes contact with the rope, which, when the friction has been overcome, makes the attachment a permanent one, and the load moves.

In operating a wire rope, be it for haulage or other purposes, avoid friction as you would poison. I would, at all times, advocate putting in a tail rope system for the foregoing reason, even if no other reasons or conditions warrant so doing. A tail rope system, properly put in, with boiler capacity and power of engines 25% in excess of any possible requirements, will, in nine cases out of ten, produce the best result for the capital invested.

It may have occured to some of you by this time that I have not referred to the fact that a tail rope system calls for about 50% more rope than an endless system. True. But actual experience by the rope makers, I think, will demonstrate the following to be a fact: Conditions being equal, two plants side by side, one going into a heading 10,000 feet from the power house with a tail rope system calling for 30,000 feet of rope, and another, an endless rope system, like distance and under like conditions, (if such a plant ever existed) would result in the ropes of the tail rope system lasting twice as long as the ropes of the endless rope system, thus producing a saving of 33⅓% on rope bills, where 50% more rope is in operation, this saving being produced by the necessity of replacing the endless rope twice as often as the other ropes.

Let me now refer to one or two tail rope systems working under favorable conditions that have produced very satisfactory results, and which, in a general way, could and should be duplicated anywhere else in the United States, where the coal to be handled would warrant the investment.

First, there is a plant within twenty-five miles of Pittsburgh, operating the tail rope system, the length of haul being 10,500 feet. This, as you see, calls for 10,500 feet of main rope and 21,000 feet of tail rope. Their engines are 14″x24″; drums 6 feet in diameter; they work under 80 pounds steam pressure; they haul a maximum of 90 cars per trip, loaded as follows: Coal 4,000 pounds, tare 1,300 pounds, gross 5,300 pounds. There is but little gradient, and that is a maximum of 1½% against the empty cars, *i. e.* in favor of the loaded cars. They make sixteen trips, and it takes 40 minutes to make a trip. The engines are geared 4 to 1. They use for the track a 30 pound steel rail well ballasted. Rollers 20 feet apart. The road bed is on a coal bottom, under which is a hard fire-clay, and under this fire-clay, a limestone. This, as you will see, gives what might be termed an almost ideal condition for a road bed in a coal mine. The mine is well drained to the opening or openings.

Again, I have in my mind's eye, a plant within 200 miles of Pittsburgh. The engines are 20″x30″; they are geared 3 to 1; they develop 450 H. P. while hauling the trip of 40 cars up a grade of 1 in 20; the gross tonage of load being 234 tons 880 pounds, divided as follows: coal 160 tons, cars 60 tons, weight of rope 14 tons 880 pounds. The haulage is 9,000 feet from the heading to power house. They use a 1½″ hauling rope, and a ⅞″ tail rope. One of the main ropes of this latter plant is still in service, and its mate was taken off this last summer. I forgot to state that this is a double tail rope system. The main rope and tail rope taken off last summer, hauled 1,200,000 tons of coal; consequently, you will see, by a short process of figuring, the cost of the rope per ton hauled was remarkably low.

The plant first referred to does not have any hard conditions of grade; in other words, the maximum grade is 1½% in favor of the load. They have hauled out over 1½ million tons of coal with 30,000 feet of ⅞″ crucible steel haulage rope, costing as you will see, 2⅕ cents per 1,000 tons for haulage.

Having now referred to a couple of plants hauling coal under favorable commercial results, I now want to switch back again to general conditions to be observed for operating rope haulages, be they endless, or tail rope. Perhaps one of the most vital and beneficial changes that our engineers have made, is that, where we have to make a turn in our gangway at a right angle (or nearly so), they, wherever it is possible, now introduce the reverse curve to overcome the strain resultant from using a guide wheel or carrier. By using the reverse curve, you can see at a glance we get a much greater radius, and naturally much less bind or set in the rope than under the old conditions. Again, the mining engineer reverses the conditions of the steam railway engineer in the following way: He elevates the inside rail above the level of the outside rail, owing to the fact that the pull of the rope will have a tendency to increase friction if the rails are on a level, while on the contrary *it is a question of momentum* to be overcome when the engineer of a steam road elevates the outside rail of a curve instead of the inside, as the mining engineer does.

It will not do to leave this discussion without noticing another important factor in a well equipped plant—that is, the kind and construction of the rope that you use. The kind most commonly used for haulages is composed of six strands of seven wires each laid around a hemp centre. The wires (generally speaking) being made of steel.

A rope that has received more attention than its merit warrants is what is known as the "Lang lay" rope. This rope is composed of the same number of wires and strands as the commonly used haulage rope, but differs in this respect: The strands when being twisted together are twisted in the same direction as the wires have been in each particular strand.

This produces a much more *flexible* rope than the rope made in the way known as *standard* lay, the strands in the standard laid rope being laid up in the opposite direction to the lay of the wires in the strand.

A flexible rope is a desirable one, if we do not sacrifice some element of vital force equal to or greater than what we gain in flexibility.

There are exceptional cases (which the discussion of this paper may bring out) wherein the Lang lay rope is the most advisable, but, generally speaking, the Lang lay rope does not give as good service as the standard lay.

By examining a section of a Lang lay rope, you will see that the wires run over the pulleys at an angle of about 45 degrees, if each and every pulley is in an ideal condition, *i. e.*, running true, well lubricated, and in first-class condition. This will not make a material difference in the life of the rope; but, are these conditions ever lived up to? We would say "No;" consequently, at just exactly the ratio of the condition of the passing from the ideal to the actual, just at the same ratio does friction come in in the wear of the wires on the Lang lay rope over and above what would be the case with the standard lay.

To further illustrate this, you will notice that when a mechanic is using a file in filing a piece of metal, he takes the position of the file at exactly the same angle at which these wires are laid, to produce the best results, *i. e.*, cut away the metal to the greatest amount with each stroke of the file. If the mechanic will do it with that object in view, does not the same result follow with the Lang lay rope, when passing over the pulleys full of grit and dirt? Such being the case, rope manufacturers (generally speaking) recognizing that fact, have insisted on the use of the standard lay rope to produce the best results for the operator.

You will notice in the standard lay rope that the wires lay parallel with the motion of the rope, and for this reason, when passing over pulleys, expose the smallest amount of surface of each wire for friction that is possible, and by so doing the rope has a tendency to *slide* over the pulleys rather than scrape them.

Again using the file for an illustration, if you put the file in the mechanic's hand and tell him to push it over the metal he is filing, with the teeth of his file parallel with the motion of the stroke, he will at once tell you that his file will slide over the material instead of cutting it. This illustration will best serve my purpose in my effort to indicate why the Lang lay rope will not give as good service (generally speaking) as the standard lay.

There are (as I have intimated) exceptional cases where the Lang lay rope will work, but only exceptional, they being perhaps controlled by the following conditions: "A high speed motion, very small drums, and numerous angles in the operation of the plant."

Under these conditions, perhaps it might be advisable to use the Lang lay, on account of its extra flexibility over and above the ordinary haulage rope made of seven wires to the strand; and even in this condition, it is a question which only a rope manufacturer should decide, as to whether a rope made of nineteen wires to the strand (standard lay) would not give better service than a rope made Lang lay, seven wires to the strand.

This illustration once more forces upon us—and, like Banquo's ghost, "will not down"—the fact that friction is an expensive luxury, and only those who need not care what the expense of the luxury is so they have it, should ignore its cost.

Before leaving the subject of haulage, we might be considered behind the time if we made no reference to the latest development, *i. e.*, "electric haulage."

Electric haulage (as being introduced to-day) means haulage by traction, and (getting back to our old hobby again) traction means friction.

The problem—a simple one—is, we must move a given load (the power needed it is presumed we have at our command) by a sufficiently heavy motor to give us the required traction, or, in other words, sufficient to reduce the friction between the motor wheels and the rail to *nil*. This (after careful investigation) I am firmly convinced has, as yet, not been successfully accomplished (looking at the question of commercial economy and success).

Of course, I realize this remark will bring down on my unprotected head, an avalanche of criticism from our electrical engineers, yet I will frankly say right here, that if I am mistaken, I am as anxious as they are to see the error of my ways, and only too gladly will make due apologies and concessions for such discrepancies as they may point out to me, but, as I now see it, there is not in operation, to my knowledge to-day, an electric haulage system giving the desired mechanical results, and I would be willing to guarantee to exceed said mechanical results on less than 75% of the capital invested in the electric installation, by substituting wire rope; hence, if this is so, electricity, is as yet, economically speaking, a failure. In fact, let me close these remarks by suggesting that some of the rules that are given us for success when seeking happiness will apply fully as forcibly when applied to seeking coal—"avoid friction."

Take the best of care of the health of your plant. See that all things work in harmony. See that "the joints" are well lubricated. See that each part of "the plant" performs its particular duty. See that it gets the daily care that it should have to enable it to do to-morrow's work as ably as it did to-day's, and rest assured it will live to a ripe old age, and make all happy who come in contact with it.

ANTHRACITE TONNAGE ALLOTMENT.

A Satisfactory Schedule Adopted by the Presidents of the Anthracite Coal Roads.

The result of the meeting of the presidents of the anthracite coal roads held in New York City on the 30th ult., is a most satisfactory settlement of a dispute that for many months has had a disastrous effect on the anthracite coal trade.

Inability to arrive at a satisfactory allotment for each road was due to the receivers of the Philadelphia and Reading Company, insisting on 21 per cent. of the total tonnage for their road. As a result no attention was paid to proportionate tonnages, and each company rushed as much coal to market as possible. This naturally glutted the market and ruinously low prices prevailed. The claim of the Reading Company to 21 per cent. of the tonnage was one that the receivers of the company, and many others conversant with the Reading's coal property, considered a fair one, but the management of the other roads claimed that the advent of new roads, in the transportation business, together with certain other features, had changed old conditions so much that the Reading as well as some of the other older roads would have to submit to a smaller percentage of allotment.

A meeting of the presidents of the coal roads was called for January 23rd, but failed to come to an agreement, and a committee was appointed to make up a report relative to the division of the tonnage for the year 1896.

This committee made its report on the 30th ult., to a meeting which was attended by the following gentlemen:—Samuel Sloan, Delaware, Lackawanna and Western Company; E. P. Wilbur, Lehigh Valley Railroad Company; J. S. Harris, Philadelphia and Reading Railroad Company; J. Rogers Maxwell, Central Railroad of New Jersey; Eben B. Thomas, Erie Company; Alfred Walter, Delaware, Susquehanna and Schuylkill Company; Thomas P. Fowler, New York, Ontario and Western Company; Simon Borg, New York, Susquehanna and Western; R. M. Olyphant, Delaware and Hudson Canal Company; Geo. B. Roberts, Pennsylvania Railroad Company.

The report, which was adopted, makes the following allotments:—

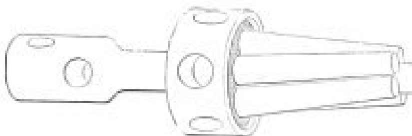
Delaware, Lackawanna and Western R. R.	13.35	per cent.
Delaware and Hudson Canal Co	9.60	"
Pennsylvania R. R	11.40	"
Philadelphia and Reading R. R	20.50	"
Lehigh Valley R. R	15.65	"
Central R. R. of N. J	11.70	"
N. Y., L. E. & W. R. R	4.00	"
Pennsylvania Coal Co	4.00	"
N. Y., Ontario and Western R. R	3.30	"
Delaware, Susquehanna and Schuylkill R. R	3.30	"
New York, Susquehanna and Western R. R	3.20	"
	100.00	

These percentages became operative on the 31st ult., and they will continue in force until January, 1, 1897. They shall be subject to revision after thirty days from that date. The satisfactory solution of this troublesome question makes easy and practicable, a rational policy of restriction of production, which is an absolute necessity. Metropolitan newspapers, and some poorly informed journals in the anthracite regions oppose this policy of restriction, but every man conversant with the anthracite coal business, and who has the interest of all classes in the region at heart, favors it. It is simply good business policy, which if properly carried out means a fair profit to the operator and fair wages to the miner. It may mean, and probably will mean, periodical suspensions at the mines, but such suspensions voluntarily made to maintain fair prices for coal are infinitely better than forced suspensions due to an over-crowded market and the consequent break in prices.

The Johnson Self-Feeding and Self-Releasing Tube Expander.

Mine managers and all who have the care of tubular boilers will be interested in the Johnson improved tube expander, which we herewith illustrate.

It is the only radical improvement in flue expanding devices since Richard Dudgeon's expander was invented many years ago. The new expander requires neither to be driven in nor out. It is self-feeding and self-releasing. It is very simple in construction, and the wear is so evenly distributed that the manufacturers claim that "while it may wear smaller, it will not wear out."



JOHNSON TUBE EXPANDER.

This is a feature that will be appreciated by all who have been worried by the necessity for continually repairing and replacing the old style expanders.

The Johnson expander has been sold extensively to the railroads and ship building trade during the past two years by a Philadelphia firm, but the Johnson Tool Co., of Wilkes-Barre, which has just been organized, will hereafter manufacture the expander, and will pay special attention to the mining trade. The expanders are made in all sizes from $1\frac{1}{2}$ inch, up, and a small publication entitled "Some Facts" issued by the manufacturers, which is sent free on application, gives important information concerning the tool.

"Watt" Mining Car Wheels.

With this issue of The Colliery Engineer and Metal Miner, the Watt Mining Car Wheel Co., of Barnesville, Ohio, begin a series of advertisements of the cars and car wheels made by them. This concern in their advertisement in this number (page xiv) show a truthful illustration of their works, which, without doubt, is the largest manufacturing plant in America devoted wholly to the making of mine cars and mine car wheels.

The business which has required the establishment of such a plant has been built up mainly on the Watt Self-Oiling Wheel, which has met a very favorable reception from mine operators and superintendents throughout all American mining regions where it has been introduced. The shops shown can, without crowding, turn out 160 car wheels and 20 to 30 finished cars per day. The Watt Co. is also prepared to furnish axles and car irons to any specification.

It will be worth while for mine superintendents and buyers to follow closely the advertisements which we shall publish for this concern, for in each one hereafter, some special style of car (with notes as to where used) or some component part of special design, will be illustrated. Some new things the Watt Co. will soon put on the market will be illustrated there at an early date.

Catalogues, Etc.

The Link Belt Engineering Co., of Philadelphia, has issued an artistic edition of advance sheets from their 1896 catalogue, which illustrate and describe the well-known and highly efficient Monobar conveyor.

Mr. Robert Allison, of the Franklin Iron Works, Port Carbon, Pa., has issued a neat catalogue of air compressors, pumps, high speed engines and general mining machinery made on the lines of his well known original designs.

Bulletin of Catalogue No. 30, Vol. I, Part 3, is the title of a folder issued by The Ingersoll-Sergeant Drill Co. It illustrates and describes air compressors and contains valuable matter pertaining to the use of such machinery.

A handsome souvenir catalogue with illuminated cover illustrates and describes the Thomson recording wattmeters. The third publication is an artistically bound set of 31 plates, illustrating by fine engravings various electrical machines and plants erected by the General Electric Co.

The Hine & Robertson Co., who make a specialty of steam plant appliances, issue a neat little pamphlet, entitled, on an artistic cover, "Waste Not, Want Not." The old adage is very applicable to the Hine & Robertson Co.'s specialties, as their goods are designed to produce the most economy possible in power plants.

We have received from The General Electric Co., No. 44 Broad street, New York, copies of three handsome publications issued in connection with their exhibit at the Atlanta Exposition. One is a twelve page folder, containing, besides other illustrated matter, three full page views of their works at Schenectady, N. Y.; Lynn, Mass.; and Harrison, N. J.

RIEDLER PUMPS.

Their Efficiency and Economy Attested by First Class Mining Authorities.

We recently published a description and cut of the Riedler Pump, manufactured by Messrs. Fraser & Chalmers of Chicago, and in a general way gave the opinions of purchasers as to its merits. We are now able to supplement the description, etc., by the following extracts from the official reports of the Montana Mining Co., Ltd.,

From report of Mr. R. T. Bayliss, general manager, to the chairman and directors, Oct. 23rd, 1895:

"*Riedler Pumping Engine.*—This plant, which has recently been erected in the 1,600 ft. level, was rendered necessary owing to the greater quantity of water met with in the developments at the bottom of the mine, and consists of a duplex differential Riedler pump, with plungers $3\frac{1}{4}$ in. and $5\frac{1}{2}$ in. in diameter, and 24 in. stroke, actuated by a horizontal compound condensing Corliss engine, with cylinders 16 in. and 25 in. in diameter, and 24 in. stroke, and has a capacity of 400 gallons per minute against a head of 1,230 feet, when running at 90 revolutions. At the present time it is working to about one-third of its capacity, therefore it will be able to handle without difficulty any quantity of water which we may reasonably expect to encounter in these workings. The erection of this pump has resulted in a saving of not less than 60 per cent. in the consumption of fuel hitherto necessary for operating the ordinary steam pumps which were previously situated in the 700, 1,000 and 1,200 ft. levels, and it is evident that by this economy of fuel alone, the Riedler pump will repay the cost or its erection in eighteen months. In addition to the saving in the consumption of fuel, a considerable economy is effected in the labor and repairs necessitated by the operation of the pumps formerly in use; and it may be safely assumed that the introduction of the Riedler pump will enable us to unwater the mine at an expenditure not in excess of 25 per cent. of that incurred under the old system. I may mention it is only within the past two years that the Riedler pump has been introduced into the United States, although it has been for some time extensively used in Germany, Austria, and other European countries.

In conclusion, I desire to assure you that the operation of your mine and works is being conducted in an admirable and economical manner by the various members of your staff, who, by their long service, are eminently fitted to occupy the positions they hold; and I further desire to express my personal indebtedness to them one and all for the assistance rendered me in the administration of the company's affairs.

Believe me, Gentlemen,

Yours faithfully,

(Signed), R. T. Bayliss."

From report of the mining engineers, Messrs. R. W. Raymond and T. A. Rickard, to R. T. Bayliss, Esq., general manager:

"The admirable Riedler pumping plant recently placed on the 1,600 level will permit operations to be prosecuted to any extent, on or above that level, without fear of any disturbance of the regular work of the mine by a sudden influx of water. This pump is undoubtedly adequate to handle all the water that can be encountered above the 1,600. It is now taxed to only one-third of its capacity; and most of the water comes from above the 1,600 level. Yours truly,

(Signed), R. W. Raymond, T. A. Rickard."

Immunity of Colliers from Cancer.

Mr. T. Law Webb, of Ironbridge, whose labors to elucidate the cause of cancer are well known, in an interesting paper on the subject, states that he has practiced for twenty-five years in a district overlying the Shropshire coal-field, and during that time he has been surgeon to two collieries, yet he has never seen a single case of cancerous disease in a collier who was working in the pits. "Moreover," he says, "an examination of the books of the district registrar shows that of all persons whose deaths are registered as due to malignant disease during the past thirty years, only two are described as 'coal miners.' Of these, one I know positively had long retired from the arduous occupation of coal-getting, and had for many years followed the more gentlemanly occupation of rat-catching. The other died in the workhouse, and had not worked in the pit for some time. It should be borne in mind that in this same locality cancer is very common, and is often seen among the furnacemen, moulders, iron-workers, and general laborers." Another practitioner living in the same district is also unable to recall the case of any collier suffering from cancer. The explanation lies partly, Mr. Webb thinks, in the habitual cleanliness of the collier, who "tubs" daily as soon as he comes home from the pits; partly in the fact that his habits rarely lead him to drink water from casual sources. He goes to work early, and habitually in his working hours carries with him a quart can containing cold tea or coffee, without milk. He always returns home to dinner, at which he usually drinks tea, or, if he can get it, small beer, while his supper consists of bread and cheese, with sometimes an onion and a pint of beer. The colliers in Shropshire are a temperate, peaceable, law-abiding class, not given to excesses of any kind. Though they are often seriously injured in their dangerous occupation, they survive the most dangerous wounds and fractures, and although they look pale and anaemic, they are in reality a healthy set of men.—*Science and Art Mining.*

EXPLOSIVES FOR COAL MINES.

Their Classification, Composition and Gaseous Products of Combustion.

A Comprehensive Study of the Safest Explosives for Use in Gaseous and Dusty Mines.

By Prof. Vivian B. Lewes, Royal Naval College, Greenwich, Eng. (From Transactions of the Federated Institution of Mining Engineers.)

Last winter the writer had the honor of delivering a course of Cantor lectures before the Society of Arts, on the subject of "Explosives and Their Modern Development," and in the last lecture of that course dealt with mining explosives, and showed, to his own satisfaction at any rate, that all explosives which give rise to carbon monoxide as a product of their combustion ought to be strictly tabooed for use in coal mines, not only because of the risk of injury to health and life from the poisonous nature of the gas, but also because even small traces of carbon monoxide render mixtures of coal dust and air highly explosive, a point which has, he thinks, been entirely overlooked in all experiments upon this most important subject.

Up to thirty years ago, gunpowder and a modified form known as blasting-powder were practically the only explosives used in mines, and the discovery of the detonation of nitro-glycerine by Mr. Alfred Nobel in 1864, and its introduction under the name of "Nobel's blasting oil," marks perhaps the most important epoch in the history of blasting explosives. After that date many and varied attempts were made to introduce new explosives which should combine the important properties of safety and efficiency. Blasting oil soon showing its dangerous character, restrictions were placed upon its use and transport, and very shortly after its introduction attempts were made to tame its explosive properties without reducing the strength of the explosive itself, efforts in this direction giving rise to dynamite and other mixtures of this class, in which nitro-glycerine was taken up by some absorbent material, and by practically converting it into a solid form did away with many of the dangers inseparable from the liquid state, and also enabled it to be more effectively detonated.

As time passed on it became manifest that there was still room for improvements in explosives for mining work, and Dr. Sprengel suggested in 1873 the possibility of mixing together hydrocarbons, built up from the elements carbon and hydrogen and containing them in a condition easily available for combustion, with highly oxidizing bodies—in such proportions that complete combustion would be ensured. Many attempts were made to utilize this suggestion, and thirteen years after he had read his paper before the Chemical Society, several so-called safety Sprengel explosives were introduced into this country, and have proved themselves to be a considerable advance in safety and reliability over their predecessors.

In reviewing the properties of the various mining explosives now in use in coal mines, it will be convenient to classify them according to the way in which they produce the gas which gives the explosive effect.

Class I.—Explosion due to simple combustion, as in the case of blasting gunpowder.

Class II.—Explosion due to detonation of the whole of the explosive, as in nitro-glycerine, nitro-cotton, and some Sprengel explosives.

Class III.—Explosion due to detonation of part of the explosive and combustion of the remainder, as in carbonite, westfalit, etc.

This may at first sight seem to be an awkward and unreasonable method of classification, but inasmuch as the claims of any explosive for mining purposes must in the first place be based on its safety as regards the non-ignition of explosive mixtures in the workings of a coal mine, and as this in turn largely depends upon the way in which the explosive generates its force, the writer prefers to adopt it in view of the considerations which he wishes to bring before the members.

COMPOSITION OF POWDERS.

	Gunpowder.	Blasting Powder.		
		England.	France.	Italy.
Potassic nitrate	75	65	62	70
Sulphur	10	20	20	18
Charcoal	15	15	18	12
Totals	100	100	100	100

GASEOUS PRODUCTS OF COMBUSTION.

	Gunpowder Fine Grain.	Mining Powder.
Carbon dioxide	50.62	32.15
Carbon monoxide	10.17	33.75
Nitrogen	33.20	19.03
Sulphuretted hydrogen	2.18	7.10
Marsh gas	0.19	2.73
Hydrogen	2.96	5.22
Oxygen	0.08	0.00
Totals	100.00	100.00

The most characteristic types of the first-class are ordinary black gunpowder and blasting powder, both mixtures of the combustibles carbon and sulphur with potassic nitrate as the oxidizing material, the great difference between the two being that whilst in ordinary gunpowder the proportions are so arranged as to give great heat-energy to the explosion, in blasting powder a slight lowering of temperature is obtained by increasing the proportion of sulphur present, and reducing the oxidizing material, the result being that during explosion, the products of combustion although increased in volume, consist largely of imperfectly oxidized bodies which are themselves inflammable.

Gunpowder itself is practically never used, and the only word that can be said in favor of the blasting powder is that it is cheap. It is absolutely unfitted for use in coal mines, and its abolition would do away with more than three-quarters the number of deaths annually returned as being caused by mining explosives. The great danger attending its use, however, consists in the combustible nature of the products evolved during decomposition, a factor in coal mine explosions which the writer ventures to think cannot be overrated.

On firing a charge of 1½ lbs. of blasting powder, over 3 cubic feet of combustible gas, consisting chiefly of carbon monoxide, would be produced, and this when mixed with pure air, would give over 10 feet of an explosive, or at any rate rapidly burning mixture, and experiments which have been made upon the effects of fire-damp and dust combined in causing colliery explosions, show conclusively that even when fire-damp is present in such minute quantities as to form a mixture very far removed from the point of explosion, it makes the mixture of coal dust and air highly explosive. Traces of carbon monoxide will do exactly the same thing when the air is laden with coal dust, whilst the temperature of ignition is lower than with methane, so that when the air of the mine is charged with coal dust, the probabilities are that a very large volume of explosive mixture is formed by the rapid escape of the products of combustion into the dust laden air, and this (being ignited either by the flame or by red hot solid products driven out into it by a blown out shot) initiates a considerable area of explosion.

As the explosion takes place, and as the carbon monoxide already produced is oxidized to carbon dioxide by the action upon it of water vapor present, and also by its direct combustion with oxygen, the hydrogen of the water vapor is set free, whilst the heated coal dust also yields certain inflammable products of distillation to the air, and partial combustion of the coal dust gives a considerable proportion of carbon monoxide once more, and this, driven rapidly ahead of the explosion, forms, with more coal dust and air, a new explosive zone, and so, by waves and throbs, the explosion is carried through the dust laden galleries of the mine.

In this way any explosive which generates inflammable products of incomplete combustion is unsafe, and should never be used even in mines where fire-damp is unknown, as such explosives are quite capable of setting up an explosion with coal dust alone.

A still greater danger arises if any trace of fire-damp exists in the mine, as this, together with dust, provides an already explosive atmosphere, whilst the products evolved by blasting powder are capable of playing the same part as sulphur on a match, and causing ignition of the explosive mixture.

Fire-damp, as has been shown by the numerous experiments made since Sir Humphrey Davy's memorable researches, is not easily inflamed, and explosive mixtures containing it not only require a temperature of over 1,200° F., but require this temperature to be applied for several seconds, sometimes as many as ten, before ignition takes place.

This phenomenon is due to the absolute ignition point of methane being extremely high, far higher than the temperature at which it decomposes into hydrogen and acetylene, and the result is that at a temperature, such as 1,200° F., decomposition of the methane molecules first takes place, and the liberated hydrogen then igniting raises the mass to the true ignition point of the methane. This dual action requires an appreciable time, and it is this alone which gives the comparative safety in mines where any trace of fire-damp exists.

If we take the temperature developed by the more prominent explosives, we find them to be far above the ignition point of explosive mixtures of methane and air for a steadily applied heat.

	Degs. Cent.	Degs. Fahr.
Blasting gelatine	3,220	5,828
Nitro-glycerine	3,170	5,738
Dynamite	2,940	5,281
Gun-cotton	2,650	4,802
Tonite	2,648	4,798.4
Picric acid	2,600	4,712
Roburite	2,100	3,812

Whilst the ignition point of explosive mixtures of the various combustible gases which could be present in the working of the mine, either produced by the use of improper explosives, or liberated by the coal, are about:

	Degs. Cent.	Degs. Fahr.
Methane	660	1,220
Ordinary coal gas	648	1,198.4
Carbon monoxide	640	1,184
Hydrogen	620	1,148
Ethane	605	1,121
Ethylene	580	1,076
Butylene	540	1,004

It is manifest, therefore, that if the products of explosion escaped into the mine at this temperature, any explosive mixture in the mine must be ignited. This temperature, however, only exists while the gases are under the pressure generated by the explosion; and directly they blow out into the workings, expansion instantly cools them below the temperature necessary to bring about the changes leading to the ignition of mixtures of methane and air, or methane, air, and coal dust.

It is important that it should be fully realized that the factor of safety depends to a great extent upon the retarding influence of the chemical changes necessary before the ignition takes place, and it is the absence of this with explosive mixtures of other gases that constitutes a real source of danger.

Fortunately the inflammable constituent of pit gas is practically only methane, and with the use of proper explosives, *i. e.*, explosives which can be completely detonated, and which give neither combustible products nor burning solids on explosion, a very fair degree of safety is attained.

Directly, however, inflammable gases, other than methane, are introduced, the margin of safety disappears, and with explosive mixtures which contain carbon monoxide, hydrogen, or ordinary illuminating coal gas, the point of ignition being the true one, no time is given for the products of the explosion to cool themselves down below the ignition point, and the gaseous mixture is fired.

It will always be noticed that in making trials with various explosives where pit gas is used for the mixture in which the explosive is fired, ignition is rare, whilst with mixtures of air and coal gas, ignition is the rule rather than the exception; and surely no one can believe that this depends upon the few degrees higher point of ignition which the methane is supposed to possess, and it is this obliteration of the factor of retarded ignition which makes it imperative to discard any explosives generating combustible products of incomplete combustion for use in fiery coal mines.

It is also evident that the more rapid the explosion the safer will it be, and no explosive should be used which relies upon simple combustion either as a primary or secondary principle in its action.

A still greater source of danger found in the explosion of most blasting powders is the excess of sulphur which it contains, and which during explosion shows its presence by the evil odor of the escaping gases which contain over 7 per cent. of sulphuretted hydrogen, whilst under certain conditions traces of carbon bisulphide are also produced.

As has been already pointed out, the ignition point of carbon monoxide is about the same as ordinary coal gas, and may be taken as being 1,184° F., but the vapor of carbon bisulphide has an extremely low point of ignition, and the admixture of only 3 per cent. of its vapor with carbon monoxide lowers the igniting point to below 400° F.

Blasting powder and other explosives of the first class should unhesitatingly be discarded not only as being unsafe in use, but also as deleterious to health, the products of incomplete combustion all having a distinct toxic effect on the system.

Taking now explosives of the second class, we come to nitro-glycerine, nitro-cotton, and some of the Sprengel explosives, and the distinctive characteristic of this division is that all the members of it are capable of complete detonation, provided always that the right sort of detonator is employed.

Nitro-glycerine, which first inaugurated the modern era of high explosives and commenced its career as blasting oil, stands apart from all other nitro compounds, owing to the fact that it contains more oxygen than is necessary to complete the oxidation of the carbon and hydrogen found in its molecule.

Nitro-glycerine

$$2\,[\,C_3H_5\,(NO_3)_3\,] =$$

Carbon dioxide, Water, Nitric oxide, Nitrogen

$$6\,(CO_2) + 5\,(H_2O) + NO + N_2.$$

The result being that it evolves no combustible products, whilst its rapidity of detonation would make it the safest and best of all the blasting explosives—were it not for the danger inseparable from its physical condition and sensitiveness to shock.

When first introduced it achieved considerable success, as the fact of its being unaffected by moisture gave it a great advantage, whilst the rapidity of its explosion made it only necessary to prepare a borehole, partly fill it with nitro-glycerine, and then fill up the hole with water, the water forming just as good a tamping for the nitro-glycerine when fired by detonation as if the hole had been plugged with wood or metal. The use of nitro-glycerine for blasting purposes is however attended with several inconveniences, as being fluid it can only be used for downward boreholes, whilst its transport in the liquid form has given rise to many accidents; and, finally, the liquid state is not very suitable for detonation, as the fluid yields to the sudden blow, and is often scattered instead of being completely exploded, so reducing its power and becoming a source of danger in subsequent operations.

When cautiously heated to 100° Cent. it slowly evaporates, at 200° Cent. it burns, and detonates at 257° Cent. When a lighted match is applied to it, it burns quietly away, and when the light is removed the flame generally goes out; indeed a lighted match may be extinguished by plunging it into nitro-glycerine. It is, however, detonated by a sudden blow, or by heating it to 257° Cent. Nitro-glycerine becomes solid at 4° Cent., but so much depends upon the length of exposure to cold that this may happen at from 8° to 11° Cent., and in this condition it is comparatively inert; hence it is necessary to thaw it before use, an operation attended with considerable risk. It is stated that exposure to the direct rays of the sun will convert it into a very unstable and explosive substance, and also that the presence of ozone will sometimes cause its spontaneous decomposition.

The general instability of nitro-glycerine, the liability to freeze, and the danger in thawing extends to the mixtures in which it plays an important part, and exudation of nitro-glycerine from mixtures containing it is a danger so well realized that it is needless to dwell upon it.

Moreover, some of the best of the nitro-glycerine class of explosives, such as blasting-gelatine, are among the worst offenders as regards the evolution of combustible products of combustion, as the deficiency in oxygen of the nitro-cotton employed is not made up for by the excess present in the nitro-glycerine used.

Such smokeless powders as cordite and ballistite are of much the same character as blasting-gelatine, and in all of them we find the same evolution of combustible and poisonous products marring otherwise beautiful explosives.

PRODUCTS OF COMBUSTION OF MIXTURES OF NITRO-COTTON WITH NITRO-GLYCERINE.

	Blasting Gelatine.	Ballistite.	Cordite.
Non-combustible—			
Nitrogen	20	22.2	19.2
Carbon dioxide	34	35.9	24.9
Combustible—			
Carbon monoxide	36	32.6	40.2
Hydrogen	10	9.0	14.8
Methane	trace	0.3	0.7

It is the nitro-cotton present in these explosives which is responsible for the bulk of the carbon monoxide, whilst in cordite the vaseline present, by supplying extra carbon, gives a still larger quantity, although more highly nitrated cellulose is employed in making it than in the case of blasting-gelatine.

Nitro-cotton alone has from time to time been used for blasting work, but in this case we obtain the maximum amount of combustible products. The following analysis shows the products from a nitro-cotton containing 13.3 per cent. nitrogen on detonation :—

Non-combustible—	
Nitrogen	16.9
Carbon dioxide	22.3
	39.2
Combustible—	
Carbon monoxide	45.1
Hydrogen	14.9
Methane	0.5
	60.8

The amount of carbon monoxide produced can be reduced by admixture with various oxidizing materials, and Prof. Harold B. Dixon's observations as to the oxidizing action of water vapor upon carbon monoxide are well illustrated by the fact that if wet and dry nitro-cotton be detonated there is a notable reduction in the quantity of carbon monoxide yielded by the wet sample, and an increase in the hydrogen, showing that the water present has been acting as an oxidizing agent.

When detonated the gaseous products of the composition are :—

	Wet Gun-cotton.	Dry Gun-cotton.
Carbon dioxide	32.24	24.24
Carbon monoxide	27.12	40.50
Hydrogen	26.74	20.20
Nitrogen	14.00	14.86
Methane	0.20	none
Totals	100.30	99.80

Several explosives have been made on the principle of mixing nitro-cotton with oxidizing materials, but the only one of these still in the market is tonite, in which the generation of carbon monoxide is reduced by mixing the nitro-cotton with mineral nitrates. Such mixtures, however, give rise to a residue of fused salts, which, if blown out into an explosive atmosphere, would be extremely liable to ignite it, and although the combustible gases evolved are reduced in quantity they are not done away with.

Besides nitro-glycerine and nitro-cotton, such of the Sprengel explosives as are capable of complete detonation come under this group. The Sprengel explosives have been largely used for blasting purposes, both abroad and in this country; those used here consist of mixtures of nitrated hydrocarbons and ammonium nitrate.

Roburite, introduced by Dr. Carl Roth, is a simple mixture of nitrate of ammonium with chlorinated meta-dinitro-benzol. The ammonium nitrate is first dried and ground, then heated in a closed steam-jacketed vessel to a temperature of 80° Cent., and the melted organic compound is added, and the whole stirred until an intimate mixture is obtained. On cooling, the yellow powder is ready for use, and is stored in air-tight canisters, or is made up into cartridges. Owing to the deliquescent nature of the ammonium nitrate, the finished explosive must be kept out of contact with the atmosphere, and for this reason the cartridges are waterproofed by dipping them in melted wax.

This mixture is not exploded by ordinary percussion, firing, or electric sparks. If a layer of the explosive is struck a heavy blow with a hammer, the portion directly receiving the blow is decomposed, owing to the heat developed, but no detonation whatever takes place, nor are those portions of the substance around the spot in any way affected, whilst if roburite be mixed with gunpowder, and the gunpowder be then ignited, the latter explodes and scatters the roburite without firing it.

Roburite can only be exploded by a specially powerful detonator, and on decomposition the gases evolved contain no combustible constituents, but consist only of carbon dioxide, water, and nitrogen, with a small trace of hydrochloric acid gas, which is at once condensed by the large volume of water vapor evolved, and gives rise to no inconvenience.

Ammonite is another explosive of this class, which is manufactured from ammonium nitrate and dinitro-naphthalene, these substances being blended in the proportions necessary to give as the products of combustion carbon dioxide, water vapor, and nitrogen, but during the decomposition taking place, probably some more complex action occurs, as small traces of ammonia can generally be detected.

Bellite consists of a mixture of dinitro-benzene with ammonium nitrate, the latter being kept rather in excess.

Securite consists of ammonium nitrate and dinitro-benzene, but from the proportion of nitrate used it is probable that carbon monoxide is produced. The cartridges are coated with nitrated resin, in order to protect them from the action of the atmosphere.

There is no doubt but that this group of explosives approaches more nearly to real safety-explosives than any which have yet been introduced.

The low temperature of explosion secured by the use of ammonium nitrate, the absence of any combustible products of decomposition—except perhaps with securite—and the fact that both the oxidizing material and the combustible are capable of complete detonation with a sufficiently powerful fuse, gives these explosives enormous advantages over any others to be obtained, whilst they are absolutely safe in handling.

The safety of the Sprengel explosives in handling and use is to a large extent dependent upon the fact that when the mixture of ammonium nitrate and the nitrated organic body is ignited by ordinary flame, the ammonium nitrate requires a large amount of heat for its decomposition, in order to render the oxygen which it contains available for the combustion of the carbon and hydrogen in the organic body, and the temperature of the burning substance is not sufficiently high to propagate this action throughout the mass, the result being that to cause continued combustion you must have a continuous supply of heat, or the flame first started simply dies out.

The effect of this is that in handling, such bodies are practically non-inflammable, and when they are made to explode by detonation, a more than usually powerful detonator has to be employed, so that although with nitro-glycerine mixtures a charge of 7 grains of mercuric fulminate is amply sufficient to produce detonation, such a body as roburite needs at least 15 grains. Moreover, when detonation has been produced, the amount of heat absorbed by the decomposition of the ammonium nitrate causes a very considerable lowering of the temperature of explosion.

To the writer's mind, it is an absolute *sine qua non* that in an explosive mixture for mining work, all the constituents should be capable of detonation, and the reason for this is that under these conditions the shock of the detonator resolves both the oxidizing and combustible bodies into their respective molecules, and that these then recombine into the gaseous forms which give the explosive force, the whole action being practically instantaneous, and causing the projection of the hot products with such velocity as to give no time for the decomposition of the methane in the pit-gas, and the ignition of its constituents.

In order to obtain the requisite rapidity of explosion for ensuring safety as regards the ignition of gaseous mixtures in the pit, the reacting portions of the explosive must be in the condition of molecular division, and for blasting purposes this can only be obtained by complete detonation. It is impossible to obtain safety by any attempt at mechanical division. An excellent example of this is to be seen in westfalit, which is said to be made by mixing 95 per cent. of ammonium nitrate with 5 per cent. of shellac or resin dissolved in alcohol, the alcohol is driven off by heat, and the mixture is ground and made up into cartridges. In this mixture the resin or shellac cannot be detonated, and the presence of the inert material necessitates the use of a No. 9 detonator, containing 2.5 to 3 grammes of fulminate, to explode the mixture, and when detonated the ammonium nitrate only is decomposed, and the simple combustion of the resinous matter by the products follows as a secondary reaction, with the result that the period of explosion is very sensibly increased, and the risk of ignition of the pit gases becomes much greater. The resinous material undergoing combustion is also a grave source of danger, as, instead of being in a molecular state of division, the smallness of the particles is governed by the degree of fineness to which it is ground, and a blown-out shot would be accompanied by a shower of sparks of the burning resin. The fine condition into which it must be ground must also increase the troubles due to the hygroscopic nature of the ammonium nitrate. On these grounds one would expect westfalit to be the least efficient and least safe of the Sprengel explosives.

In deciding as to the relative claims of the other members of the Sprengel group, ammonium nitrate being common to all, the best will be the one in which the nitrated combustible is the most susceptible to detonation, as this reduces the chance of miss-fires or partial detonation as well as increases the rapidity of explosion, and the writer should expect the chloro-dinitro-benzol used in roburite to answer best to this requirement.

The third group of explosives consists of mixtures of the first and second groups, in which a body susceptible to detonation, and generally of an oxidizing character, is exploded and the products made to act upon a combustible.

Westfalit, which has just been contrasted with the rest of the Sprengel explosives, is an admirable example of this group, but the most important member is carbonite, which consists of a mixture of about 25 parts of nitro-glycerine, 30 parts of nitrate of potassium, 4 parts of nitrate of barium, 40 parts of wood-meal, and 1 part of carbonate of sodium. On detonation, the nitro-glycerine is decomposed and combustion of the wood-meal at the expense of some of the oxygen of the nitro-glycerine and the metallic nitrates takes place. There is no doubt that the admixture of so large a proportion of carbonaceous material reduces the temperature of the explosion, but it also makes it one of the worst offenders as regards the generation of combustible products, and if carbonite be exploded in an experimental bomb, the escaping gases can be ignited and will burn with a characteristic carbon monoxide flame, over 40 per cent. of the products of its combustion consisting of this gas.

So far, carbonite has come out in trials and in practice in a very satisfactory manner, but a blown-out shot in a dusty mine would be quite likely to lead to an explosion, whilst the fumes must be very injurious to health.

For the reasons which the writer has brought before the members, he thinks that the selection of a safety-explosive should be based upon the following points :—

1. The explosion must be due to detonation and not to simple combustion.

2. If the explosive be a mixture, both the combustible and oxidizing material must be susceptible of detonation.

3. The products of explosion must be non-inflammable and non-poisonous.

4. The explosive must be safe in handling as well as in action, and compounds of an unstable character which are liable to change should be avoided.

5. The temperature of explosion should be as low as is compatible with rapidity of action.

The following table gives an idea of how far the explosives most in use comply with these requirements, and it will be seen that the Sprengel explosives occupy the foremost place :—

MINING EXPLOSIVES.

Name.	How Exploded.	Products of Explosion.	
		Combustible.	Non-combustible.
Gunpowder	Combustion	14	86
Blasting powder	"	42	58
Nitro-glycerine	Detonation	nil	100
Nitro-cotton	"	61	39
Gelignite	Detonation and combust'n	7	93
Carbonite	" "	41	59
Roburite	Detonation	nil	100
Ammonite	"	nil	100
Bellite	"	nil	100
Securite	"	trace	100
Blasting-gelatine	"	46	54
Tonite	Detonation and combust'n	8	92
Westfalit	" "	trace	100

Given an explosive which answers to these requirements, and using electric firing with detonators containing sufficient fulminate to ensure complete detonation, accidents from explosives ought to be reduced to a minimum.

The Preservation of Mine Buildings.

Mine owners and mine managers are gradually adopting the plan of painting breakers, tipples, engine houses, boiler houses, and all other buildings connected with mines.

The prime object of this painting is the preservation of the lumber, and the added neatness given the plant. The cost of applying the paint is at least as great as the cost of the paint itself, therefore it is good economy to use only a paint of recognized merit, and one that combines the most good qualities. It does not cost any more to apply such a paint than it does to apply a poor quality.

The manufacture of paints has kept pace with other industries, and to-day paint can be obtained which not only possesses all the essential paint qualities, such as covering capacity, beauty of finish, lasting quality, etc., but which also has the property of enormously limiting the combustibility of wood to which it is applied, and consequently will resist fire, where formerly paint would increase the combustibility. These paints, furthermore, cost no more than good ordinary paints, such as our grandfathers used.

The value of fire-resisting paint can be readily understood, for while it serves every purpose for which it is designed, it is an *absolutely automatic* fire extinguisher, as it is not necessary, as is the case with buckets and hose, to have someone on hand to extinguish the fire, but as soon as the flames reach the paint they will die out for want of fuel.

The Jamieson Fire-Resisting Paint, made by the Jamieson Fire-Resisting Paint Co., of 62 and 64 William St., New York, is an especially good paint for mine use. It has been on the market long enough to establish all claims made for it, and its fire-resisting qualities are of a high order.

Novel Plans for River Gold Mining.

A highly interesting and ingenious method of river gold mining has recently been evolved by Mr. Charles Bell, of St. Leonards, whose name readily recurs to the mind in connection with this important, but comparatively little-known, branch of activity. The method in question is best illustrated by a description, necessarily brief and fragmentary, of the plant recently manufactured in a north-country town to carry out Mr. Bell's idea. The apparatus in question, if so it may be called, consists of a floating pontoon, 70 feet long by 25 feet broad, 5 feet deep in the middle, and drawing at work about 2 feet 4 inches. In the centre is a well, inside of which moves up and down a cylinder 2 feet 6 inches in diameter; and at the bottom there is a working chamber 6 feet in diameter and 7 feet in height, and at the top an air tight door. When the cylinder is lowered towards the bed of the river—its upper rim being kept at a height of more than a foot above water level—a workman enters, and the water is gradually forced out by means of compressed air. At length the bottom of the cylinder rests on the bed of the river, and the operator is able to proceed with his work dry-shod, and by the aid of electric light. The sediment on the river bottom is raised to the sluice-boxes by suction-pipes working either inside or just beyond the edge of the cylinder. The boxes retain the gold and reject the gravel, &c., into the river behind the dredger. This is the ideal theory of the process, and if, in practice, it only works out fairly successfully, a distinct advance will have been made in the methods of river mining. In any case we shall watch the further development of this novel and improved application of an old principle with considerable interest.—*Mining Journal, London.*

PROSPECTING FOR GOLD.

GOLD PLACERS; HOW THEY ARE WORKED.

Theories of the Origin of Gold Sands and the History and Distribution of Gold Placer Deposits Throughout the World.

Written for THE COLLIERY ENGINEER AND METAL MINER by Prof. Arthur Lakes.

In these days, when all the world is after gold, any information as to where to find it and how it is extracted and mined is of interest. In former articles we have given some account of its occurrence in veins, how to prospect for these, and how they are mined. We have also given some account of placer mining and cited one or two typical examples. Now we propose to give in succeeding articles a full history of placer deposits and their mode of exploitation. Placer mining will, we predict, soon come more and more to the front. Although in early times it was the only kind of gold mining, yet for a long interval it has been thrown in the shade by the discovery of gold veins in place. The prospect of getting suddenly rich on these and striking a bonanza caused the more steady, regular and less exciting work of placer mining to be in a measure laid aside. Now gold in any form or condition and in any sort of place or circumstance will be sought for, and we predict that more attention than ever will be given to these humbler deposits.

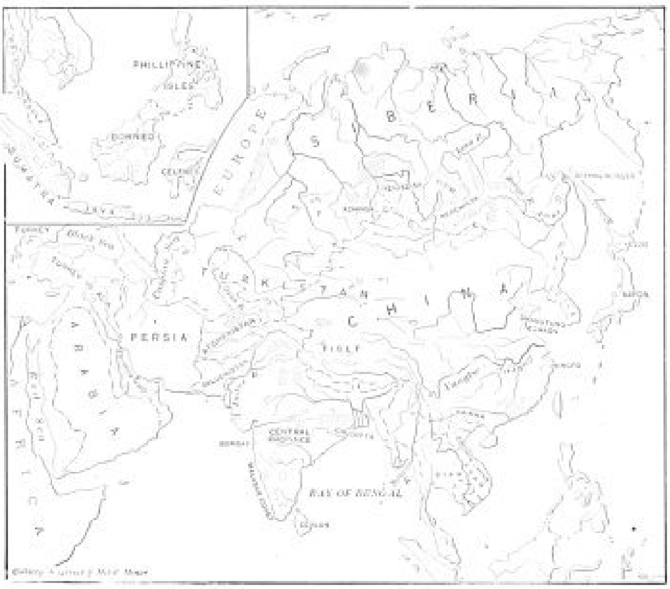
In Colorado the signs of this are already apparent. Old, abandoned placers that were just skimmed over by the old-timers of '59 are being reexamined and efforts on a large scale made to reach down to bed rock, which the "old-timer," with his simple appliances, never dreamed of doing. New tracts of placer ground are being taken up and long lines of ditches constructed for bringing water to bear on placer deposits which were never touched in the old days, because there was no water at hand. New schemes on large scales are being started, and with the newest and most approved appliances, like the placer at Roscoe familiar to our readers. Besides going down to bed rock in river beds whose dry banks were just skimmed by the prospector with his little sluice and Chinese wheel, the water of the rivers themselves is being turned from its natural course, exposing long reaches of river bed and entirely new and virgin ground, and this ground is being worked down to bed rock, though it be 50 or 60 feet deep, by deep and continuous trenches with the help of giant nozzles and Ludlum elevators and approved series of undercurrent sluices. The old-timer with his "Long Tom" or "rocker," and his little squirt of hose pipe would look on in amazement at great 30-inch stave pipes and giant nozzles and Ludlum elevators and sluice after sluice in long succession.

Placer mining is the earliest form of gold mining known. All the gold of the ancients was obtained by some sort of simple placer mining, in most cases from the sands of flowing rivers. The gold of Ophir that made Solomon so rich was extracted by washing river sands. The gold of the Aztecs and Indians was all derived from the same source. The ancients never seem to have thought of looking for or working leads in place. Even their tin, which was procured so abundantly by the Phenecians and so much used in making bronze implements, was derived from surface washings or "stream tin," and their extensive surface placers are visible in Great Britain at this day. It was not till quite a late date in the world's history that gold leads in place were looked for and mined. Even in our own country the old prospectors of '59 were all placer miners, all gold washers, relying more on their pan than on their pick, and it was not till some time after gold was discovered at Sutter's Mill, in California, and an elaborate system of placer mining established, that the miner bethought him of looking up the localities where all this gold might come from, and found leads of gold and silver in place and developed them.

Placer mining or gold washing on a small or large scale is being and has been carried on in nearly every country of the known world, even in countries not generally considered as carrying gold veins in place. Every great river of the world has been more or less worked for gold, and even the sands of the sea beach.

ORIGIN OF GOLD SANDS.

And here let me correct what I believe to be a popular mistake, and that is, it is supposed that all gold must originally occur in veins and that all gold found in placers and in the sands of rivers must at one time or other have been derived from the breaking up of such veins by glaciers and the winnowing of the material by streams and floods. I do not think this is entirely or in a large part the case. It is very certain that many placer deposits derive their gold from such veins, but by no means all; still less the amount distributed over the rivers of the world in regions not remarkable for gold-bearing veins. I believe that gold is concentrated in veins, but is widely and perhaps minutely distributed also through the rocks themselves, more especially the granitic and igneous rocks, lavas, porphyries, etc. If we could break up and mill as glaciers and erosion have done, whole mountains of granite, we should undoubtedly find a small residium of gold irrespective of quartz veins. Many of our lavas in Colorado, especially those known as andesites and rhyolites or porphyries, if ground down, will yield gold, and often even on a small scale will assay in gold. In the Cripple Creek region, which is covered with a dense mass of andesite and phonolite lavas, the gold is by no means found to be restricted to so-called veins, but almost any piece of lava picked up at random will assay in gold and sometimes even as high as $25. Nor in the so-called veins or in the mines is the gold found restricted to orthodox quartz veins or veins of any kind, or even to fissures of any kind, but quite often it is diffused through the substance of the lava along a certain broad zone or in a dyke penetrating previous flows of andesite lava. In some cases large masses of rotten, honey-combed granite are shipped as ore, being thoroughly permeated with ore matter. Again, at Leadville, in the Little Johnnie and Ibex, in the great gold belt, as it is called, the gold is by no means in veins, but permeates a thick mass or belt of decomposed pyritiferous porphyry, quite one of the leading rocks composing the structure of the Leadville region. Supposing, now, a glacier, followed by streams, to break up and winnow whole mountain sides of such porphyry, we might readily account for the gold placers formed from such, and by no means think of attributing the gold to gold veins in place. The same may be said of many other crystalline rocks, and if Sandberger's lateral secretion theory has any weight, most crystalline rocks contain in these elemental crystals and minerals minute portions of gold as well as of the other metals. In experience in the West it will be found that by far the largest and most important gold mines are decomposed dykes impregnated with gold, and in other rocks the expert is often sorely put to it to define his ore body, as there is no visible vein in place, but the ore-yielding body is an indefinite impregnation of the country rock along certain not sharply defined zones. To the breaking up of granite and other mountain ranges over the earth's surface by the wear and tear of erosion and time, we attribute in most cases the gold found far and wide in rivers, though possibly a mythical Pactolus river flowing golden sands may derive its extraordinary wealth from gold veins not far distant.



DRAINAGE MAP OF ASIA; DOTTED LINES SHOW LOCATION OF GOLD DEPOSITS.

THE HISTORY AND DISTRIBUTION OF GOLD PLACER DEPOSITS OVER THE WORLD.

Among the early records of gold washing we learn that the Greeks from the earliest times carried on an extensive commercial intercourse with the people who lived north and east of the Black Sea, and drew largely on the gold fields of Siberia, from which source the Gothic tribe of the Massagetoe also obtained their wealth. These gold deposits are supposed to have been situated in latitude 53° to 55° North and are said to be identical with those worked by the Russians during the present century. In Asia Minor the mountains and streams of Phrygia and Lydia yielded gold in ancient times, and there was supposed to be, according to Herodotus, the wonderful Pactolus river, from whose golden sands Croesus is said to have derived his wealth. The sands of Asia Minor, however, have long since ceased to yield the precious metal.

Strabo says that imperial Rome was inundated with a glut of gold from her northern mountains, the Alps. (These mountains, be it said, are largely composed of granite and other crystalline rocks.) Polybius says that in his times gold mines were so rich about Aquileia * * * that if you dug but two feet below the surface you found gold, and that the diggings generally were not deeper than fifteen feet. * * * Italians aiding the barbarians in the working for two months, gold became forthwith one-third cheaper over the whole of Italy. Gold alluvia occur in various localities in upper Italy, but appear to be poor, and at the present time no gold-washing is carried on except by a few individual workers. The sands of the Orco, the Jassin, the Po and Serio are estimated to have yielded 300 ounces gold in 1862. In Spain and France the Romans are stated to have washed the sands of streams along the base of the Pyrenees, which are also composed of crystalline rocks.

The Phenecians obtained gold from the bed of the river Tagus 1100 B. C., and washings are reported along this stream as late as 1883 A. D. The Douro sands were worked for gold by the Arabs until 1147 A. D. Up to the close of the fifteenth century the deposits of the Ariege yielded annually about 100 pounds of the precious metal. As late as 1846 gold washings are reported along the Rhine between Strassburg and Philipsburg. (It is worth noting that all these rivers mentioned have their sources in, or drain regions of crystalline rock.)

DRAINAGE MAP OF EUROPE; DOTTED PORTIONS SHOW LOCATION OF GOLD DEPOSITS.

In Africa the ancient Egyptians mined the precious metal in Nubia, and there are mines extant between Berenice and Suakim on the Red Sea. These are spoken of by Diodorus Siculus, and shown on one of the oldest topographical maps extant, preserved in Tunis.

The earliest record of the Egyptian mines dates from the twelfth dynasty, and those of Kordofan, in Abyssinia, are mentioned by Herodotus.

That crystalline rocks exist in these regions is shown by the great monoliths that have been dug up, many of which are of red crystalline syenite, a rock very like red granite. In fact, a very large portion of the continent of Africa is of granite, hence it has been claimed as one of the oldest countries geologically in the world.

Nearly all the gold obtained in Africa till within the past few years has been from alluvial deposits. The country south of the desert of Sarah contains numerous gold-bearing alluvions worked by negroes. The product is conveyed by caravans to Morocco and Algiers as a principal article of export from the Guinea coasts. Gold dust was also obtained on the southeast coast opposite Madagascar, in the country of Sofala, where by some is supposed to be the region whence Solomon obtained his wealth. Of the diggings in the past few years in the Transvaal and Leydenburg district, where coarse nuggets weighing as much as 11 pounds have been found, we will speak later. The gold export of all Africa from 1493 to 1875 is estimated at £106,857,000. In India, in the Bombay presidency, gold-bearing deposits exist in the district of Belgaum, Dharwar and in the Mahratta country. The sands of the Surtar are gold-bearing also. The central provinces of India contain many small deposits of gold, but the number of gold washings is comparatively limited. The ancient gold mines of Madras have been rediscovered. The great wealth of the nabobs of India is supposed to have come from these mines and from Malabar. Regions are in places covered with tailings showing the industry of some of the ancient tribes. Gold quartz is being mined in different parts of the province of Mysore. A number of rivers having their sources in the State of Travancori contain gold-bearing sands and gold washing is carried on in these places at the commencement and termination of the rains, just as in Colorado at the beginning of spring and in most of our western states, with the close of winter to its commencement again, for placer mining is a summer occupation and dependent on the openness or freezing up of its water supply. The sands of the streams of Ceylon, the Philippine Isles and the Indian Archipelago carry gold. At Borneo there has been extensive mining by the Chinese and natives, over 30,000 of the former being now employed in the gold fields. (We may note here that the rocks of these islands are for the most part volcanic and crystalline and the whole archipelago is more or less volcanic.)

In the seventh century the Chinese traveler Hiuen-thsang describes the country north of Kuen-Lun toward the desert of Gobi as a gold-bearing district. Somewhere in this district Humboldt locates the land of gold sand spoken of by the Dardai. Pumpelly states that

Map of Africa; Dotted Portions Show Gold Deposits.

gold is found in fourteen out of eighteen provinces of the empire. The greatest number of washings is in the province of Se Chuen, also the Kuen-Lun mountains penetrating central China. Placers are not uncommon yielding coarse gold. Hundreds of thousands of natives work the sands of the river Kinsha Kiang. (That placer mining to "John" is no new business is evident from the ready way in which he takes hold of our western placers and manages to get both gold and wages where no white man can.)

In Japan gold was first discovered in 749 A. D., and the art of mining is said to have been introduced from China. Marco Polo in the thirteenth century says of Japan: "They had gold in the greatest abundance, its sources being inexhaustible." The Portuguese between 1550-1639 exported 300,000,000 dollars in gold, till the Japanese government forbade further export. The deposits were mostly shallow placers. The gravel beds are of river origin, limited in extent and uniformly poor. The richest deposits near Yesso contain less than 7 cents per cubic yard and the average of the best does not exceed 5½ cents.

Russia has extensive gold-bearing deposits and in these northern regions we may expect that many of them were laid down through the agency of ancient glaciers as well as by modern rivers. The principal mining districts are those of the Ural, the Altai region in western Siberia, western Turkestan, the northern and southern Yeniseisk fields, the circuit of Atchinsk, Irkutsk, the basin of the Lena and the country along the Amur and Nerchinsk. The total yield of gold washing from 1814 to 1860 amounted to 35,487 poods or 1,548,661 pounds Troy of alloyed gold. From 1753 to 1876, $730,000,000. The gold fields of the Ural extend 600 miles north to the Arctic ocean and south to the Cossack districts. The districts of Miask and Kashgar are the richest. At the former the largest nuggets have been found and at the latter emeralds and pink topazes associated with gold. The whole eastern slope of the Ural is gold-bearing. The first washings were commenced in 1814. In the southern Ural the rivers are remarkable for their minerals and precious stones. (It is not uncommon to find gems and precious stones in the tailings of placers. Quite a number of diamonds have been so found. Garnets are exceedingly common. Rubies, too, are found, and many other heavy crystals and gems characteristic of crystalline rocks.) The Altai region in Siberia was early discovered. On the Yenashimo river very productive placers were found, although the gravel was but 10 feet deep but 700 feet wide. They work from May to September. In some districts there is a scarcity of water. In the great Pit river, 250 miles long, the valley is 3,000 feet wide. The river in places is very rapid and narrow. The pay in places is confined to a channel 56 to 100 feet wide and 12 feet deep. Rubies, zircons and tourmalines are found. On some of the most promising grounds on the Lena the climate is very severe and the ground frozen the entire year. (In Alaska they break out large blocks of frozen ground and thaw or pound the gold out of it.)

(To be Continued.)

MINE FIRE EXTINGUISHED.

A Fire in Port Royal Mine at Port Royal, Pa., Extinguished by Successfully Cutting Off the Air from the Burning Portion.

Written for The Colliery Engineer and Metal Miner by H. E. Gray.

Port Royal Mine is situated in the Ninth Bituminous District of Pennsylvania, and the coal worked is the "nine feet semi-bituminous seam." It is worked by the pillar and chamber method. The ventilation, which is at all times ample, is produced by large blowing fans, the whole current being divided into two main splits.

The plant is owned and operated by the Port Royal Coal and Coke Co., of Youngstown, Ohio. It is well equipped with all the latest and most approved machinery. The under-cutting of the coal is done by the Jeffrey air power mining machine. The holes for blasting are made by the Jeffrey Giant air power coal drill. A large compressor manufactured by the Norwalk Iron Works Co. of South Norwalk, Conn., furnishes the power required in the mine for all machinery including the pumps. When the machinery is all in motion the exhaust air materially assists the ventilation. The coal mined is very gaseous and it requires considerable care on the part of the miners when using explosives, to prevent the flames from the powder igniting the gases given off from the freshly blasted coal.

Some time ago, by the carelessness of a miner, a fire was started at the working face of No. 16 butt entry, and it had made such rapid progress and covered such a large area when discovered, that the ordinary methods of dealing with such fires were of no avail. Temporary stoppings of suitable material were hastily thrown up and later substantial stoppings of brick and stone were erected, the object being to exclude all air from the fire. An iron pipe fitted with a valve was placed in each stopping and tests were made from time to time of the gases which flowed out when the valves were opened. It was finally concluded from tests made at the mouths of the pipes, that the fire was extinct.

The mine was safely operated from the time the fire was first discovered, except a few days during which time the stoppings were being erected, and not a single accident has occurred.

On Saturday, January 4th, at 5 p. m., after all the workmen had left the mine, a party of explorers headed by the mine foreman, descended No. 1 shaft and proceeded to the stoppings already mentioned. Two fire bosses were sent to examine the workings and also to see that every workman was out of the mine. As soon as they returned and reported all safe, work was commenced on the brick and cement and soon air was moving into Nos. 16 and 17 butt entries for the first time in about five months. Two of the exploring party soon followed in the direction of the air current and in a short time all were able to reach the working face of No. 17 entry. There we found the entries almost closed with fallen strata, and we could scarcely crawl over the falls to No. 16 entry. The opening was not sufficient for good ventilation, so the men went at it systematically and soon removed enough stone to allow a sufficient opening for air.

Meanwhile, the ventilating current was efficiently doing its work, and by 11 p. m. a continuous current of air was passing through both entries. We found that the fire was entirely extinguished, and there was not the slightest indication of heat anywhere.

I examined the territory to endeavor to learn the extent of the fire. I found charred coal, coke and ashes scattered profusely in all directions. Canvas hanging on posts was crisp, charred and blackened by the fire, and if touched by the hand, it fell in dust to the floor. Everywhere it was clearly demonstrated that the fire had been on a large scale. Many mining authorities assert that a mine fire cannot be successfully extinguished by the method described. That it has been a success in this instance cannot be denied. Its extinguishment reflects great credit on the management of the mine, and more especially on the mine foreman for the careful and scientific manner in which he conducted the whole enterprise to a successful termination.

WOODEN WATER PIPE.

Its Advantages Over Iron Pipe for Use in and About Mines.

The wooden water pipe (patented) made by Messrs. Ayrault Bros. & Co., of Tonawanda, New York, is worthy the attention of mine owners and mine managers. Owing to its non-corrosive qualities it is the best type of pipe for use as column pipe under moderate heads. As water supply pipe it cannot be excelled, as it is practically indestructible for such service if properly protected from freezing. It is made from first growth Michigan pine, with the sap entirely turned off. Ordinary wooden water pipes will not meet the requirements for two reasons:—First, they will rot on the outside, in some kinds of soil. Second, they are not strong enough to sustain the pressure they are generally subjected to.

These deficiencies are overcome in the pipe manufactured by Messrs. Ayrault and brothers in the following manner:—

Imperishable cement is applied to the outside of each section of pipe after the sap is removed from the timber, thus protecting it from the action of the soil, and effectually obviating the first objection, as given above, to the common pump logs. The second deficiency is supplied by spirally winding the pipe with iron before coating, so as to make it sufficiently strong to sustain any ordinary necessary pressure.

As a water pipe it possesses the following advantages:—

(1) It is cheaper than iron; (2) it is more durable; (3) it can be laid for less money; (4) service connections are more easily made; (5) it better maintains the purity of the water; (6) mineral water will not corrode or destroy it; (7) cost of repairs is much less; (8) it is not so liable to freeze; (9) if frozen, the elasticity of the timber in the pipe allows the action of the frost without injury; (10) this quality renders it less liable to burst from hammer action of pump or hydrant; (11) no section of pipe has been known to be so weak that 80 lbs. pressure could not be kept on the line in case of fire; (12) its weight being much less than iron, freighting it is much cheaper.

As a column pipe its advantages are practically enumerated above.

Messrs. Ayrault Bros. & Co. issue a neat illustrated catalogue that describes the pipe more fully than can be done in such a notice as this. They will cheerfully send a copy to any mine owner or mine manager.

Garlock's Water-Proof Hydraulic Packings.

The constant demand for a superior packing for the plungers and pistons of pumps, induced the manufacturers of the Garlock packings to produce a packing which would meet all requirements. After many years of experiments and at a considerable expense, they have succeeded in producing a water-proof hydraulic packing which they claim is sure to answer all purposes. This packing is the outcome of numerous experiments and practical tests in the water end of pumps, hydraulic elevators and hydraulic machinery, with results that fully justify their claim that they have produced a first-class water-proof packing for light or heavy duty, made of the best flax, and thoroughly lubricated with a water-proof compound which is strictly free from acid. This packing is made in all sizes up to two inches.

Garlock's Water-Proof Hydraulic Packing.

Heretofore, the best rawhide hydraulic packing answered the purpose well for a time, but soon became water-soaked and soft from the use of oils, losing its strength, and piston plungers were sure to leak badly, requiring constant repacking. This packing is intended to resist excessive pressures and retain its solidity. One of the principal claims for this packing is that it is absolutely water-proof and oil-proof. Engineers who daily experience the difficulties of leaky pump plungers will no doubt greatly appreciate the advent of this packing.

The Chicago Drainage Canal.

We have received from the Ingersoll-Sergeant Drill Co., of New York, an artistic illustrated pamphlet describing the Chicago Drainage Canal, which ranks among the leading engineering projects of the century. The book contains much interesting data concerning the canal, and while intended to show the success attending the use of Ingersoll-Sergeant air compressors and drills, it is not merely an advertising catalogue. The views given show various mechanical contrivances used on the work, and, therefore, illustrates the productions of other manufacturers as well as those of the publishers. It is a pamphlet that will be read with interest by every person interested in excavating, quarrying or mining. It will be sent free to any address on application to The Ingersoll-Sergeant Drill Co., Havemeyer Building, New York.

The Westinghouse Electric and Manufacturing Company of Pittsburg has received a number of awards at the Atlanta Exposition for the handsome exhibit of electrical apparatus made. Several gold and silver medals are among them.

ELECTRIC MINING MACHINERY.

Electric Pumps, Fans and Blowers, Showing Latest Electrical Designs.

The operation of mining apparatus by electricity is daily growing more widespread as the steady work of the plants now running drives home the conviction that by means of electricity mines may often be operated more conveniently than by any other system, better work be effected and greater economy induced. Coal and metal mine operators are animated by no sentimental inclination in favor of older methods. It is simply a question with them of an outlay and resultant profits and the electrically driven apparatus is in many fields slowly, but effectually, displacing apparatus operated by steam or compressed air.

Of all the companies manufacturing electric mining apparatus, the General Electric Company has, perhaps, more than any other, contributed to the bringing about of this result. Since it first entered the field, it has kept steadily in view the improvement of its electrically operated mining apparatus and its adaptation to the peculiar conditions of the mining industry. The illustrations show a few examples of apparatus produced at its works and now in successful operation.

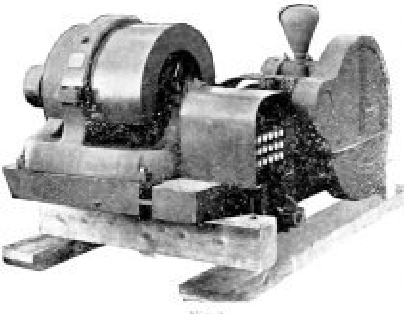


Fig. 1.

Fig. 1 shows a 6½ inch by 8 inch horizontal triplex pump, directly driven by a 10 H. P. four pole, slow speed motor through two reduction gears, the entire combination on the same base, being mounted on a truck for ready transportation from place to place in the mine. The motor is controlled by a rheostat set at the side and, like the motor, housed in with a sheet iron cover. The illustration shows the truck mounted on wooden base for shipment.

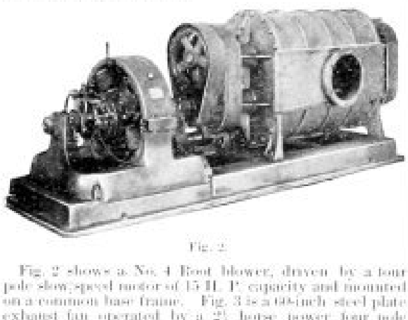

Fig. 2.

Fig. 2 shows a No. 4 Root blower, driven by a four pole slow-speed motor of 15 H. P. capacity and mounted on a common base frame. Fig. 3 is a 60-inch steel plate exhaust fan operated by a 2½ horse power four pole motor. The fan makes 480 revolutions per minute and has a capacity of 8,300 cubic feet of air per minute at ¾ inch W. G.

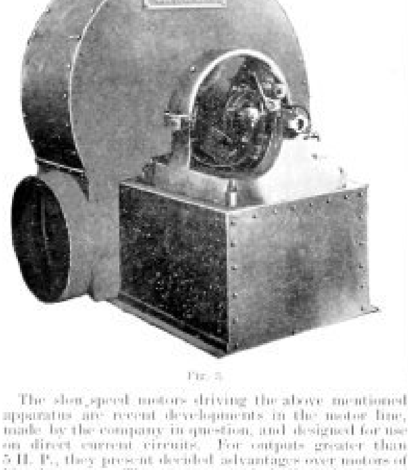

Fig. 3.

The slow-speed motors driving the above mentioned apparatus are recent developments in the motor line, made by the company in question, and designed for use on direct current circuits. For outputs greater than 5 H. P., they present decided advantages over motors of bi-polar types. They are compactly built and admit of direct combination with machinery without increasing the space occupied to any great extent. They operate at slower speed than any other motors of similar capacity yet built, and although reduction of speed must necessarily imply increase of weight, yet in this case it is amply compensated for by economy of material effected by the adoption of the four-pole type. The frames and fields are of special soft cast steel, which, possessing high magnetic permeability, allows the construction of a motor lighter than other motors of the same output at higher speed. The armatures are thoroughly ventilated; and the windings of copper wire, first formed and insulated, are embedded in slots in the armature core, and bound down securely on the projecting flange of the armature spider. The coils can be easily removed and replaced; the insulation is the excellent result of years of experience. The machines are sparkless and the load can be varied from nothing to full load without the necessity of shifting the brushes. Precautions are taken to prevent any tendency on the part of the bearings to get out of alignment and proper contact of brushes with the commutator is insured by special construction of the brush holders.

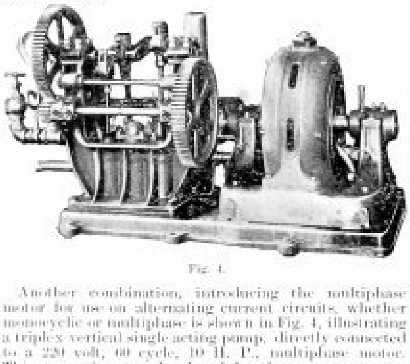

Fig. 4.

Another combination, introducing the multiphase motor for use on alternating current circuits, whether monocyclic or multiphase is shown in Fig. 4, illustrating a triplex vertical single acting pump, directly connected to a 220 volt, 60 cycle, 10 H. P., multiphase motor. This type of motor developed by the same company, aside from its compactness, which allows of its erection in a restricted space, has the additional advantage of being absolutely without brushes, commutator or moving wires. It requires no attention and may be stopped and started under full load or no load; in fact it has all the advantages of the best type of direct current motors, with better regulation and without any of the disadvantages which the presence of commutators, brushes and a wire-wound armature may develop. These motors are now in use on all the three phase monocyclic power transmission circuits in this country, operating without attention and without accident and to the entire satisfaction of the user.

IRON ORE MINING.

Systems of Mining Used in Minnesota Iron Mines.

(By Charles Dean Wilkinson.)

[From the Year Book of the Society of Engineers, University of Minnesota.]

The iron mines of Minnesota may be divided into two general classes according to the condition of the deposit.

I. Mines in which stripping will pay:

II. Mines in which stripping is not possible or will not pay.

The dividing line of these two classes is determined by a rule formulated by Mr. Denton, engineer of the Soudan mine at Tower:

"Stripping will pay when the volume of the ore is equal to, or greater than, the volume of the material to be stripped." It must be noticed that volume and not depth is considered in this rule.

The first class comprises:

A. Mines in which the deposit is thin and covers a large area;

B. Mines in which the deposit is thicker and covers a more restricted area.

The second class comprises:

C. Mines in which there is a poor hanging wall, especially where the deposit is directly under glacial drift;

D. Mines which have a good hanging wall, or in which the deposit is at a great depth.

These divisions merge into one another, as for example the first general division into the second, or *A* into *B*, etc.

The systems applied to each of these conditions of deposit are as follows:

To *A*. Open-cut mining with steam shovel as in the Oliver mine.

To *B*. The "milling" system as used in the Auburn mine.

To *C*. The "caving" system as used in the Canton mine.

To *D*. The ordinary system of "stoping-out" as used in the Minnesota mine at Tower.

Mining by these different systems is carried on as follows:

First, open-cut mining with steam shovels.

The exploration preliminary to the location of mines on the Mesabi range is generally carried on by means of test-pits until the ore is reached. After striking the ore, investigation as to its general quality, the thickness of the deposit, etc., may be carried on with diamond drills.

When the location has been made the stripping is done either by steam shovels or by hand. The larger number of mines do the stripping by steam shovel, but where many bowlders are encountered, as in the Biwabik, it may be necessary to do the work by hand. While ore is being taken out benches must be left around the edges of the area already stripped, for the operation of the stripping shovels.

In removing the ore if the deposit is very soft the shovels may work directly into it, but if the ore is hard it must be loosened by blasts and loaded into the cars by the shovel. The working as carried forward gradually slopes downward, so that a great depth may be obtained without making the gradient of the tracks too heavy. The ore is loaded directly into cars by the shovel and the cars for one shovel may be handled by a single locomotive. The crew for a shovel consists of an engineer, crane-man and helper. The claim is made that a good shovel and locomotive can load and dispose of a 20-ton carload of ore every six minutes. This estimate is approximately true.

This system is peculiar to the Mesabi range and to some of the workings in the Alabama iron regions.

Second, the "milling" system.

Exploration and stripping for mines operated on the "milling" system is carried on in the same manner as for the steam shovel method.

When the deposit is stripped, a shaft is sunk at one side deep enough to run in a level to the lowest point of the ore. Another shaft is sunk to connect with the end of this level and at the bottom an ore-chute is placed. Blasts are now fired around the mouth of this second shaft in such positions that the loosened material will fall to the bottom into the ore-chute. In the Auburn mine the ore is trammed from this chute to the main shaft, the haulage being done by mules. The material is hoisted by skips and dumped either into small cars and conveyed to the stock piles, or loaded directly into the railroad cars.

As the work proceeds radially outward from the secondary shaft the hole presents the form of a volcanic crater. The men doing the drilling for the shots are suspended from the edge by ropes and the blasts are fired at change of shifts.

The only level driven is the one which connects the main shaft with the ore-chute, and the only timbers necessary are the pit frame, shaft-timbers of the main shaft and the level timbers.

With a correct gradient, gravity haulage may be substituted for mule haulage in the level.

The "milling" system is peculiar to the Mesabi range and was first introduced at the Berringer mine by Dr. J. A. Crowell and Mr. F. R. Whittelsey.

Third, the caving system.

Where the overlying material is too thick to strip and not firm enough to furnish a good roof for ordinary stoping out, it is necessary to use another system of mining, and this is provided in the "caving" system as used in the Canton mine at Biwabik and in part of the Chandler mine at Ely.

In operation the shaft is sunk and the top level driven first. At the extreme end of the level a room is cut out and the roof supported by light timbers or pillars of ore. When all the material from the room has been excavated, the pillars are "robbed" and the roof allowed to cave. The next room is then taken out, and so on till the level is completed. Then the second level is treated in the same manner. If the roof in any case refuses to cave, blasts are placed at the four corners and fired simultaneously. After caving, the material thus brought down may be excavated. Thus when the bottom of the deposit is reached there is nothing left but the glacial drift or other overburden. Trouble is often caused in mines operated on this system, by matting or wedging of timbers after caving down one or two levels, so that the roof will not fall.

Fourth, "stoping-out" system. Most of the work on the Vermillion range is carried on by means of the ordinary system of stoping-out.

The Minnesota or Soudan mine furnishes the best example of this system, as it has been the longest in operation and has the most finely equipped plant.

The exploration is done with diamond drills and after the deposit is located a shaft is sunk to the lowest part. Cross-cuts are run in for about 100 feet. From the ends of the cross-cuts, levels are run at right angles to them, as far as the ends of the deposit. Beginning at the end, the material is taken out by overhand stoping. The ore is milled to the level below, mills being provided at short intervals. The space opened is filled with broken country rock taken from the side walls or brought in from outside. A permanent roadway is left at the bottom of the level and is timbered with sets consisting of two posts and a cap, no sills being necessary. Round lagging is used. No other timbers are necessary in the levels as the hanging wall is very strong.

Ore-chutes are provided at the bottoms of the mills and open into the permanent roadway. The ore is trammed to the shaft by men and hoisted in cages. Both percussion and diamond drills are used in drilling for blasts. This use of the diamond drill for blast holes is peculiar to the Minnesota mine. Two roof holes running nearly parallel to the level are put in at opposite sides of the level and meet to form a V. The holes are about thirty feet long and are loaded with thirty pounds of dynamite which fills the hole to about two-thirds of its length. The two shots are fired simultaneously and bring down an immense amount of ore.

The following comparison of systems may be stated. That the open-cut steam shovel method is the cheapest for shallow deposits where the stripping is thin, cannot be questioned. However, when the deposit becomes thicker, the milling system would seem the more efficient for two special reasons: First, if the ore body contains much water it will be necessary to drive shafts and tunnels for drainage, and such tunnels and shafts once driven, the milling system will be cheaper. Second, as the working goes deeper and deeper the gradient of the railroad track becomes heavier and heavier until the engines will have great difficulty in hauling out trains.

The first of these reasons has much weight, as nearly all the Mesabi mines are very wet at the lower levels, and the second, because a steam shovel and a locomotive are both machines of poor efficiency when compared with the results obtained from strong, well constructed and proportioned stationary engines, such as are used for winding in the milling mines.

The last two systems are the product of well defined conditions. To the present time no better methods have been found for such mining. They are certainly more costly than the open cut and milling systems, but with high grade ores and fair prices, can be operated with profit. The permanent plant necessary including winding engines, compressor plant, machine shops, shaft-houses, pit-frames, pumping engines, and possibly crushers for hard ore mines, must be considered in comparing the cost of the systems.

The open-cut mine with its machinery consisting of two or three steam shovels, a locomotive, a small pumping engine, compressor plant if necessary, and a repair shop, certainly has the advantage as to first cost. The question remaining to be answered is, how will the expenses of operating compare. This can be answered when some of the open-cut mines have worked out a deposit.

LEGAL DECISIONS ON MINING QUESTIONS.

(Reported for THE COLLIERY ENGINEER AND METAL MINER.)

Location of Mining Claim in Another's Name.—The Supreme Court of California says that where one, acting under the statutes of the United States, vesting in a locator of a mining claim the exclusive right to its possession, locates and has a mining claim recorded in another's name, the legal title thus vested in the other cannot be defeated by a subsequent parol agreement that it is to be held by him in trust.

Moore v. Hammerslag, 41 Pacific Reporter, 805.

Sale by One Cotenant of Mining Lands.—The Supreme Court of Pennsylvania says that the terms of a contract of sale by which one cotenant of mining lands disposed of his interest will not bind the others to accept the royalty reserved by such sale as a fair measure of their rights. It also held that such purchaser should not be enjoined from mining, but that an account should be kept of the coal mined, and that he should pay into the hands of a receiver twice that reserved by the contract to be paid, until the values could be determined.

Mercur v. State Line & S. R. Co., 32 Atlantic Rep., 1126.

Homestead Right Royalty from Coal Mined Under.—The Court of Civil Appeals of Texas holds that royalty due a homesteader from coal mined on the homestead is subject to his debts.

Collins Mfg. Co. v. Carr, 32 S. W. Reporter, 336.

Negligence of Employer.—It is not negligence, of itself, for an employe to warm his hands in cold weather at a fire where dynamite is being thawed, where there is evidence that the fire was built for the purpose of allowing the employes to warm themselves, as well as thawing the dynamite, and that the employer knew that his men were so using the fire.

In thawing dynamite such reasonable care is required of the employer as is commensurate with the danger that may be apprehended from such use and such ordinary care as reasonable and prudent men under like circumstances use in thawing such material. This kind of care must be ascertained by the general usages of the business, as "ordinary" care must depend upon the peculiar circumstances of each case.

Bertha Zinc Co. v. Martin's Adm'r (Supreme Ct. App. Va.), 22 S. E. Reporter, 869.

Construction of Mining Laws.—Picking rock from the walls of a shaft or outcropping of a ledge, in small quantities, from day to day, and testing it, in order to find paying vein, cannot be credited as part of the $100 worth "of work and improvements" required to be made by the locator on his claim within one year from the date of his location, by the Revised Statutes of the United States.

Bishop v. Baisley (Supreme Ct. Ore.), 41 Pacific Rep., 936.

Negligence of Fellow-Employe in Mine.—A party employed to load ore into cars brought to the floor by the miners. It was the practice, as successive spaces were cleared of ore, to support the roof by timbers put in on notice from the miners, or through the shift boss. Before a newly opened space had been put in condition for the timber men, and before they were notified that their services were required, this party was injured by ore falling from the roof. There was evidence that too large a space had been mined, and that just before the accident the foreman's attention had been called to the roof, and he said it was all right. The Supreme Court of Michigan held that if there was any negligence it was that of a fellow-servant.

Petaja v. Aurora Iron Mining Co., 64 N. W. Reporter, 335.

Laws Applicable to Construction of Mining Lease.—The rights of the parties under a mining lease of land in Pennsylvania must be determined by the laws of that state, though the lease was made at the residence of the parties in another state. The question of how the courts of Pennsylvania have construed mining leases is one of fact, on which the testimony of jurists as experts is admissible, when tried in another state. The courts of New York will not, on a bill to rescind a contract of lease of land in Pennsylvania, decree that a party should remove his machinery from the land and deliver possession of it to the complainant in the suit in New York.

Genet v. President Del. & H. Canal Co. (Superior Ct. N. Y. City), 35 N. Y. S. Rep., 147.

When One May Not Claim Coal.—One who was present at the sale of coal under the surface, and made no objection; nor protested against its being mined for seventeen years, is thereby prevented from claiming title to the coal under an alleged gift, as against such grantee.

Moreland v. Frick Coke Co. (Supreme Ct. Penn.) 32 At. Rep. 634.

Payment of Royalties Without Working Mine.—Where a contract expressly permits the cessation of mining on a parties' land, by providing that if no coal be mined the lessee shall make a payment for a certain number of tons per year, then so long as they make this payment they are entitled to use and enjoy the rights and privileges otherwise granted, and the openings, buildings, fixtures and appurtenances made and constructed for mining, preparing and forwarding coal on the land of the lessor, as well as for mining, preparing and forwarding coal from the adjoining or contiguous lands; where the right to use the land for the mining of coal on adjoining and contiguous land is not limited by the agreement to any particular time, it is to continue until the coal of the contiguous land is exhausted. It does not depend upon the amount of coal taken from the land of the lessor, and the court will not make such construction as will be to make a new contract between the parties.

Genet v. Del. & H. Canal Co. (Superior Ct. N. Y. City) 35 N. Y. S. Rep. 147.

Contributory Negligence.—The law is, that the employer is bound to furnish a reasonably safe place for the employe to work in, and must furnish such information as to dangers latent, or not apparent, as may reasonably put the employe on his guard. Where the locality or the appliance is dangerous, and the means of knowledge are equally within the knowledge of the employe and the employer, the latter is not obliged to take any greater care of the former than he (the employe) does of himself. In an action against a mining company, for injuries, it appeared that there was a walk, made several years before the accident, resting on timbers, and made in the usual way; that it is not customary to repair such walks; that the employe was an experienced timberman, and knew the planks were rotten; that he undertook to walk across one of such planks, when it broke, and he was injured; that it was not necessary for him to cross such plank; and that there were plenty of new planks to be had by him, by asking for them. Even though it should be held that the employer was negligent in not notifying him, or sending some one with him to warn him of the condition of the plank which broke, the evidence shows that the accident occurred through the negligence and rashness of the employe himself, directly contributing to the injury. He had all the knowledge which any one could have as to the general condition of the timbers, and of the probable rottenness or soundness of the planks by which he attempted to cross. The omission to take these ordinary precautions, under the circumstances, was an assumption of the risk involved, and the consequences cannot be thrown upon the employer. He knew that, if the plank happened to be decayed or defective, there was no custom of the employer, or of any mine, to repair it. He knew that he was thrown entirely upon his own discretion and judgment, and could expect nothing on account of any care on the part of the employer. The courts, without hesitation, in all cases like this, deny relief to the party injured.

A contrary rule would make the employer not only an insurer, but an insurer against the recklessness and carelessness of the employe himself.

Cook v. Bullion-Beck and Champion Min. Co. (Supreme Ct. of Utah.) 41 Pac. Rep. 557.

Construction of Mining Contract.—The owners of a mine, which was being worked by a party under an agreement that the ore extracted should be worked in a mill belonging to the mine owners, and the proceeds divided as follows: The mine owners were to be paid $25 per ton for milling; the party working the mine was then to be paid the expense of extracting the ore; and the balance was to be equally divided between him and the owners of the mine. It was held, that these parties were simply tenants in common of the ore and its proceeds, and no partnership existed between them.

Vietti v. Nesbitt. (Supreme Ct. of Nevada.) 41 Pac. Rep. 151.

Duty of Master to Furnish Safe Place to Work.—It is the duty of a mine owner to adopt all reasonable means and precautions to provide a safe place for a miner in which to prosecute his work. A miner engaged in running a tunnel in a mine, under the immediate supervision and direction of the foreman and manager of the mine, is not engaged in creating a place, on his own judgment, and at his own risk. He assumes the risks naturally attendant upon driving a tunnel. It is the duty of the mine owner to keep that part of the tunnel or place already created safe, by whatever reasonable means are necessary. If the miner is injured while in the actual work of drilling or blasting in the face of the tunnel he is driving, he may have no claim for damages; for these are risks he assumed as a miner. But he does not assume the risk of the mine owner's failure to keep that part of the tunnel or place already created reasonably safe and secure.

For instance: If a stone or material blasted or dug from the tunnel by the miner should have blown against, or should have fallen upon him, he would have no remedy against the mine owner for any injury sustained thereby. This is a risk belonging to his employment, and which he assumes. But he does not, by his employment as a miner in driving a tunnel, assume the risk of the failure of the mine owner to take such reasonable precautions as are requisite to prevent the caving and falling of the roof of that part of the tunnel already created, upon him, while engaged in his work. Nor does he assume the risk of the failure of the mine owner to keep the floor of the tunnel so free from rock and debris as not to materially hinder or obstruct his escape from his place of work, in case of accident, which might occur by premature or unexpected explosions of the dangerous materials he is using in his work. He assumes the risks incident to the work in front of him, and not the risks of the failure to properly care for that part of the tunnel or place behind him, which he has completed, and turned over to the care and control of the mine owner.

Kelly v. Fourth of July Min. Co. (Supreme Ct. of Montana.) 41 Pac. Rep. 273.

When Machinery Becomes a Part of the Reality.—Machinery placed in a building and fastened by bolts to a brick foundation thereby becomes a part of the reality, and, with the latter subject to an existing vendor's lien thereon.

Simpson, Hartwell & Stopple v. Masterson. (Court of Civil Appeals of Texas.) 31 S. W. Rep. 419.

Mining Liens.—The statute securing a lien on mining claims for labor performed thereon, does not authorize a lien for labor in working a mine on lands held under an agricultural patent from the United States.

Morse v. DeAdro. (Supreme Ct. of California.) 40 Pac. Rep. 1018.

Mining Partnership.—A partnership agreement to locate mining claims being within the statute of frauds, one partner cannot claim an interest in a claim located by another under an oral agreement that they should be partners in all such locations, when no trust arises because partnership capital was employed in locating the claim. The statute declares: "Sec. 55. No estate or interest in lands other than leases for a term not exceeding one year, nor any trust or power over or concerning lands, or in any manner relating thereto, shall hereafter be created, granted, assigned, surrendered or declared unless by act or operation of law, or by deed or conveyance, in writing, subscribed by the party creating, granting, assigning or declaring the same, or by his lawful agent, thereto authorized in writing." Equitable relief may be given against the partner holding the legal title when the property has been acquired by partnership capital upon the theory that a resultant trust exists, a trust arising by operation of law, and within the exception of the statute.

Craw v. Wilson. (Supreme Ct. of Nevada.) 40 Pac. Rep. 1076.

Construction of Mining Lease With Regard to Royalties.—A joint lease for mining purposes, executed by owners in severality of two adjoining tracts, provided that the lessee should pay as royalty a certain sum monthly to the lessors. One of the lessors subsequently conveyed his separate tract to the lessees. It was held that the remaining lessor was entitled to royalty thereafter in an amount equal to the value of his distinct tract as compared to that conveyed to the lessee. Where the lease provided that the lessee could extract asphaltum from any part of the leased premises, and the share of one lessor was subsequently conveyed to the lessee, it is no defense, in an action by the remaining lessor for royalties, that no asphaltum was taken from his separate tract. Under the statute providing that twenty hundredweight constitute a ton, the words "gross ton," as used in a mining lease as the basis for payment of royalties, means a ton of two thousand pounds. Under a mining lease of a "deposit of bituminous rock," and a "deposit of liquid asphaltum," providing that the lessee should pay a royalty "for each and every gross ton of bituminous rock and liquid asphaltum which he may have mined, taken, or removed" from said premises, the words "mined," "taken," or "removed" were used in the same sense and do not mean that a royalty shall be paid on the basis of the crude rock, or the refined product, after being shipped from the premises. In such a lease, a provision that the lessee should pay a certain royalty per ton on liquid asphalt, applies only to the asphalt taken from the the liquid deposit, and not to liquid asphalt taken from the crude rock.

Higgins v. California Petroleum and Asphalt Co. (Supreme Ct. of California.) 41 Pac. Rep. 1087.

What Constitutes Negligence in Case of Injury to an Employe.—In an action for personal injuries received while blasting rock, testimony was given by the superintendent of the work, that though he had never before had charge of dynamite blasting, he knew how it ought to be done. It was held that this did not show negligence in the selection of a superintendent. Where workmen were drilling a blasting hole, and a charge which one of them did not know was there exploded, he receiving injuries, the evidence showing that the employers had requested the workmen to commence work at five o'clock in the morning of the accident, had directed two men to manipulate the drill because it was too heavy for one, and had sent the workman in charge of the blasting to sharpen tools, supposing the charge in the hole had been exploded, personal negligence on the part of the employers is not shown. One whose duty it is to superintend blasting in a quarry, but who spends most of his time in attending to the fires under the boilers, in sharpening tools, and doing other acts of manual labor, is not a person whose sole or principal duty is that of superintendence, within the meaning of the statute relating to fellow servants.

O'Neal v. O'Leary. (Supreme Judicial Ct. of Massachusetts.) 41 N. E. Rep. 662.

Rights of Lower Riparian Owner.—If a mine owner places the refuse from his own mine on his own land, in a position from which it is washed into a creek by ordinary storms, and damage thereby results to a lower owner, he is liable. Thus, where, in an action by a lower riparian owner to recover for damages by the overflowing of a stream which flowed through another's mining lands it appeared that the water used by the upper owner in washing the coal passed through a trough constructed by him to a point from which it was discharged on his own land but from that point it passed into the stream thickly charged with coal grit, depositing a fine coal dust in the bed of the stream until it was filled to its banks, when it overflowed over the land of the lower owner to a depth of several feet, completely destroying the land and also growing timber, the upper owner was liable for the damages.

Hindson v. Markle. (Supreme Ct. of Pennsylvania.) 33 At. Rep. 74.

This department is intended for the use of those who wish to express their views, or ask, or answer, questions on any subject relating to mining. Correspondents need not hesitate to write for supposed want of ability. If the ideas are expressed, we will cheerfully make any corrections in composition that may be required. Communications should not be too lengthy, and personal criticisms should be carefully avoided.
All communications should be accompanied with the proper name and address of the writer—not necessarily for publication, but as a guarantee of good faith.
The Editor is not responsible for views expressed in this Department.
Correspondence should be in as simple language, and as free of technical terms and formulæ as possible, consistent with clear solution.
Questions on subjects not directly connected with mining will not be published.

A Fan Problem.

Editor Colliery Engineer and Metal Miner:

SIR:—I will be obliged if one of your readers will answer the following question for me, and before asking it I will take the liberty of explaining the conditions that have given rise to it. We had a fan 12 feet in diameter, which was run at 105 revolutions per minute, and produced a ventilation of 43,000 cubic feet of air per minute with .4 inch of water gauge. We have replaced the old fan with a new one, also 12 feet in diameter, and run at 105 revolutions per minute, but the water gauge is still .4, and yet the new fan gives an increased quantity of 60,000 cubic feet of air per minute, and this we think should have been done with an increased water gauge. I will therefore be glad to know what is the cause of the small gauge in the last question, for, I may say, the old fan was driven with an engine of 15 H. P., whereas the H. P. of the double engine for the new fan is 70. Yours truly,

JAMES HANN.

Ventilation.

Editor Colliery Engineer and Metal Miner:

SIR:—Will you kindly publish the following questions for answers in your valuable paper?

1. Two shafts 6 feet by 6 feet, each 1,000 feet deep, pass 45,000 cubic feet of air per minute. How much must they be enlarged to reduce the power required one-half?

2. In a certain mine there are 10,500 cubic feet of air per minute passing in an airway 5 feet by 6 feet and 2 miles long. Work was continued until the airway was 2½ miles in length, when a creep came on, which reduced the airway in area for 1 mile to 15 feet, or 5 by 3 feet, and for a further distance of one-half mile to an area of 10 feet, or 4 feet by 2½ feet. What quantity of air should then pass, the power remaining the same?

3. What action takes place when tobacco smoke comes into contact with marsh gas? I have seen a small quantity of marsh gas disappearing, or at least, I could not detect it with the safety lamp, after a small pipe of tobacco had been smoked in the place. No air current or other disturbance removed the gas.

Yours, etc.,

P. C.,

Dominion No. 1, C. B., Nova Scotia.

Jan. 6th, 1896.

To Find Any Root.

Editor Colliery Engineer and Metal Miner:

SIR:—I think the following method of extracting any root will be useful to many of your readers:

1. Let G be the number given and R the root to be found, and n the index.

2. Find by trial a number that is near the required root and represent it by r. Raise this number to the required power and represent this power by A. Then, as the sum of $n+1$ times A, and $n-1$ times G, is to the sum of $n+1$ times G, plus $n-1$ times A, so is r the trial root to R the true root.

For example, suppose in this case we require the fifth root of 9 or $\sqrt[5]{9}$.

By trial, we find 1.5 is too little, because raised to the fifth power it gives 7.59375, and 1.6 is too large because its fifth power is 10.4857; so we take 1.5 for r. Then, the correct root R can be found by compensation by the above rule, as follows:

$$[A\times(n+1)]+[G\times(n-1)]:[G\times(n+1)]+[A\times(n-1)]::r:R.$$

Substituting the values already obtained, we have

$$[7.59375\times(5+1)]+[9\times(5-1)]:[9\times(5+1)]+[7.59375\times(5-1)]::1.5:R,$$

or, reducing, 81.5625 : 84.375 :: 1.5 : 1.551724, the root required.

By the above formula any root can be found with near approximation.

Yours, etc.,

THOS. HANNAH,

Dunlo, Pa.

Pumping.

Editor Colliery Engineer and Metal Miner:

SIR:—I submit the following in reply to Assistant Superintendent, Nelsonville, Ohio, in the November issue of your valuable journal: "Will some correspondent please give a simple rule for determining the size of steam pump necessary to pump 30,000 gallons of water per day from a mine where the vertical lift is 100 yards. The steam pressure at the boilers on the surface averages 90 lbs. per sq. in. and the pipe which is covered with asbestos covering runs on the surface for 56 yds. then down the shaft 100 yds., and then 8 yds. to the pump? What size steam pipe and what size column pipe should be used? Also will a separator placed in the steam pipe near the pump permit of the use of a cheaper plant than if there is no separator?"

To compute the area of water cylinder or plunger,

$$\frac{N}{P\times G}\times 144 = A.\qquad \sqrt{\frac{A}{.7854}} = \text{diameter.}$$

N = Number of gallons to be pumped per minute. P = Piston speed in feet per minute. G = Gallons in a cubic foot. A = Area of cylinder in sq. in. In good practice the discharge pipe should not be less than .6 the diameter of the water cylinder or plunger, and the suction pipe should be ½ inch larger than the discharge for ordinary purposes. To determine the pressure in pounds necessary to overcome the friction of the discharge, Weisbach, gives us the following formula:

$$\left(.0144+\frac{.01746}{\sqrt{V}}\right)\times\frac{L}{D}\times\frac{V^2}{5.4} = H\times .434 = B = \text{pressure in lbs.}$$

H = Head in feet necessary to overcome the friction of the discharge pipe. L = Length of pipe in feet. D = Internal diameter of pipe in inches. V = Velocity of water in ft. per second. B = Pressure in lbs. necessary to overcome the friction of the discharge.

Having determined the value of B, or the pressure in lbs. necessary to overcome the friction of the discharge, the area of the steam cylinder can be computed in the following manner:

$$\frac{H\times P+B\times S}{E} = A.\qquad \sqrt{\frac{A}{.7854}} = \text{diameter.}$$

H = Height in ft. the water has to be pumped. P = Pressure per sq. in. due to vertical height of column which is equal to .434 lbs. for each foot in height. B = Pressure in lbs. due to friction of discharge. S = Sq. inches in water cylinder. E = Effective steam pressure which should be taken at ⅔ the boiler pressure. A = Area of cylinder in sq. inches. The diameter of the steam pipe should be .125 the diameter of the cylinder where the cylinder does not exceed 15″ in diameter, but where the cylinder exceeds 15″ in diameter the steam pipe should be .175 the diameter of the cylinder, and the exhaust pipe must be from ½″ to 1″ larger than the steam pipe. When computing the area of the respective cylinders, due allowance must be made for leakage, friction, etc.

For example, required the size steam pump necessary to deliver 30,000 gals. of water per day of 10 hours, from a mine 100 yds. deep. Boiler pressure 90 lbs. per sq. inch,

Ans. $\frac{30,000}{10\times 60}$ = 50 gals. per minute to be pumped; now make the piston speed 75 ft. per minute, then $\frac{50}{75\times 7.5}$ = .0888. Now if the pump gives an efficiency of 90 per cent., then $\frac{.0888\times 100}{90}$ = .0986 +,

.0986 × 144 = 14.1984 sq. in. area of water cylinder, $\frac{14.1984}{.7854}$ = 18.07, $\sqrt{18.07}$ = 4.25″ diameter, 4.25 × .6 = 2.55″ diameter of discharge pipe, 2.5 + .5 = 3″ diameter of suction. Now before we can determine the area of the steam cylinder, we must find the pressure in lbs. necessary to overcome the friction of the discharge, and in order to do this we must ascertain the velocity of discharge in ft. per second. Therefore, 2.5² : 4.25² :: 75 ft. : 216.75 ft., and $\frac{216.75}{60}$ = 3.61 + ft. per second velocity of discharge, and $\sqrt{3.61}$ = 1.9; then, $\frac{.01746}{1.9}$ = .00918 +, .00918 + .0144 = .02358, $\frac{160\times 3}{2.5}$ = 192 and 192 × .02358 = 4.52736, $\frac{3.61^2}{5.4} = \frac{13.0321}{5.4}$ = 2.413 +; 4.52736 × 2.413 = 10.92451968 feet, 10.9 × .434 = 4.73 + lbs., say 5 pounds. Now to find the area of the steam cylinder, $\frac{[(100\times 3\times .434)+5]\times 14.2}{60}$ = $\frac{2029.144}{60}$ = 50.48 sq. inches, and if the engine gives an efficiency of 75 %, then $\frac{50.48\times 100}{75}$ = 67.3 sq. in. area of steam cylinder, $\frac{67.3}{.7854}$ = 85.68, $\sqrt{85.68}$ = 9.25 in. diameter, 9.25 × .125 = 1.15625 in., say 1¼″ steam pipe, 1¼″ + ½″ = 1¾″ say a 2″ exhaust pipe. Therefore, a steam pump of the following dimensions will do the work required:

Water cylinder	4¼	inches in diameter
Discharge pipe	2½	" "
Suction pipe	3	" "
Steam cylinder	9¼	" "
Steam pipe	1¼	" "
Exhaust pipe	2	" "
Stroke	18	"

A separator is nothing more than a water trap, and will not permit of the use of a cheaper plant. But a good separator will add to the efficiency of the plant, furnish drier steam, and allow of better lubrication.

Yours, etc.,

YTNAC, Oskaloosa, Iowa.

Jan. 18th, 1896.

Air Compressors.

In this age of power transmission of compressed air, particularly in mining operations, any first class literature on air compressing machinery is of interest. The new catalogue of the Norwalk Iron Works Co., a copy of which is at hand, is a first-class text-book on compressed air and compressed air machinery, as well as a handsome catalogue. It is a well arranged and substantially bound volume of over 100 pages, and the matter contained in it will not only interest, but will prove of value to every mine manager and mining engineer. Copies are sent free, on application to The Norwalk Iron Works Co., South Norwalk, Conn.

PRIZE CONTEST.

Prizes Given for the Best Answers to Questions Relating to Mining.

For the best answer to each of the following questions, the value of $1.00 in any of the books in our book catalogue, or six months' subscription to THE COLLIERY ENGINEER AND METAL MINER.

For the second best answer to each question, the value of 50 cents in any of the books in our book catalogue, or three months' subscription to THE COLLIERY ENGINEER AND METAL MINER.

Both prizes for answers to the same question will not be awarded to any one person.

Conditions.

First—Competitors must be subscribers to THE COLLIERY ENGINEER AND METAL MINER.

Second—The name and address in full of the contestant must be signed to each answer, and each answer must be on a separate paper.

Third—Answers must be written in ink on one side of the paper only.

Fourth—"Competition contest" must be written on the envelope in which the answers are sent to us.

Fifth—One person may compete in all the questions.

Sixth—Our decision as to the merits of the answers shall be final.

Seventh—Answers must be mailed us not later than one month after publication.

Eighth—The publication of the answers and names of persons to whom the prizes are awarded shall be considered sufficient notification. Successful competitors are requested to notify us as soon as possible as to what disposal they wish to make of their prizes.

Competition Questions for February.

QUES. 205.—As we are determined to leave no stone unturned until we secure all the necessary facts for constructing a new lamp on correct principles, will you tell us how much the illuminating power of the light of a safety lamp is reduced in its passage through the glass cylinder that surrounds it? Base your calculations on the following thicknesses: $\frac{3}{16}$ inch, ¼ inch, $\frac{5}{16}$ inch.

QUES. 206.—We are constructing boilers for raising steam by the burning of bituminous coal in the State of Tennessee, and as we are going to manufacture fine white paper we wish to consume all the volatile matter and soot given off by the burning coal; will you, therefore tell us how this objectionable matter could be consumed, and thus increase our available energy instead of wasting it by allowing this combustible matter to escape? We do not want any plans or sections for the construction of a furnace, as we can do them ourselves when you supply us with the principle required for the burning of this waste carbon.

QUES. 207.—Our bituminous coal is of excellent caking quality, but the demand for coke is small and the price is low; the vein is tender and we make 40 per cent. of slack. We have a good market for household coals and I have recommended the manager of the company to make the slack into briquettes, and he replied, if you can furnish me with a successful plan for doing so, I will advise the company to raise your wages $50 a month. This being so, I will be obliged to you if you will assist me by supplying the following facts:

First—Which of the following materials will make, from a physical point of view, the best binder for the briquettes: Clay, hydraulic lime, Portland cement, asphaltum, pitch?

Second—Which binder gives the best appearance to the briquettes?

Third—Which binder is the best for its price and commercial advantages?

Fourth—What are the best forms and dimensions to give the briquettes?

Fifth—How are the briquettes made, and where are any briquette presses with their mixing appliances to be seen in the United States.

QUES. 208.—Where is asphaltum mined on the continents of North or South America? What are the characteristics of its physical and geological environment; that is to say, is it found in veins or in solution in oils? Has it any connection with salt lakes? Was its origin vital or chemical? And further, to what general uses is it applied? And what is its chemical composition?

QUES. 209.—By closely watching four men at work, namely, a, b, c, and d, we found that a and b could fill 65 tons of coal in 5 days; a and c could fill 84 tons in 7 days; a and d could fill 44 tons in 4 days; b and c could fill 135 tons in 9 days; b and d could fill 42 tons in 3 days; and that c and d could fill 78 tons in 6 days. Will you tell us, then, how many tons of coal each of the men, that is, a, b, c or d, separately can fill in one day?

QUES. 210.—A shaft for a coal mine has been sunk to a depth of 1,000 feet, and at a depth of 898 feet we tapped a feeder of water that shed 500 gallons per minute, and after an accident to the engine that caused the stoppage of the pumps, the water rose to a height in the shaft of 700 feet. The sectional area of the shaft is equal to 140 square feet, and I will be obliged if you will make a diagram to scale, showing by the ordinates the velocities of the inflowing water at eight equally distant points in the elevation, and while you are busy, please calculate for me the time required for the feeder to fill the shaft to a height of 700 feet.

Answers to Questions which Appeared in the December Issue, and for which Prizes Have Been Awarded.

QUES. 193. As we are trying to make our new patent safety lamp the best in use, we cannot be over careful in avoiding the errors that may spring from our own ignorance. Now there were two of the primitive lamps that were furnished with glass chimneys, and one had it set within the gauze cylinder, as in the Stephenson lamp, and the other had the chimney set over and outside of the gauze, as in the Jack lamp, and to make the use or intention of these glass chimneys so clear that we may discover any essential principle in them that should be incorporated in the structure of the new lamp, will you please explain to me four things?

First. What was the use of these glass cylinders in promoting safety?

Second. Did these glass chimneys increase or diminish the light from the lamp?

Third. Did these glass cylinders increase the motive column and make the lamp burn where other lamps would go out?

Fourth. Was the safety of the lamp increased or decreased when by accident the glass cylinder was broken?

ANS. First. The object of the glass cylinder was to act as a shield or bonnet and prevent the possibility of swift currents of air and gas blowing the flame through the meshes of the gauze.

Second. The glass chimney could not allow the passage of more than 60 per cent. of the light, and this was still further considerably reduced by the wire lines of the gauze.

Third. The glass cylinders no doubt increase the motive column in pure air, while in foul air they reduce it.

Fourth. The safety of the lamp was decreased below that of the standard of a Davy lamp, because the diameter of the Stephenson gauze was at least ½ an inch larger than that of the Davy, and as a consequence its contents of flame were greater.

WILLIAM GILLIE,
Grindstone P. O., Pa.

Second Prize, CHARLES E. BOWRON, Tracy City, Tenn.

QUES. 194. Before commencing to sink we are boring to find the thickness of the seams, and those of the intervening and overlying strata, and the general direction and amount of the dip. We have two good seams, and the top one *A*, according to the prevailing thicknesses east of us, should be 4.5 feet, and that of *B*, the lower seam 3.75 feet, and in addition we know that the thickness of the rocks between *A* and *B* should be 104 feet; but if the excited story of our master borer is to be believed, these thicknesses will be found to be quite different for the following reasons:

At 2 o'clock this morning our house door-bell rang most violently, and running to the stairs I shouted, "Who's there," when a voice replied, "It is me, the master borer from Hardrock," and he continued, "I bring good news, we have cut seam *B* with the bore tubes at 57 feet instead of 104 feet," and I said "Good, that will save the expense of boring the other 47 feet," but he replied, "That is a trifling consideration, and this is what you should know. The thin intervening rock indicates a thick seam, and instead of 3.75 feet, the *B* seam will most likely be 6 feet." Now this is good hope if it is not good news, and I will be obliged if you will tell me on what geological facts or principles the master borer founded his opinion. I may say that all the mines east of us are deeper to the *A* seam than we are.

ANS. The master borer founded his opinion on the facts of his experience supported by the teachings of geology, for he knew that the decreased thickness of the rocks between the seams *A* and *B*, at the western side of the field, proved that the vegetable deposit that originated the seam *B* was submerged on its eastern side before it had completed its thickness on the west where our royalty is situated, and it is known to all observing miners that when the covering rocks of an underlying seam are thick, the coal vein is sure to be thin, and *vice versa*.

WM. R. PRICE,
Chandler, Colo.

Second Prize, WILLIAM GILLIE, Grindstone P. O., Pa.

QUES. 195. Will you calculate for us the quantity of air in cubic feet per minute we will obtain with a 2 inch water gauge. The fan is 30 feet in diameter and runs with an angular velocity of 90 revolutions per minute, the diameter of the central orifice of intake is 12 feet, the area of the throat of the fan is 130 square feet, the area of the orifice of discharge is 60 square feet and the radial length of the blades is 9 feet.

ANS. The diameter of gyration will be $30 - 9 = 21$ feet, and therefore the mean velocity of the radial column in feet per second will be $\frac{21 \times 3.1416 \times 90}{60} = 98.96 = v$. The weight per square foot of section of the radial column will be $.0766 \times 9 = .6894$ of a pound; and the pressure due to the velocity will be $\frac{98.96^2 \times .6894}{3.1416 \times 32.16} = 66.87$ pounds $= T$. Then $\sqrt{\frac{(66.87 - 10.4) \times 1,800,000}{(2130 + 10.4^2)}} = 213.11$ is equal to the velocity of the air in feet per second rushing out of the smallest orifice, that is in this case equal to 60 square feet, and if we take the *vena contracta* at .62, the quantity will be $213.11 \times .62 \times 60 \times 60 = 475,664.5$ cubic feet of air per minute.

CHAS. E. BOWRON, Tracy City, Tenn.

Second Prize, DAVID P. BROWN, Dunbar, Fayette Co., Pa.

QUES. 196. We are passing 86,400 cubic feet of air per minute through an airway 10 feet high, 12 feet wide and 3,000 yards long with a water gauge of 3.29 inches, and as we do not now require such a large quantity for this district, we are going to reduce the supply with a regulator and pass instead only 36,000 cubic feet per minute, and we will be obliged to you if you will calculate for us the area required in square feet to pass the stated quantity through the regulator. Make the coefficient for the *vena contracta* .65, and the co-efficient of friction .00000001.

ANS. The pressure required to overcome the friction of the airway will be $\frac{36000^2 \times 3.29}{86400^2} = .57118$ of an inch of water gauge, and the effective pressure at the regulator will be $3.29 - .57118 = 2.71882$ in inches, and in pounds $2.71882 \times 5.2 = 14.137864$. The velocity in feet per second will be $\sqrt{\frac{14.137864 \times 1,800,000}{2120}} = 108.335$, and the area at the regulator will be $\frac{36,000}{108.335 \times 60 \times .65} = 8.52$ square feet.

ADOLPHE COOK, Houtzdale, Pa.

Second Prize, ALFRED C. BLAKE,
East Peoria, Tazwell Co., Ill.

QUES. 197. We have sold a conical heap of coals to three persons *A*, *B* and *C*, and to prevent injustice of any kind, we will be obliged for your assistance in furnishing us with the heights at which each purchaser will have obtained his correct weight. For example, the cone is 42 feet high, and the diameter of the base is 90 feet, and as a cubic foot of these broken coals weighs 53 pounds, will you first tell us what is the total weight of the heap, in tons of 2,240 pounds, and as each of these persons have paid for one-third of the weight of heap, we have arranged to surround the heap at the height you give us with a platform, so that *A* can only cut off the top of the cone to get his share, and then we will erect the platform to allow *B* to obtain his share, and the remainder will be *C*'s share. Now please tell us how high the platform should be set for *A*'s share to cut off a cone, and for *B*'s to cut off a frustum, and leave *C* his just share as the remaining frustum.

ANS. When the angles of the apices of two or more cones are equal, then their contents are directly proportionate to the cubes of their heights, and if *h* is taken as the height, or 42 feet in this case, we will see that the elevation of the platform for *A* to get his share must be $h - \sqrt[3]{\frac{h^3}{3}} = 42 - \sqrt[3]{\frac{42^3}{3}} = 42 - 29.12 = 12.88$ feet, and the elevation for *B* to get his share must be $h - \sqrt[3]{\frac{2h^3}{3}} = 42 - \sqrt[3]{\frac{42^3 \times 2}{3}} = 42 - 36.69 = 5.31$ feet, and therefore the remaining frustum will rest on the ground.

The weight of the heap of coals is

$$\frac{90 \times 90 \times .7854 \times 42 \times 53}{2240 \times 3} = 2107.3 \text{ tons.}$$

JOHN A. RAY,
P. O. box 376. Westville, Picton Co., Nova Scotia.

Second Prize, JOHN BEATTIE, Danville, Ill.

QUES. 198. Why is anthracite coal broken in pieces before it is sent to the market for sale and for use as fuel?

ANS. The prime necessity for the breaking of anthracite coal is its property of slow burning when in large pieces, for then the surface under combustion is relatively small, and when broken into proportionately small pieces the surface exposed for combustion is vastly increased. Bituminous coal does not require breaking because when burning it swells, cakes and cracks, and thus by the operation of heat it increases its own surface for the action of the fire, and makes the necessary passages for the required supply of air, whereas anthracite coal only burns on its planes of fracture, and yields no pitch for binding it into cinder, and does not generate sufficient volatile matter to shatter it and make air channels through the mass.

WILLIAM HIBBS, Scio, O.

Second Prize, CHAS. E. BOWRON, Tracy City, Tenn.

The Action of Electric Currents on Mine-Surveying Instruments.

(By W. Lenz.)

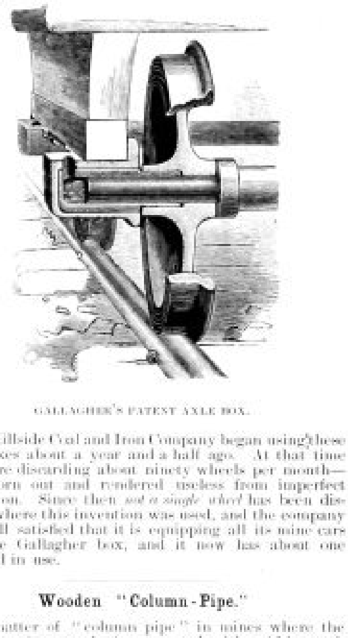
(Abstracted from *Glückauf* for the Institution of Civil Engineers, Great Britain.)

In view of the rapid increase in the number of electric railways in the Westphalian coal field and in the use of electric power under ground, the question of the action of electric currents on magnetic mine-surveying instruments is of such great interest that the author has been induced to conduct a series of experiments. A point, underground, was selected at a horizontal distance of some 100 yards from the rails of the Bochum-Herne electric railway, and 434 m (1,420 ft.) below it. There, by means of a Fennel's magnetometer with quartz fibre suspension, a series of observations of variation were made based on a fixed line. The magnetometer was previously compared for a long period with the apparatus in the Bochum Town Park, and the two instruments were found to coincide almost exactly. The first observation, in September, 1895, was made by day, the second by night, when the line was free from current, and the last again by day. Whilst the curve of the day results exhibited great irregularities, that of the night results was perfectly regular and in accord with the magnetic records. The irregularities in quite small intervals of time amounted from 2·7 minutes to 5·4 minutes. As at first it was thought that the deviations might be ascribed to the iron-free safety lamps employed, a third observation was made in the morning, the lighting being effected by a stearine candle. The results were exactly the same as on the first day. As the observations were made at a comparatively large distance from other workings, and as the shaft was 200 yards away, it is evident that magnetic observations can, under such conditions, be only satisfactorily conducted during the night in the absence of the magnetic current. Another source of error is the safety lamp. Composed of various metals, the lamp in a hot condition sets up thermo-electric currents which act on the magnetic needle. In order to obtain information on this point, the author placed six mine surveyors' safety lamps free from iron, one at a time, first in a cold condition then heated, at the pole of a sensitive magnetometer. Of the six lamps examined, two, when cold, had no action on the needle, whilst all acted on it when hot. The deviations observed amounted to from 30 seconds to 160 seconds. A new benzine lamp, that had not previously been used, caused a deviation of as much as five minutes. The deviation increased with the temperature of the lamp. A quite new aluminum safety lamp caused the same deviation when cold as when hot. From these results it follows that the mine surveyor, before making magnetic observations with delicate instruments, should carefully test his lamp. The influence of slight magnetic properties may be lessened by holding the light in the prolongation of the magnetic axis. With side lighting great care is necessary.

Mine Cars.

The Forest City Car and Manufacturing Company of Forest City, Pa., is a new manufacturing concern located in the northern part of the Northern Anthracite Coal Field. This company has recently completed new shops, equipped with the latest and most approved appliances for the manufacture of mine cars, mine car wheels, axles, etc., and the officers claim to produce first-class mine cars, wheels, etc., at very low prices.

As a specialty, this company manufactures the P. F. Gallagher patent axle box. This is a new, simple and inexpensive device for oiling mine cars, which has proven its merit in nearly two years' practical service. It does not waste oil, and cannot get out of order.



GALLAGHER'S PATENT AXLE BOX.

The Hillside Coal and Iron Company began using these axle boxes about a year and a half ago. At that time they were discarding about ninety wheels per month—hubs worn out and rendered useless from imperfect lubrication. Since then *not a single wheel* has been discarded where this invention was used, and the company is so well satisfied that it is equipping all its mine cars with the Gallagher box, and it now has about one thousand in use.

Wooden "Column-Pipe."

The matter of "column pipe" in mines where the mine water is strongly impregnated with acid is a serious one to many mine managers. To meet such conditions, Ayrault Bros & Co., Tonawanda, N. Y., (whose advertisement appears elsewhere in this issue) manufacture the coated wooden pipe shown in the accompanying

WOODEN "COLUMN-PIPE."

illustration. The construction of this pipe is so clearly shown in the engraving as not to need any detailed description. This pipe is made of various degrees of strength (according to the metal banding used) up to that sufficient to work under 240 feet head, which will cover most cases of mining service. It will pay mine managers who have serious cases of pipe corrosion on hand to communicate with the makers of this pipe.

A Good Rope Record.

The crucible steel cable tramway rope supplied by Messrs. George Cradock & Co., of Wakefield, for the Brixton Hill line of the London Tramways Company, in 1893, was removed in November last, after having been at work for 853 days at a speed of 8 miles per hour. The total rope-miles were 123,120, and the car-miles 1,791,233. The rope in question was Lang's lay. It was 30,000 ft. long and 3½ in. in circumference when new, and ¼ in. less when removed. The cost of the rope per car-mile was .1698 *d*.—*Engineering*, London.

Messrs. Cradock & Co. furnish their make of ropes to American users through Mr. T. A. Wigham, 513 First National Bank Building, Chicago, Ill.

REMOVAL.

The New York office of the Rand Drill Co. has been removed from No. 23 Park Place to the American Surety Building, No. 100 Broadway.

THE COLLIERY ENGINEER

AND

METAL MINER.

WITH WHICH IS COMBINED THE MINING HERALD.

Established 1881. Incorporated 1890.

PUBLISHED MONTHLY AT SCRANTON, PA.

Entered at the Post-Office at Scranton, Pa., as second-class matter.

THOS. J. FOSTER, }
RUFUS J. FOSTER, MINING ENGINEER, } EDITORS.

THE COLLIERY ENGINEER COMPANY, PUBLISHERS.

DENVER OFFICE, 502 Boston Building:
PROF. ARTHUR LAKES, Assist. Editor in Charge.

TERMS.

Subscription, (Postage in the U. S., Canada, or Mexico, prepaid.) **$2.00 a Year.**

To Foreign Countries in the Universal Postal Union, $2.50.

Remit by P. O. Order, Express Money Order, Bank Check or Draft or Registered Letter.

P. O. Orders.—You can buy a Money Order at your Post-Office payable at the Scranton Post-Office.

Express Money Orders can be obtained at any office of the American Express Company, the United States Express Company, and the Wells, Fargo & Co.'s Express Company.

Registered Letters.—If a Money Order Post-Office, or an Express Office is not within your reach, your Postmaster will register the letter you wish to send us on payment of eight cents.

We Cannot Be Responsible for money sent in letters in any other way than by one of the four ways mentioned above.

EXPIRATION OF SUBSCRIPTION.

The date after your name on the wrapper of THE COLLIERY ENGINEER AND METAL MINER shows to what time your subscription has been paid.

RENEWALS, ETC.

If you do not want THE COLLIERY ENGINEER AND METAL MINER continued for another year after your subscription has run out, notify us by postal card to discontinue it. The courts have decided that subscribers to newspapers who do not order their paper discontinued at the expiration of the time for which it has been paid, are held liable for the payment of their subscriptions up to the date when they order the paper discontinued.

NOTICE OF DISCONTINUANCE.

THE COLLIERY ENGINEER AND METAL MINER is sent to subscribers until an explicit order for its discontinuance is received by us, and all payment of arrearages is made, as required by law. *Papers returned are no notice of discontinuance, as we cannot tell where they are from.*

CHANGES OF ADDRESS.

A subscriber wishing to have his address changed should be careful to give his *former* as well as his present address; otherwise we cannot find his name on our mailing list.

All communications should be addressed,

WEAR ON HAULAGE ROPES.

EVERY mine manager knows that the most destructive agency in the wearing of haulage ropes is the sawing of the rope over pulleys which fail to revolve, or over pulleys that are worn unequally and fail to revolve as quickly as they should. The latter class of pulleys sometimes remain stationary with their thicker and heavier sides down, until they are cut through by the constant friction of the passing rope. This naturally wears the rope rapidly, and the friction increases the pull or strain on it.

A roller has been extensively adopted at British mines that seems to have largely remedied this fault. This roller is corrugated or grooved along its entire length, and practice has shown that each groove in the rope gets a fairly equal amount of usage, according to the limit of curvature of the track. The roller is made of rolled and stamped wrought iron or steel, well balanced and true. They can be made of equal thickness, a quality which cannot always be acquired in a cast iron roller. These rollers are said to revolve almost at the instant that they are touched by the moving rope, and they acquire a greater grip or hold than the flat surface rollers, owing to the clinging form of the grooves. Every man who has had any experience with rope haulage has frequently noticed the tendency of the rope to run in the groove worn on an original flat surface roller, or to slide to the flange of a new flat surface roller. This tendency is taken advantage of in the rollers constructed with grooves or corrugations, and excellent results in greater life for ropes are reported. The idea seems to be a rational one and is worthy a trial.

A DENVER OFFICE.

WE have opened an office for THE COLLIERY ENGINEER AND METAL MINER, in Room 502, Boston Building, Denver, Colo. It is in charge of Prof. Arthur Lakes, assistant editor. Subscriptions, etc., will be received at that office, as well as at the main offices in Scranton.

AN ENGINEERS' CLUB IN CHICAGO.

THE tendency for men of one profession, or of allied professions to meet together socially has resulted in a number of instances in the formation of technical clubs.

These clubs are practically first class European plan hotels and restaurants, the accommodations of which are limited to members, or to friends of members. As a rule, they are equipped with libraries and reading rooms that appeal to the tastes of the men composing the club.

There is a movement on foot to establish such a club, to include in its membership members of the various engineering professions only, in the city of Chicago. The indications are that the club will be a success. It will consist of resident and non-resident members. The initiation fee and dues have been fixed at very moderate figures. The gentlemen connected with the organization of the club have received acceptances from nearly enough engineers who will enroll as members to warrant us in saying that success seems assured. It is a good movement, and deserves the support of every engineer residing in Chicago, or who is a frequent visitor to that city.

CARBON MONOXIDE AS AN EXPLOSIVE AGENT.

A THEORY advanced by Prof. Lewes, of London, if correct, furnishes an explanation as to the cause of many mysterious mine explosions. The poisonous effect of carbon monoxide or "white damp" has been recognized by miners for years, but its explosive characteristic has not been commented on because it was universally supposed that its poisonous effect was made apparent before a sufficient quantity of the gas to make, with the air, an explosive mixture could accumulate.

In commenting on ordinary black powder as an unsuitable explosive in gaseous or dusty mines, Prof. Lewes calls attention to the fact that carbon monoxide is the one resulting constituent of its explosion. It has been conclusively proved that when fire-damp is present in such minute quantities as to form a mixture very far removed from the point of explosion, under ordinary circumstances, it does form, when coal dust floats in the air, a highly explosive mixture. He states that traces of carbon monoxide will do exactly the same thing when the air is laden with coal dust. Besides, the temperature necessary to ignite a mixture of carbon monoxide and dust laden air is lower than that required to ignite a mixture of fire-damp and dust laden air. Prof. Lewes, therefore, concludes that when the air of a mine is charged with coal dust the probabilities are that a very large volume of explosive mixture is formed by the rapid escape of the products of combustion into the dust laden air, and this (being ignited either by the flame or by red-hot solid products driven out into it by a blown-out shot) initiates a considerable area of explosion.

FREE MINING LECTURES.

THE Department of Mining of the Pennsylvania State College, offers to deliver a series of free lectures to mine employes, *at their customary places of assembly*, on the following subjects: The Care of Explosives, The Danger of Safety Lamps, The Cause of Mine Explosions, Propping and Pack Walls, and Wasting Energy at Labor.

These are all interesting and important subjects, and the opportunity given to Pennsylvania miners to hear instructive lectures from competent men should be taken advantage of generally. All that is necessary to secure this advantageous offer is for the miners of each locality to secure a suitable room and arrange for an audience, the State College will furnish the lecturer.

FAILURE IN MINING.

THE very common cause of failure in mining is lack of good mine management. Very often the mine itself is blamed, and wrongfully blamed. As an evidence that successful mines are not always those that produce the highest grade ores we quote the following from the report of the Director of the Geological Survey of the United States:

"In the history of the California mines, a number of claims, like the Cederberg, Chariot, and others, which yielded very rich gold specimens, such as are worked into jewelry and souvenirs, have been very disappointing; while on the other hand, the ore of many of the famous and most productive mines, hardly ever contains gold sufficiently coarse to be seen by the naked eye. The vast low grade auriferous deposits of Dakota, which have been so remunerative, had an average yield in 1880 of only $6.33 per ton. Very many large mines, both in California and Dakota, have been worked at a good profit on ore which carried much less gold."

Commenting on "Waste in Mining" our contemporary, *The Australian Mining Standard*, pointedly states this frequent cause of failure in the following statement:

"Bad management takes such a multitude of shapes that it is almost impossible to describe it, unless it be described in the general term 'ignorance of mining.' Its most common form is seen in the wastage of ore. A general proof of the fact is found in the hundreds of dumps which have been hand-sorted over and over at a profit. There is an old saying that 'a good workman can be known by his chips,' and with equal truth it can be said that 'a bad mine manager can be known by his dumps.' One thing that is indispensable in a manager is an appreciation of the necessity of thoroughly understanding the nature and value of his ore. He may not be able to understand that ore himself, but if he appreciates its importance, he can employ someone who does understand it to take charge of necessary work.

"The world sees the evidence of waste in the dumps that lie in the daylight, but there is a still greater source of waste that is hidden from the public in the dark stopes of the mine. Every practical man knows how often the ore is knocked down in the stopes, and there partially sorted, and the supposed waste left upon the stulls. If ore sorted by daylight loses much of its value in the waste, what is the loss liable to be in the dark, narrow and cramped stopes? Who that is competent to hand-sort ore gives, in the great majority of instances, any attention to this portion of the work? As a rule the miner is allowed to have his own sweet will in this labor, and his own sweet will is too often to do that which is easiest, instead of that which is best, even if he knows what is best.

"This is but one kind of waste, and the commonest one of bad management, where scores might be mentioned. To the man who understands it, the lack of assayers and assay offices, at individual mines, often suggests a doubt about the quality of the management. It is not all mines that require the constant services of an assayer, but a good many more than receive them do require them, and would find them the most valuable of all possible investments."

A Suggestion to Advertisers.

A well known concern manufacturing mine equipment begins, in this issue, a series of advertisements which will, in time, form a fair illustrated catalogue of their manufactures rather than a repetition of an illustrated business card with which most advertisers content themselves.

This innovation, though it involves more work and expense on the part of the publishers, we welcome. We would be glad to see the plan followed by all of our advertisers whose manufactures are such as to make it possible. Buyers, at the mines, like other men, buy those goods with which they are most familiar, other things being equal. There is no way in which makers of the various lines of mining goods can easier familiarize prospective customers with their manufactures than through advertising in THE COLLIERY ENGINEER AND METAL MINER.

If instead of, or at least supplementary to, the claims as to the merits of the goods, there appears in the advertisement a clear illustration of some machine or appliance made by the advertiser with a concise note appended stating the size, capacity, where in use in mining service, working conditions, etc., we feel safe in assuring our patrons of more careful attention to their advertisements than they could otherwise obtain. We know from expressions we have had from advertisers and subscribers that in few trade journals are advertisements as closely scanned as are those in each issue of this journal, but that is no reason for allowing advertisements to "run themselves."

It is worth while to spend time and money in the preparation of advertising matter in a paper which really brings returns, while it is a waste of both time and money to put good advertisements in poor papers. There is no reason why the advertiser should not give the same careful attention to the preparation and placing of his advertising matter that he does to other items of expense, such as traveling salesmens' salaries, or the preparation of catalogues.

To express the matter in the tersest manner, we would simply say a good advertising medium can be made a better one, if the advertiser will give the preparation of his advertisement careful thought.

Book Review.

COKE. A Treatise on the Manufacture of Coke and the Saving of By-Products. — *With special references to the Methods and Ovens Best Adapted to the Production of Good Coke from the Various American Coals.* By John Fulton, E. M., Member Am. Inst. Min. Engrs., Am. Philosoph. Soc., etc., etc. Large 8vo. 342 pages. Profusely illustrated. Cloth. Published by The Colliery Engineer Co., Scranton, Pa. Price, postpaid to any part of the world, $4.00.

The manufacture of coke in the United States began in a feeble way, with four small establishments, in the year 1850.

During the thirty years following, its progress was rather slow, but from 1880 to 1892 it made rapid advances, showing in the latter year 261 establishments, using 42,002 coke ovens and producing 12,010,829 tons of coke, valued at $23,536,141 at the ovens.

In the year 1869 the use of coke in blast furnaces outranked that of charcoal, and in 1875 surpassed anthracite coal.

Since the latter date it may be said that we have fully entered into the era of coke.

It is also evident that this coke fuel is destined to retain this leading place of usefulness in metallurgical operations, and its increase is destined to accompany the expansion of the iron and steel industries.

In considering the present condition and future requirements of the coke-making industry, with its paramount value in the manufacture of iron and steel, it appeared that a volume embracing the principles and practice of the manufacture of coke would prove of permanent value to those engaged in these co-related industries.

Its publication is regarded as the more needful at this time, on account of the efforts being made to introduce the modern types of retort coke ovens, with their auxilliary apparatus for saving the chief by-products, of tar and sulphate of ammonia, from the gases expelled in coking, and thus supplement the profits in the coke industry.

In the United States, the manufacture of coke has hitherto been confined mainly to localities affording the best qualities of coking coals.

It required little skill to make excellent coke from such good coals. But with the large expansion of the production of coke, and the gradual exhaustion of the areas of the prime coking coals, compelling the use of the secondary qualities of coking coals, a thorough study of the merits of the several kinds of coke ovens now being offered, is regarded of the most important interest.

In this volume, the papers on the manufacture of coke, which have been published in The Colliery Engineer and Metal Miner, have been recast and carefully revised. They exhibit the several methods of coking, with accurate results, for the consideration of those interested in this industry.

The author feels that very much remains to be learned in this department of industrial art; but trusts that this initial volume will suggest matter that will lead to an accelerated advance in useful knowledge along the several sections embraced in its pages.

The work has been undertaken with a feeling of the difficulty of doing it the justice its importance deserves, but in this respect the author trusts that some truth has been gleaned under the conditions of the old adage that "necessity is the parent of invention."

In the twenty years' experience of the author, in his official position of general mining engineer and general manager of the Cambria Iron Company, he has been required to study the manufacture of coke in its elements of quality and cost. The extensive operations of this company in the different sections of the Appalachian coal region, by several methods of coking, afforded desirable opportunities for investigation and for the comparison of results.

In the year 1875, the coke made at the works at Johnstown, in Belgian coke ovens, failed to meet the furnace requirements. The management requested an investigation of the cause or causes of the inefficiency of this fuel in blast furnace work.

It appeared at first an easy task to ascertain the nature of the defect or defects in this coke. It was assumed that a chemical analysis would disclose the whole matter; but, contrary to expectation, it did not; it showed the coke to be very pure, with much less ash than the Connellsville, and with marked exemptness from other injurious elements. The result compelled an expansion of the method of investigation, as the chemical method alone would not reveal the cause.

A study to devise a method for the physical examination of the coke was then entered upon, which, after many trials, resulted in developing a plan that disclosed the main cause of the failure of this coke for blast furnace use—its want of the principal requirement, "hardness of body."

From the softness of the body of this coke, much of it was wasted in the upper section of the blast furnace, by dissolution in the bath of the ascending carbon dioxide gas, thus lowering the temperature at the zone of fusion, and disarranging the regular operations of the workings of the furnace.

These early methods of testing the physical properties of coke were very crude and open to criticism, but the urgency of necessity, it is believed, has ultimately disclosed accurate methods of determining the true value of coke for metallurgical uses, the practical results in furnace work sustaining the reliability of these determinations.

It has become evident in the manufacture of coke from the secondary qualities of coking coals, that from the nature of the requirements of quick and high oven heat to secure the hardest bodied coke possible from such coal, the retort type of coke ovens will have to be used. It is confidently hoped that the plans and statements of the actual work of these retort ovens, with and without apparatus for the saving of by-products, will prove helpful in enabling the coke manufacturer to make intelligent selection and application of the special type of oven best adapted to assure the best coke from the coal used in its manufacture. Very much care has been given to the consideration of the best modern methods in the preparation of coals for coking, especially in the processes of crushing and washing, with the elimination of slates and pyrites.

The work is divided into nine chapters and an appendix. Chapter I. is devoted to the coal fields of the United States, their geographical position, extent, analysis, etc., etc. Chapter II. is devoted to the physical and chemical properties of coal, and the subjects are carefully, intelligently and exhaustively handled. Chapter III. is devoted to the preparation of coals for the manufacture of coke, and describes and illustrates all the latest and most approved apparatus for crushing, sizing and washing. Chapter IV. is devoted to coking in the open air, or in partially closed ovens of the beehive type. Chapter V. is devoted to the consideration of the various retort and by-product saving ovens. All types are described and illustrated, their merits and demerits discussed, and their successful application to various coals is treated on. Chapter VI. treats on the physical properties of the three principal fuels used in metallurgical operations, viz: charcoal, anthracite coal and coke. Chapter VII. is devoted to the consideration of laboratory methods of determining the relative calorific values of metallurgical fuels. Chapter VIII. is a consideration of the location of coke plants in the most convenient and economical manner. Chapter IX. consists of general conclusions on the work, cost and products of the several types of coke ovens. The appendix contains several consular reports on various systems of coking, tables of comparative tests, descriptions of new devices obtained too late for insertion in the body of the book, etc., etc., together with an official report of extended tests recently made in coking with Semet-Solvay ovens by Mr. Fulton for the Johnson Iron Co., and published by special permission of A. J. Moxham, Esq., President.

Throughout the work Mr. Fulton has realized that he was writing for practical men, and as a result, the volume is the only complete work on the subject ever issued. It is up to date in every particular, and is written in an exceedingly plain, concise manner.

MANUAL OF LITHOLOGY: Treating of the Principles of the Science, *with Special Reference to Megascopic Analysis.* Second Edition; by Edward H. Williams, Jr., E. M., F. G. S. A., Prof. of Mining Engineering and Geology, Lehigh University. 8 vo. Cloth. 418 Pages, illustrated by six full page plates. Price $3.00. Published by John Wiley & Sons, New York, and Chapman & Hall, Ltd., London. Prof. Williams' preface to this edition explains the nature and scope of the work so plainly and concisely that we give it almost in its entirety. "The microscope has forced lithology and petrography so widely apart that the layman is often at a loss to recognize old acquaintances under new names. This edition of lithology is written on the same basis as the last—for the beginner in the subject who wishes a thorough knowledge of the megascopic presentation of the subject, in a fuller and more compact arrangement than can be obtained in geological text books. It is also designed for the engineer who wishes to understand the valuation of rocks for economic purposes. The arrangement is such that those who wish to continue the work in the microscopic analysis of rock-forming minerals, as taught in petrography, will have nothing to unlearn. The reader is supposed to have a practical acquaintance with megascopic crystallography and mineralogy, the use of the blow-pipe, and the ordinary methods of chemical analysis, so that these subjects are merely touched upon in the description of the more common megascopic rock-forming minerals. An addition has been made in the line of the economic value of rocks, and the body of the book has been entirely rewritten, and is from five to six times the size of the former edition, so rapidly has the subject grown." Prof. Williams is one of the most practical and learned technical instructors in America, and in preparing this work he has carried out his usual plan of treating the subject in the most practical manner. As he states, by inference, the book is not specially written for men of very limited education, but rather as a text book and book of reference for mineralogical and geological students who have attained a certain standard of education. At the same time, each subject is so presented as to make it a useful book for men of comparatively limited education. It is arranged, and each subject classified in a very convenient and intelligible manner.

The Use of Metal Railroad Ties, and Preservative Processes and Metal Tie-Plates for Wooden Ties. By E. E. Russell Tratman, A. M., Am. Soc. C. E.; prepared under the direction of B. E. Fernow, Chief of Division of Forestry, and issued as a report by the U. S. Dept. of Agriculture. This is a very exhaustive and complete report on inventions, methods and appliances produced both in this country and Europe, by means of which the consumption of timber for railroad ties may be materially reduced either by the substitution of metal ties, or by appliances and treatments to wooden ties to prolong their life. The work is an exceedingly valuable one, as its object is to assist in preventing the rapid destruction of American forests. It shows that since 1890 the substitution of metal for wood in railroad ties has progressed steadily, until now more than 35,000 miles, or about 20% of the railroad mileage of the world, outside of the United States and Canada, is laid on metal. Although progress in this direction in America has been slow, it will be a question of but a short time till the waning of forest supplies will force on railroad companies the use of metal ties, and these, it is claimed, will insure greater efficiency, safety and final economy. In the meanwhile, preservative processes, such as creosoting, etc., and metal tie-plates may be applied to wooden ties with advantage, and this will no doubt help postpone the time when the metal tie, more expensive in first cost, will be adopted.

Personals.

Mr. Edgar G. Tuttle, mining and civil engineer, has opened an office at 221 Pearl street, New York City.

Mr. James G. Bateman, formerly inside foreman of the Albright Colliery of the Albright Coal Co., of Silverton, Pa., has been promoted to the superintendency of that company, succeeding Mr. James Archbald, jr., who becomes acting president.

Mr. Bateman was one of the first mine foreman to fight an extensive mine fire by the *direct* system successfully. An account of this fire appeared in the report of the state mine inspector for 1885, as well as in The Colliery Engineer (Mining Herald).

Following the promotion of Mr. Bateman, Mr. Charles F. Long becomes inside foreman and Mr. Charles J. Price, at present fire-boss, assumes the duties of night foreman.

Messrs. Long and Price are both students in the Correspondence School of Mines. All four are and have been for years, readers of The Colliery Engineer and Metal Miner.

Mr. A. W. K. Pierce, electrical engineer, resigned his position with The Correspondence School of Electricity, of the International Correspondence Schools, to accept a responsible position as an electrical engineer in the South African mining fields.

Mr. James P. Dickson has resigned as President of the Dickson Mfg. Co. of Scranton, after an incumbency of the office for nearly twelve years. Mr. Dickson has been succeeded by Mr. Charles H. Zehnder, who for the past three years was president of the Jackson & Woodin Co. of Berwick, Pa.

Mr. Thomas F. Downing of St. Clair, Pa., formerly assistant inside foreman at the Beechwood Colliery of the Philadelphia and Reading Coal and Iron Co., has been promoted to the position of inside foreman and will have charge of the Glendower and Taylorsville Collieries of the same company.

Mr. Downing has been a hard student and by merit alone has risen to his present responsible position. As a candidate for state mine inspector in 1894, Mr. Downing passed an excellent examination and demonstrated his ability both in the theory and practice of coal mining.

Messrs. George Mair and F. C. Whitmore, in charge of the General Electric Co.'s branch office in Scranton, have closed the Scranton office. Mr. Mair resigned his position with the General Electric Co., to accept a lucrative appointment in South Africa, and Mr. Whitmore, who continues with the General Electric Co., will make his headquarters at the Phila. office, No. 509 Arch street.

The Board of Examiners to examine candidates for State Coal Mine Inspectors for the State of Washington, completed its labors on the 16th ult. Messrs. David Edmunds of District No. 1, and Joseph James of District No. 2, were recommended for reappointment. Messrs. Edmunds and James have been readers of The Colliery Engineer and Metal Miner for years, and Mr. James is a student in The Correspondence School of Mines. His record as a student shows him to be a close student and a man of ability. He is well advanced in the course, in fact has almost completed it.

Messrs. Frank G. Clemens and H. W. Althouse have opened offices as mining engineers at Pottsville, Pa. Both gentlemen have had a number of years experience as engineers for prominent mining companies, Mr. Clemens having been for many years connected with the Lehigh Valley Coal Co. as an engineer, and lately with the Midvalley Coal Co., as superintendent of their extensive operations. Mr. Althouse was connected with the engineering department of the Phila. & Reading Coal and Iron Co. for several years, and later with the Consolidated Coal Co. of St. Louis, and other western and southern coal companies.

Mining Machinery.

To many of our readers, the name of Mr. Robert Allison as a builder of mining machinery is very familiar. After having to a large extent withdrawn from the business of manufacturing mining machinery for several years he has again assumed the direct management of his Franklin Iron Works, and in an advertisement in this issue solicits business in the line of hoisting and haulage engines, air compressors, pumps and mining machinery generally.

Mr. Allison's well known ability as a mechanical engineer and inventor, and the reputation of the work turned out at his shops in the past, guarantees that his customers will get machinery fully up the highest standard. He reports orders for a pair of 24″x60″ first motion hoisting engines 8 ft. drums, from the South, two pairs of large duplex air compressors from the Connellsville region, a lot of hydraulic cylinders for elevators, and sufficient smaller orders to keep his shops running full time. A new catalogue, which he has just issued, will be sent free to any mine owner or mine manager.

THE PROGRESS IN MINING.

Abstracts From the Proceedings of the Mining Societies

And Journals of Europe and America, Illustrating the More Modern Developments in all Branches of the Mining Industry.

WESTERN PENNSYLVANIA CENTRAL MINING INSTITUTE.—A meeting of the members of this Institute was held at Pittsburgh, Pa., on Thursday, December 26, 1895, under the Presidency of Mr. T. K. Adams, Mine Inspector, and after the Secretary, Mr. Seddon, had read the minutes of the last meeting, and they were approved, the President then read his annual address.

He began by making an apology for intruding with a sharply defined question of duty instead of with an interesting novelty, and drew attention to the by-laws and aim and object of the Institute "and the dangers that menace it, and our duty as members thereto." "We are solicitous that nothing shall occur to mar the prosperity of the Institute, impede its progress, destroy its usefulness, or threaten its unity, peace and harmony.

After advising the members not to allow the intrusion in their meetings of matters foreign to their interests and the aims of the Institute, he drew attention to the provisions of the by-laws such as:

"The object of this Institute shall be the mutual improvement of its members in the science of chemistry, geology, steam, hydraulics, hydrostatics, mechanics, mine surveying, and other branches of science directly or indirectly connected with mining," and further "To aid and advocate in legislative bodies such laws as will be beneficial to the practice of mining, and to advocate the repeal of all laws detrimental to the interests of mining and the health and safety of the miners." Again, "Or such other matters as shall be agreed upon, but all such matters shall be in relation to the sciences directly connected with mines and mining." The President then proceeds to draw attention to the fact that their time has been wasted by cunning advertisers who strive to monopolize the attention of the members at the meetings with their wares and schemes, to the exclusion of such subjects as are sanctioned by the by-laws for investigation, and he says: "See to it, therefore, that these grand aims and and objects of our association are not perverted by allowing it to become the advertising and endorsing agency for the wares and schemes of selfish men."

This last paragraph furnishes the key-note of the President's address, and it is no doubt true that this institution in common with others in this and other coal regions of the world, is subject to these incursions of traders who damage their own cause by trying to force their wares on unwilling patrons and buyers. Altogether the speech is that of a brave, earnest and worthy president.

Mr. T. B. De Armit, in moving a vote of thanks to the President for his able address, endorsed the carrying out of the by-laws of the Institute, and he was supported by Inspector Jenkins, who thought the address and remarks were timely, and the vote being put to the meeting by Mr. T. B. De Armit it was unanimously received.

The President then called on Mr. Callaghan for his paper on stoppings.

* * *

STOPPINGS.—By Mr. Bernard Callaghan, Connellsville, Pa. Mr. Callaghan's paper treats on a very important subject, and aims at directing attention to a matter of prime importance, affecting as it may do the safety of life, and the prevention of great destruction of property. The writer begins by referring to the provisions of the mine law for the construction of the main stoppings in a mine; that is, they shall be built of suitable materials and be satisfactory to the mine inspector.

The general interpretation of this law is practised by building brick or stone stoppings, with the joints made close with mortar, so that they are strong enough to resist all normal pressures, and tight enough to prevent leakage.

Mr. Callaghan, however, points out that in the event of an explosion these solid stoppings would be all broached and destroyed, but being so strong, the force of the blast would extend to the shafts and do incalculable mischief, while on its journey there, it would draw out the timbers and break up the roof; and he points out what many practical men know, that when these brick stoppings are destroyed, current ventilation is impossible, and consequently the rescue of those living in the interior of the mine is prevented by the after-damp. He proposes the general use of hanging-door stoppings to act as relief valves, and therefore they will open by the pressure generated by the explosion, and so relieve the compression by diffusion, that comparatively little damage will be done, and the ventilation will be at once restored and the after-damp carried off with the normal return current. Mr. Callaghan's views are not only good, but we may say they are in actual use partially in England, for by act of parliament it is provided that relief doors or valves shall be placed over the outlet of every upcast shaft that is connected with a fan drift, to open and give relief to save the fan in the event of an explosion, and close after the force of the blast has expended itself. Again, T. E. Hall, Esq., superintendent of the Haswell and Ryhope collieries, England, is the holder of a patent right for the construction of doors in the floors of crossings, to lift and turn on hinges, and thus give relief to the blast of an explosion, and fall and close to restore the ventilation after the force of the explosion is over. But the act of parliament and the patent for crossing doors are only the same in character, but not the same in kind, as Mr. Callaghan's stoppings, and as he takes the wider view of providing a more copious relief, he deserves at any rate more than a passing notice, first, for his valuable practical paper, and second, for introducing to the notice of mine engineers the valve stoppings put in use by Mr. James Jackson in the Valley mine. The construction and mode of action of these door stoppings is as follows: The door is hung like the end gate of a mine car, and leans against a frame securely fixed, and the door is made air tight at the closure with canvass sheeting, so that these stoppings are practically as good in preventing leakage as the stone or brick ones. We hope no explosions will occur to test the automatic action of these door valves, but they are a provision that deserves the highest commendation, and are well worthy of being put to a practical test by an experimental explosion in an extemporized drift.

After the reading of Mr. Callaghan's paper, Mr. Stinner said that he hardly believed that door stoppings could withstand the force of an explosion, and he would rather make the rock stoppings stronger. Mr. Clifford, M. E., of Pittsburg, said that in cases of explosions it was always found that the most disastrous results occurred where the stoppings were not moved and the blast was confined, and he believed that door stoppings could be made to open and not be destroyed. Messrs. Connor and Hall then took sides with Mr. Stinner, and Messrs. Rigby and Britt took sides with Messrs. Callaghan and Clifford. After the reading of a report by a committee appointed to make some tests with ventilating fans, a paper on endless rope haulage was read and discussed, and then the president *pro tem.* called on Mr. Blick to open a discussion on the prevailing system of working the Pittsburg seam, but as he pleaded that his views were well known, the president then called on Mr. Hartley, who in a few well selected words went straight to the weak point, and showed that the present system of working was wasteful and required to be remedied, and he was supported by other speakers.

The following paper was prepared to be read at the meeting:

* * *

THE USE OF ELECTRIC MACHINERY IN COAL MINING.—By Mr. L. L. Brande. This paper is highly characteristic of the innovations of the time we live in, and the claims of the writer strongly emphasize the use of electric appliances in all the operations in mines where power is applied to do work. He claims that transmitted electrical energy secures greater efficiency and economy and thereby considerably enhances the profits of the mine operators.

The strong points in the paper may be summarized as follows:

First—Seeing that the loss by transmission of the current is so small, it may be neglected in the gross result, and therefore the power may be applied through a motor directly at the points where it is wanted, and that may be for pumping, drilling, coal cutting, and hauling, in the most distant nooks of the mine.

Second—As electrical transmission has advanced beyond the speculative and experimental period, its reliability and relative efficiency and economy is now undoubted, and stands within the compass of numerical values that can be calculated with certainty.

Third—As the principles of action of electric plants are now so well understood, the generators, cables and motors are constructed to secure durability with few repairs.

Fourth—Only one prime source of power is required to generate the current for lighting and for the multifarious motors that are located just where the work is required to be done.

Fifth—For undercutting coal the electric cutter does the work in one-half the time, and effects a saving of from 10 to 12 cents a ton.

Sixth—Mr. Brande gives his experience of eight months at the Nos. 2 and 3 mines of the Essen Coal Co., Hazletine, Pa., and the plant at these mines consists entirely of "Independent" electric machinery. The prime steam power is equal to 200 H. P. and these engines are used to drive three 150 kilowatt generators. There is always one engine and one generator kept in reserve. The three generators have had nothing done to them since last May save cleaning the commutator occasionally, and the oil in the bearings has been changed only once.

Seventh—Two electric locomotives are used for haulage, and each of them is capable of hauling 1,000 tons per day. They are giving excellent satisfaction. On a nearly level track the longest train hauled in No. 3 mine was 64 bank cars, each carrying from 25 to 30 cwt. In No. 2 mine the longest train was 38 bank cars, the grade varying from 1% to 2%. The lengths of the hauls were 3,600 and 4,200 feet.

Eighth—All the important partings and tipples of these mines are furnished with the electric light, and each motor has a headlight.

In conclusion, Mr. Brande predicts: "That the time will soon come when the price of coal will be based on the output of machine mines," and then operators will find their interests best served by using, wherever and whenever they can, these labor and time saving and profit-making appliances.

* * *

COLLIERY EXPLOSIONS PRODUCED BY COAL DUST.—The following is taken from the *Colliery Guardian*: Mr. Stuart's argument, that every colliery explosion in which coal dust plays a part is made up of a multitudinous number of distillations and explosions, will best serve the purpose of illustration if we quote the Udston explosion, which is one of the explosions referred to by Mr. Stuart in his last book. Certainly no other explosion of which we have the fullest details exhibits such strong evidence of instantaneous action, and personally I have always quoted the indications of this accident as more nearly approaching those afforded by detonation than of any other form of explosion with which we are acquainted. A few days since Mr. Dickinson (late her Majesty's inspector of mines), and who specially reported on this disaster, when writing to me in reference to the effects of sudden compression of the ventilating air-current in mines, called my attention to what he then reported on this subject. "The evidence showed that the main roads were the most dusty part of the mine, and not the rooms. It was, however, in the rooms not cut through and least dusty that there were the greatest signs of coking, extending not quite up to the face, and not in the main roads, some of the principal coking being in the rooms which were not at work.

"As regards the air being impregnated with fire damp, and an explosion being spread over a wide area by pressure, we (Messrs. Dickinson and Maconochie) would refer to a paper read before the Manchester Geological Society by Dr. Angus Smith, late chief inspector of alkali works, in which he described an apparatus (which he also exhibited to the society), by which he then thought that the mixture of small quantities of fire damp in atmospheric air might be detected by percussion. Soon afterwards, however, an improved instrument of the same nature, made by Mr. Dancer, optician, proved that the same result could be arrived at by the pressure of ordinary air without gas, on the principle of lighting tinder by percussion. This would afford a more likely solution of the widespread nature of the present explosion, with the force coming towards the shafts from different extremities, than that afforded by the supposition that it was the dust alone that carried the flame throughout the workings, especially in the dook, which it would have to enter quietly first, and then return, leaving the indications of the force outwards. The pressure of air, both in the dook and Blantyre sections, had been so strong as to draw every shred of clothing off some of the bodies, and to tear up tram roads there and elsewhere.

Now, referring to the Tinsbury explosion it would be interesting to know how either flame or heat were kept alive, when the distance from the shot to No. 1 explosion is stated to be 191 yards, and the total number of explosions 18, spread over a distance of 2,614 yards.

In the Camerton explosion, the explosion traveled against the air current, but at Tinsbury the reverse way. How does Mr. Stuart account for this fact?

Another of Mr. Stuart's arguments requires a great deal of elucidation, for he argues that because after the explosion at Clifton Hall in 1885, at Llanerch in 1890, and at Spring Hill, in Nova Scotia, in 1891, the lamps burned in the after damp, that, therefore, the explosions could not have been caused by fire damp. This is certainly a very strong statement and we ought to know what did originate Clifton Hall and Llanerch, if it were not fire damp. As far as the Spring Hill disaster is concerned I can quote from a letter received only a few weeks since from my friend. W. H. S. Poole, of the Acadia Coal Company Limited, referring to this very disaster in the following words "The presence of gas was known, precautions were taken, but they turned out insufficient."

* * *

WHAT ARE THE CAUSES OF MINE EXPLOSIONS.—By Mr. Thos. Hall, Van Meter, Pa. This paper was read before the Western Pennsylvania Central Mining Institute at the December meeting.

Mr. Hall classes the causes of mine explosions under three heads, as

1st.—The use of open lights;

2nd.—The use of defective safety lamps;

3rd.—Shot firing.

The paper noticed the fact that is common to all human conduct, namely, that no steps were taken either in Europe or America to prevent the recurrence of explosions in mines, until the great sacrifice of life cried for prompt attention, and he averred that the amended mine laws of Western Pennsylvania, if fully adhered to, were as good a common sense remedy for the prevention of explosions, as is known. The remarks on defective safety lamps are important, being those evidently, of a prudent, practical man. Mr. Hall says that notwithstanding all the supposed improvements in safety lamps, there remains with us still the old Clanny lamp with his "*new coat*," meaning the bonnet, as seen in the bonneted Clanny or Marsaut, and he thinks it is likely to remain until the electrician displaces it, but he urges that the chief shortcomings of the bonneted Clanny, arise when its use is abused, for he says that neither a man nor a lamp should be allowed in explosive mixtures of gas and air, and even where sudden outbursts of gas may be expected he thinks the self-extinguishing lamps afford the required safety, but the best remedy of all is, not to be satisfied with the minimum ventilation allowed by the law, but to provide a quantity of air sufficiently copious to carry off gas as quickly as it is given off and to dilute it below the ignitible point.

Mr. Hall's remarks on shot firing are excellent, and for point and pungency they are the best we have heard. He says that marsh gas can be removed by a swift current of air, but the danger from coal dust *increases*, instead of diminishing with the speed of the current, and this is the whole matter in a nut shell, and what is true of swift air currents he urges is equally true of powerful explosives, as dynamite contrasted with gunpowder. But he emphasizes the dangers due to the heat developed by black powder in exploding. The paper further urges that practical men ought to provide for increased safety in the mines of Western Pennsylvania, for in working the deeper seams, increased temperatures and greater dryness are sure to be the natural concomitants of increased dust in the air currents of the mines.

The comments on this paper were very interesting and some pertinent questions were asked and answers given by Mr. Hall and others.

MINE MAPS.—By Mr. Ben W. Robinson, M. E. The following is an extract from an article in the Eleventh Annual Report of the Inspector of Mines of the State of Kentucky, 1894, and it is well worthy of special attention:

A good, accurate, carefully made mine map will many times repay the operator for the outlay attached to keeping it in such a way that it accurately represents the workings from month to month, and from year to year.

The map should be a basis from which to make all estimates, such as materials for tracks, timber, drainage and ventilation. It shows how much coal has been taken from a certain block or tract, and how much has been left in pillars. It should be a basis from which to locate all new workings, pumps, hauling machinery, ditches, crossings, air-ways, brattices, doors, and ventilating machinery.

A full and complete map of the surface should be made before the pick of the workman comes on the ground. The boundary lines of the tract should be accurately located, and a convenient base line permanently marked. This map should be filled in with all important details, showing railroads, public and private roads, houses, fences, streams, lines of outcrop of measures, general direction of hills and valleys, and all permanent objects which shall serve as landmarks for future reference. Elevation of all prominent points above a certain datum should be plainly marked.

The underground map should be a complete representation of the works, just as they are. It should show all shafts, all openings to the surface, all haulage lines, ditches and water crossings, faults, brattices, doors, pumps, engines and machinery; should show all places which are worked out, and those working; should show where pillars have been drawn, and where left standing.

All elevations of principal points, such as entry crossings, sumps, etc., should be plainly marked thereon at the proper point. Also, height and character of the roof should be noted.

In connection with the map, there should be kept a profile, showing in detail the levels on the principal entries, grades of existing tracks, water-ways, etc.

I want to say that accuracy is, above all, of the most importance in a mine map. An inaccurate, carelessly made map is not worth the paper that contains it. It is an incorrect basis for estimates, conveys but a general idea of the workings, and, if depended upon for the location of boundary lines, is a producer of endless litigation.

The importance of accurate maps increases as the workings become more extensive and the problems of mining more intricate. The map should be kept co-extensive with the workings, as the parts of a mine which are abandoned soon become inaccessible, and the chain of record is broken.

In making a map, neatness is a desirable feature. While I do not believe in putting any extra flourishes on them, such as delicate shading or elaborate lettering, and while I know that a map of mine workings does not, at best, appeal to the artistic eye, still I think we should have due regard to the workmanship which we put on them. The one idea to maintain constantly in view is to make the map answer its purpose in as simple a manner as possible, avoiding all lines and marks which are not essential to that purpose. Engineers themselves are too prone to place a low standard upon their own work.

Tunnel surveying has reached an almost incredible accuracy, owing to improved instruments, improved methods, and especially to the high standard which is expected for such work; and should not the practice of mine engineering also demand a high standard? A mistake in the alignment of a tunnel would cause financial loss, but a mistake in a mine survey might even cause a loss of life.

The engineering instruments of to-day are being brought to a high state of perfection, which is simply to meet the demand being made by the engineering profession. No workman is able to turn out a creditable piece of work without good tools and of the proper kind.

A good survey cannot be made with a Jacob-staff and a surveyor's chain. These may have answered the purpose for which they were designed, but they have no place in mine work.

It excites our mirth, and also our pity, to see some of the antiquated instruments which comprise the engineering outfit at some of our mines. Good guess work and a good guesser could accomplish equally as good results as could be arrived at by the use of these instruments. Yet, no doubt the manager congratulates himself that he has left nothing to be desired when he becomes the proud possessor of these same instruments.

It is not necessary to enter into a discussion of how a survey should be made, as each engineer probably has a method of his own. Given a good set of instruments, plenty of time, good assistance, encouragement to do his part well, and any engineer who has not mistaken his calling will do creditable work.

It should not be forgotten that permanent monuments, whose positions are shown on the map, should be established. From data supplied with these monuments, every point in the mine should be quickly found, not only after a few years have elapsed, but in years after, when others have taken charge in our places.

When our map is complete it should be a perfect representation of the underground workings. Not only should the engineer make accurate surveys of the work as it progresses, but he should see that the workings are made in the right direction. He should endeavor to educate the miner, the mine boss, and all who have any part in the direction of the work, for this is an absolute necessity, and he should cause them to take not only an interest, but a pride in it.

Finally, the engineer's note book should be regarded as a valuable piece of property, to be taken care of and preserved, and it should be his constant aim to make it so. The notes of all surveys should be classified and indexed, so that any particular point may be quickly found. We should endeavor to leave our business in such a shape that should death call us, or should we move to new fields of labor, another could take up our work where we left it.

* * *

THE LIMITATION OR LOCALIZATION OF COLLIERY EXPLOSIONS.—By James Ashworth, M. E. Taken from the *Colliery Guardian*. One of the most noticeable features in connection with colliery explosions is the vast area of workings and great length of roadway affected by the flame of the explosion. Official reports, even when considered in connection with a plan of the workings, convey no adequate impression of the vastness and completeness of these disasters excepting to those who have actually seen the effects underground. No effect that is ever seen on the surface of the earth, excepting only that of lightning, can in any way convey to the human mind an idea of the enormous power exerted and expended in a very few moments; and it is only by transforming the underground roadways through the mind's eye into some familiar length of turnpike with its many branch roads, that it is at all possible to imagine what sort of force must have been at work to cause a flame to traverse so far without being naturally extinguished by the cooling surface exposed to the flame. Thus, at the Albion Colliery in a very few seconds of time seventeen and a quarter miles of roadway and 4,041 yards of working face, or a total length of 30,000 yards, were devastated, human beings dismembered, doors, trams and other materials smashed into matchwood—and all because our science and engineering have not provided us with an effective restraining agency at the point of origin.

The effects produced have in many cases been so sudden and so unexplainable, that our scientific knowledge of the causes and chemical reactions affecting this subject have been unable to afford a lucid explanation, and they have often been seriously attributed to lightning striking the pit and traversing the roadways—for instance, at Risca in 1880, where every life below ground was lost (120), and at Elemore in 1886, where the flame was seen to pass from a higher to a lower mine down the shaft.

That some means should be discovered by which these accidents can be limited or localized is most desirable, and that the want is universally acknowledged no one will deny, more particularly as the tendency of present-day management is to lessen the cost of coal-getting by increasing the output from one pair of shafts, and therefore to add to the already large number of work-people engaged on each shift. The safety of the whole mine is dependent on the strength of its weakest part, and therefore we cannot say, after the practical demonstration afforded by the Albion Colliery explosion, that the division of a mine into separate districts is any effective safeguard.

What, then, are the palliative measures which are available? First and foremost of these is the total abolition of blasting with gunpowder or any other of the flame-producing explosives, and, in fact, of all explosives which depend for their safety on something which is not incorporated in the explosive itself, such as water-cartridges and flame-quenching mixtures; secondly, the use of water in the form of sprays for damping the intake air-current of the mine, wetting the floor, etc., where shots are to be fired; and lastly, by wet lengths of roadway.

Of all these means the strongest official support and approval have been bestowed on the use of flameless explosives and some form of water-spraying apparatus, although the latter have not as yet been tested by the experience of actual explosion nor yet by any experimental research, excepting by the Prussian Commission. Thus we find ourselves totally without proof of their utility or any justification for the dependence which is now being placed on their efficiency to arrest an explosive flame or to localize the latent forces it is necessary to keep under absolute control.

To show how impotent water-sprays are to effect any localization of explosive effects, it is only necessary to refer to information which has been before us for some considerable length of time. Professor Dixon, who was an active member of the late Royal Commission on Explosions from Coaldust, read a paper before the Federated Institute of Mining Engineers on the rate of explosion in gases, and he there says: "In the detonation of carbonic oxide in a long tube, the oxidation is effected indirectly by means of steam, as it is in the ordinary combustion of the gas. Measurements of the rate of explosion of carbonic oxide and oxygen in a long tube showed that the rate increased as steam was added to the dry mixture, until a maximum velocity was attained when between 5 and 6 % of steam was present." Quoting from Berthelot, carbonic oxide is not combustible when mixed with dry air or with dry oxygen, as may be readily shown by experiment. A jet of carbonic oxide, burning in ordinary moist air, is at once extinguished if a cylinder filled with dry air is brought over the flame.

Only a few weeks ago there was published a most interesting and instructive paper on "Humidity and Temperature Observations at the Maybach Colliery, near Saarbrucken," and the conclusions arrived at are of such great practical importance that no excuse is needed for the reproduction of some of the conclusions arrived at. The temperature of the air-current at the working faces was only lowered 1° Cent. by the spraying.

"It has been observed that moistening the coal dust in deep workings was calculated to diminish the temperature considerably and continuously, and that the danger of fire-damp ignition would be greatly diminished, because it is well known the inflammability of fire-damp, and also the severity of the explosion, increases in direct proportion to the mine temperature. Now, however, that only a temporary cooling of the air is found to be effected by the spraying, it would appear that too great importance has been attached to this practice. In order to determine the action of damp air-currents on coal dust accumulations, samples of coal dust were taken from various places in the field of working, and their humidity found to vary between 2.05 and 3.65 per cent. According to the conclusions of the Prussian Fire-damp Commission, the capacity for explosion of coal dust is only removed when it has taken up 50 per cent. of its weight in water. If it be reflected that the coal dust experimented upon only contained 3.64 per cent. of water at the outside, although it was always subjected to the influence of very damp air-currents, the result follows that even in the dampest mine atmosphere the dangerous property of coal dust is not eliminated.

"It is, therefore, perfectly clear that all methods for rendering coal dust harmless by the artificial introduction of water into the entering air-current are absolutely worthless in practice."

The practical experience of Mr. Martin, of Dowlais, quoted in the Coal Dust Commissioners' report, does not show up the value of spraying in any better light than the practical results obtained at the Maybach Colliery; thus, the reduction of temperature was only 2° F., and there was as much aqueous vapor (7.3 grains per cubic foot) in the air at the working face when the sprays were not at work as when they were at work.

It would seem, with the above facts in view, that it is of the very greatest importance that all the facts bearing on this subject, which affects the daily safety of thousands of miners and a vast capital expenditure, should be taken in hand for collection and collation by some recognized body of mining engineers, such as the Federated Institute of Mining Engineers.

One branch of this subject has already been introduced to the North of England Institute of Mining and Mechanical Engineers in a short paper written by Mr. Simon Tate, of Trimdon Grange, entitled "Saving of Life from Afterdamp: Smoke or Fumes in Mines," which was read at the general meeting at Newcastle-on-Tyne on the 13th of October, 1894. This paper was well received, and although the suggestions thrown out were shown to be impracticable in application to old mines, yet it was allowed that they were applicable to new mines.

In exemplification of the class of useful facts which occur to the writer as bearing on this subject the following have been selected:

At the Albion Colliery no effects of the explosion, excepting afterdamp, were found in the Pantddu dip. It is suggested that this was in consequence of its wet state, but those who saw the place at the time did not consider it very wet, and as the Bodwenarth incline, which is nearly opposite, and is also wet for some considerable distance, did not escape from the full effects there seems to be something here worth careful investigation. One difference observed by the writer is that there are stables at the top of Pantddu and not in Bodwenarth.

That the position of stables may have some influence in arresting the flame effects of a colliery explosion seems to be borne out by the escape of the New East haulage road at Altofts, where the stables are at the top of the road. This is a very remarkable instance, because the top of this road was in a direct line with the West chain road, were the disaster originated, and within a very short distance of where the haulage engine was smashed up, and from which point the flame afterwards traversed the entire length of the No. 1 chain road.

At Elemore there were stables near the Dale Way haulage road, and the flame did not traverse these workings, one man and one boy escaping unharmed; also in the George Hutton seam there were stables near the main road, and seven men escaped unharmed.

It has also been proved on many occasions that a thoroughly wet length of road will arrest the flame of an explosion and limit it to the district in which it originated, as, for instance, at Hyde in 1889, at Apedale in 1891, and at Albion in 1894, and it would appear to be the only practical means of limiting or localizing an explosion at the present time, unless we admit the case of the blown-out shot disaster in the Black Mine at the Ashton Moss Colliery in 1891, where the only restraining influence was the excessive dryness of the mine.

After an explosion the greatest loss of life is caused by the disarrangement of the ventilating air current, and, as a consequence, the non-dilution and escape of the gases produced by the action of the explosive flame and its residual heat. These, if quickly removed or diluted by fresh air, would save the lives of the majority, but unfortunately, as the ventilation of the mine is stagnated by the destruction of doors and air-crossings, the only chance of rescue for those in distant parts of the mine is to build themselves in and depend on the air thus bottled up to sustain them until found by the rescue party.

It has, however, occurred to the writer that a much better plan than this would be to put into operation a remedy which may be said to have stood the test of a very severe explosion, and which suggested itself from an incident of the exploration after the Swaithe Main explosion. A carpenter's assistant had gone down the pit shortly before the explosion, and as neither he nor his body had been found, it was surmised that he might be under one of the heavy falls, and a lookout was kept for any signs of a saw, a hammer, or strips of wood. One party of explorers in passing through an opening found a door completely smashed, and a little farther along another door shut and not in the least injured. On opening this door a saw was found just inside, and many yards up the heading the body of the man. It appeared, therefore, that at the precise moment of the explosion the man had the door wide open, and that the same force which smashed the first door threw him on to his face many yards through the second doorway, and that the door had then quietly closed behind him. Probably this small incident would have been the means of saving a great many lives in the boundary bord, had not an air-crossing close by been completely destroyed. This incident proves that if we provide a door which is always standing open between two or more closed doors, and so arranged that the smashing of one of these will close it, there is no secondary force which will disturb it, and the air-current will automatically, and after only a very temporary disarrangement, revert into its proper direction. Thus, men who would succumb for want of a little fresh air might be revived, and the time which always elapses between the moment of an explosion and the arrival of a rescuing party will not prove so fatal as it has done in past time. If, in addition to this precaution, all important air-crossings are constructed in the solid strata (as at Albion, where all of this class stood firm), all permanent stoppings made of brickwork backed by dirt or rock, and with wet lengths of roadway at important junctions, we shall be better fortified against the possibility of a huge disaster than we are at the present moment.

There is doubtless something important still to discover to show why roads which are not haulage roads are almost universally exempt from being traversed by the flame of an explosion, and it can only be by the closest observation of hygrometrical, electrical, chemical and other differences that any lucid light can be thrown on this exception, and the writer would therefore commend this part of the subject as being also well worthy of the earnest attention of all mining institutes.

* * *

CONCENTRIC ELECTRIC WIRING SYSTEM FOR MINES.—At the opening meeting of the present session of the Institution of Electrical Engineers Mr. S. Mavor read a paper descriptive of of "Concentric Wiring" for electric light installations. The following is an abstract of the details of the system and its applicability to mining work, taken from the *Colliery Guardian*:

The method of concentric wiring is based upon a full recognition of the fact that electric light wiring, in order to be permanently durable and reliable, must be impervious to moisture. The main switch board has the usual single-pole switch and fuse arrangement, and the board is surrounded by the negative omnibus bar, which receives in sockets attached to it the outer conductors and sheathings of the concentric cables. The main cables, which are lead-sheathed throughout, and are generally armored with galvanized iron wires laid over the lead on a cushion of jute, are carried without break or joint direct to their respective distributing boxes, where the central conductors are soldered to the omnibus bars, and the outer conductors terminate in gun-metal sockets secured to the boxes. The distributing boxes are of cast iron or cast brass, enameled white inside, and fitted with fuses, or switches and fuses, as required. These boxes have close backs and hinged fronts closing upon an india rubber ring, thus rendering them proof against dust or moisture. The concentric branch cables which radiate from these boxes are under all ordinary circumstances of uniform section—namely, 7/21½—equal in area to 0.005 square inch. The outer conductor of the cable has the same section of copper as the core, and the whole is enclosed in a solid-drawn tube of lead. Whenever a joint is to be made, or the cable led into a switch or fitting base, the center wire is soldered to its contacts, and the outer conductor and its lead sheathing are received and terminate in a jointing pocket cast upon the switch-box or junction. The central wire and its insulation are thus enclosed throughout their length in a hermetically sealed metallic sheathing. The section of the branch conductor 0.005 square inch is carried into every switch and into every lampholder, no reduction being made. There is no necessity for any fuses other than those in the cast iron fuse-boxes, and these are all uniform and interchangeable. It is very rarely that occasion requires any departure from this plan. Many large installations have been carried out on the lines indicated, some of these amounting to several thousands of lamps, where only two sizes of fuses—main and branch, respectively uniform and interchangeable—have been used. The simplicity and reliability of such a system must be too obvious for emphasis.

The branch cables are led through buildings like flexible gas pipes, but they are not liable to damage as composition gas pipes are. The conductors and the insulation within the lead sheathing serve as a backing for the lead, so that it is not at all easily damaged.

In support of the claim that this method of wiring is reliably waterproof, the case of Messrs. Nobel's Explosives Company's West Quarter Factory may be cited. The buildings to be lighted are isolated and scattered over a large area in order to reduce the risk and minimize the effect of explosions. The regulations issued by the Home Office regarding electric lighting were so very stringent that it was impracticable to comply with them except by the use of concentric wiring. With concentric wiring everything was made easy. Its waterproof and fireproof properties overcame all the difficulties. Every joint and every yard of the conductors is outside and exposed to the weather, cleated for the most part to the gangways. The switches, of cast brass, and distributing boxes, of cast iron, are also all outside, protected only by water-sheds. The work of wiring was completed more than three years ago, and, notwithstanding three years' exposure to the elements in this climate, the insulation resistance is as high as ever. Monthly tests of the insulation are required by the Home Office, and on the 10th of October the insulation resistance was two and a-half times higher than the most stringent of the fire office rules require for indoor wiring. In the nitrating department of the same factory, which is a quarter of a mile distant from the other installation, the insulation is equally satisfactory, although the wiring is subjected to the profuse fumes of nitric acid. It is noteworthy that the insulation of the wiring at both these places is not india rubber, but is fibrous. The exclusion of moisture is therefore solely due to the lead sheathing and waterproof nature of the joints.

For mining work, concentric wiring is specially adapted. The mechanical nature of the fittings, and the ease with which they and the conductors may be made waterproof, are important features. A concentric cable for mining purposes is more safe than two separate cables. A fall of material from the roof may rupture one of two conductors, and if current is passing, the inevitable result is a spark at the point of parting. In fiery mines this might have serious consequences. With a concentric conductor, however, the fall would crush the outer conductor in upon the core, and so cause a dead short-circuit and melt the fuse before the cable parted. The spark would thus take place at the fuse at the pit bank. In the only case of such accident within the writer's experience the fuse did promptly melt. Several devices have been proposed for the purpose of preventing a spark at the point of rupture of cables used in pit work. There is room for doubt as to the liklihood of these devices performing their functions in case of need. There can be no question that the concentric cable is much more simple, and it is probably more reliable than any of them. Further, none of these arrangements afford to the miner the immunity from personal danger from shock which the concentric cable does. An E. M. F. of 500 volts is frequently used for such work, and it is usually considered that such a pressure, although sufficient to give a disagreeable shock, is not dangerous to life. That this feeling of security is not well founded is unfortunately proved by recent fatal accidents. For power transmission in mines an ideally safe system is furnished by concentric cables with earthed sheathing, and switches, fuses and other appliances enclosed in cast iron cases, also earthed, and, if need be, enclosed-type motors with their castings earthed.

* * *

GERMAN TRADE AT HOME.—Taken from *Kuhlow's German Trade Review and Exporter.* At the general meeting of the Society Versuchs-und Lehranstalt fur Brauerei in Berlin, Goslich read a paper on this subject, the most important details of which are here reproduced. A large quantity of brown coal, appraised at some 200,000 tons per annum, is consumed in the breweries of Berlin alone, and another 80,000 tons or so in other industries, but up to the present the earthy brown coals found in Anhalt, Saxony and the Lausitz district have only been available for use in step-grates, on account of their high (50 to 60) percentage of water, in crude state, and the increased expense of carriage due to this cause. To remedy this it has been proposed to first dry the coal and then, in order to prevent loss in the shape of dust, and render the coal suitable for use in ordinary grates and furnaces, to compress it. This pressed coal has begun to compete with the Bohemian brown coal, but the blocks are unfortunately very badly made, a condition due both to the nature of the raw material and the method of manipulation. The coal is obtained from surface workings and pits, the former when the circumstances are favorable—*i. e.*, when the cover earth can be cheaply removed—and in these cases the coal, having been exposed to but slight pressure by the small amount of overlay, is not so compact as that obtained at greater depths. Furthermore, this surface coal is generally impregnated to a depth of a couple of yards with sand and other matters forming dross and ash when burned, and, consequently, when these upper layers are not kept separate from the lower a more drossy and ashy product is obtained than if the latter were used alone; wherefore pit coal must be considered as better than surface coal.

The value of compressed coal also depends on the way it has been treated in the manufacturing processes of drying and pressing. The first-named operation is carried out in kilns, either flat or cylindrical—the latter for choice, as giving better results, since the more completely the drying is effected, the less water remains behind, and consequently, the greater is the pressure required to form the coal into a cohesive mass. Only, therefore, those collieries that possess sufficiently powerful machinery for the production of the necessary enormous pressure can carry on the drying process very far, and these work at about 1,500 atmospheres pressure. The older works, where the manufacture of blocks has been established for some considerable time, being without such machinery, and disinclined to discard what they have, are constrained to leave a comparatively large amount of water in their coal to be able to produce the compressed article at all.

There is no product or manufactured article exhibiting such variations in price, or with which the public is so deceived, as compressed coal, both as regards quality and quantity. There are some works where only surface coal is manipulated, and only an inferior article is produced; in others, again, half surface and half pit coal is used, whereby a better quality product is turned out; and, again, there are some where only best pit coal is used, and consequently, the best article, commanding a good price, is made. The latter have their own trade marks, which are, however, imitated as closely as possible by the manufacturers of inferior goods, so that it is very difficult for the consumer to find out which is the best. Another practice, opening a wide door for deception, is that of making blocks of different sizes—some makes will go 35,000, while others are only 18,000, to the wagon load—particularly as retailers always sell by number instead of by weight. The desire on the part of consumers is to have a clean, bright-looking block, for which they will pay a higher price, although these external indications have no connection with the quality or calorific value of the coal, but merely increase the cost of manufacture.

For industrial purposes, small cubical blocks are the best to use, being easier to shovel up, and burning regularly in the furnace without falling to pieces. No concern need be had for smooth surface and clean edges, these being luxuries, and unconnected with the quality. It is, however, well to see that the coal is dry and leaves but little dross or ash, and these properties are not discernible to the eye, but must be made the object of experimental determination.

A number of coal blocks examined in the laboratory for ash and water content exhibited marked individual differences in these respects, the best coal tested having 9.5 per cent. of water, while the worst held more than 18 per cent., a difference of 50 per cent. in value. Again, one coal contained 5.8 per cent. of ash and dross, whereas in another 11 per cent. was found. The best Bohemian brown coal tested for the sake of comparison gave 13.13 per cent. of water, another 19.09 per cent., while ordinary qualities exhibited a content of 24 to 30 per cent.

TRAP DOORS FOR FAN DRIFTS.—Work has been in progress for some time past on a new fan at the Hoyt shaft of the Pennsylvania Coal Company, and it is now in operation. The mine is quite gaseous, and it was deemed advisable to erect the new fan for use in case of emergency or in conjunction with the old fan. The fan house is of brick almost entirely, the girders in that portion where the air circulates as it comes from the mines being of iron, inlaid with brick. The fan itself is twenty feet in diameter, and it has a capacity of about 144,000 feet of air each minute. Several features of the plan of the new fan are of special interest, by reason of the fact that they are here adopted for the first time by the Pennsylvania Company. There are two brick passage-ways through which air is drawn from the shaft to the fan, and at the entrance to each of these passages is a massive iron door. One is 14x4 feet in size and the other about 14x5. These are so set on upright axles as to work automatically if anything should occur to stop the fan. Thus, if the new fan should be injured, the old fan would be started and the change in the current of air would of itself be sufficient to close the iron doors leading to the idle fan, and *vice versa*, since it is the intention of the company to place a similar arrangement in the old fan. Should the doors fail to operate automatically, levers running from the engine house will enable the engineer to open or close the doors with but little effort. The idea is to make it possible to change from using one fan to the other with the least possible delay. It is hoped, too, that the two fans will work together, if such be desired. In a Wilkesbarre shaft a somewhat similar arrangement is proving very satisfactory. The new fan will be an important addition to the equipment of Hoyt shaft, and its operation is being watched with interest by the company's officials. The fan has been in operation for several days in order to get the machinery working smoothly, but has not yet been connected with the shaft.

* * *

THE ENGINEERING ASSOCIATION OF THE SOUTH.—This association, besides its regular meetings for the reading of papers, discussions on the same, etc., holds informal meetings, when the contents of leading technical publications are discussed by members, to certain of whom are assigned a particular journal. At an informal meeting held Dec. 26, 1895, the following assignments were made: *Engineering Record*, to Mr. Ruhm; *Engineering*, (London), to Prof. Schuerman; *Scientific American Supplement*, to Maj. Locke; *Colliery Engineer and Metal Miner*, to Mr. J. J. Ormsbee; *Engineering News*, and *Journal of the Franklin Institute*, to Mr. Kirkpatrick; *Railroad Gazette*, to Mr. W. N. McDonald; *Engineering Magazine*, to Mr. Geo. F. Blackie; *Stone*, to Mr. J. S. Walker; *Journal of the Association of Engineering Societies*, to Capt. Biddle; *Iron Age*, to Maj. Lewis; Mechanical and Electrical Engineering Literature, to Prof. Magruder; Architectural Literature, to Capt. Smith; Reports of the American Society of Civil Engineers, to Mr. H. McDonald; *Engineering and Mining Journal*, to Lucius P. Brown; The Literature of the English Iron and Steel Industries, to Mr. Lodge. An interesting discussion of a recent paper in the proceedings of the American Society of Civil Engineers was opened by the President. The paper was entitled "The Life of Iron Bridges." Among other things, the author of this paper took the position that the "Factor of Safety" now usual was too high. The general opinion of the members present, however, seemed to be against this view, because of the slight advantages to be gained by a change, which were reduced to a minimum when compared with the consequences of any accident that might follow such a change.

* * *

A NEW SAFETY EXPLOSIVE.—From the Science and Art of Mining. Prof. F. Kleinpeter draws attention to a new mining explosive which is said to be coming into vogue in Austria. It is known as Dahmenite A, and is said to be 33 per cent. stronger than the best gelatine dynamite, and in consequence of the large volume of gas which it produces (being approximately double that yielded by dynamite) it has a wedging rather than a pulverizing action resulting in a materially increased fall of lump coal. It can be compressed without losing any of its explosive force, and in this state, far surpasses every variety of dynamite. A much weaker detonator is required to bring it to explosion than is required for any other known safety explosive, and it is better able to withstand the effects of storage. If properly packed no decomposition can take place. The last illustration of the safety with which Dahmenite A can be handled is the fact that the German Board of the State railways allow it to be carried in any trains, even in mixed passenger and goods trains. Extensive experiments are in progress in the several mining districts of the country, and when these have been completed no doubt we shall hear something further of the nature and properties of the new explosive.

Foreign Orders for American Electric Plants.

That the product of the Westinghouse Electric and Manufacturing Company is of world wide demand has again been demonstrated, recently, by the company receiving orders to equip an electric railway in the "Isle of Man," the little island near the coast of Ireland, which has been made famous by Hall Caine, the great novelist; another order for electric railway apparatus for the City of Coventry, England, and a third order for electric motors and railway generators for Capetown, South Africa. The company is also about to ship an order for electric railway apparatus to Bangkok, Siam, India.

EASY LESSONS ON MINING.

This Department contains articles to assist ambitious Miners to educate themselves, and obtain Certificates of Competency as Mine Foremen, or to become Mine Superintendents.

The articles are written to be understood by the unlearned and the learned alike. Plain language is used, no obscure terms are employed, and each subject treated, is made as clear and easy to understand as possible.

Further: The Questions asked at the different Examinations for Mine Foremen and Mine Inspectors, are printed and answered.

*** The Series of Articles "Geology of Coal," "Chemistry of Mining," "Mining Methods" and "Mining Machinery" was commenced in the issue of March, 1894. Back numbers can be obtained at twenty-five cents per single copy, $1.00 for six copies, and $2.00 for twelve copies.

MINING METHODS.

Accumulations of Gas—How to Approach Accumulations of Gas—How to Remove Gas—Underground Fires—A Gob Fire in a Mine—Fires in Coal Heaps—The Breathing of a Gob.

80. Accumulations of Gas.—Sudden accumulations of gas are often the results of causes that can be predicated from known conditions, such as when gas is pent up *in situ* at a very high pressure in a thin vein that lies at a few feet above or beneath the working vein; for here it is easy to foresee that sudden intrusions of gas may be expected in the rooms, by finding a passage through open fissures that are uncovered during the extraction of the coal, or the pent up gas may be expected to break the roof, or lift the floor, and thus find vent into the working places. Sometimes the working vein is a reservoir of gas at a very high pressure, and especially so in virgin coal that is in course of being tapped in new districts, for here sudden outbursts of gas occur that derange the ventilation, and yet the outrush may be no surprise, but an expected event. Again, during the course of longwall working, the covering rocks forming the roof often break up into coal pipes, or thin seams of coal, and make open channels for the outflow of large volumes of marsh gas, yet the outrush of the gas may be foreseen in this as in the other cases, but there are cases in which sudden accumulations of gas are totally unexpected, as when, during the course of working, the vein is found to be cut by a fault that pours out a flood of marsh gas and sulphureted hydrogen. Our greatest concern should not, however, be to assure ourselves of whether the outburst was unexpected or not, but to remove the danger by a correct method in the ventilation, and this conclusion brings us to the practical point in the lesson, for seeing that we have shown the causes of the accumulations, we ought now to be able to remove the intruder and render the mine healthy and safe, and in doing so the following dictum should be taken as our guide. "Advance to the point of danger with the fresh air, but never go in before it."

81. How to Approach Accumulations of Gas.—To assist in establishing this conclusion Fig. 123 is introduced, and it will be seen that the sketch is a good illustration of the principle that has just been insisted on. Here the point of danger occurs at *P*, where there has been a great fall of the roof, and an outrush of gas, and as this has taken place at an elevated point we may be sure that the gas will not be carried off unless a sufficient ventilation is provided, and as this cannot be done until the obstruction of fallen rock is removed, it would be unwise and unsafe to do otherwise than obey the commands of the dictum, and "advance with the fresh air" to the point *P*, for should we advance to the rear of the fall as at *F*, we would have to proceed by way of *G*, *G*, *G*, through a dangerous mixture of air and marsh gas, and such a proceeding would be inexcusable, even for an inspection, but to send the workmen in by the road *G*, *G*, *G*, to clear away the fall and secure the roof, would be a great mistake, because they would have to advance through the off-coming gas, and work in it until the work was done. No person should be allowed in the return airway *G*, and the fall could be better removed and with perfect safety by placing the men in *A*, *A*, *P*. There is one thing however about this illustration that is self-evident, and that is the comparative ease with which the right method of proceeding can be carried out, but there are other cases in which sound judgment and practical experience are required to secure the results of safety, and such is the one that will next engage our attention, and to explain which we will use Fig. 124.

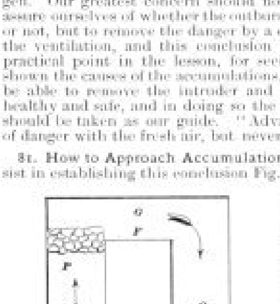

Fig. 123.

82. How to Remove Gas.—Suppose a room that is in course of being driven, and is ventilated with a brattice that confines the ingoing fresh air to the narrow side, as shown on the right hand side of the figure; a practical eye can see at a glance that this arrangement is a mistake and ought to be rectified, or otherwise the workmen would have to do the clearing away in an atmosphere highly impregnated with inflammable gas, and therefore the direction of the ventilating current should be reversed as it is at *I* on the left hand side of the figure, for this arrangement would carry the gas from the men, instead of to them, and would thus secure perfect safety. To carry out the latter plan a small temporary crossing like that shown at *c* should be fixed, then the fresh air would enter the room by passing under the crossing, and the return foul air would leave the room by being carried over the fresh air by the crossing. We see then that the fixing of this crossing is the result of the exercise of sound judgment, such as can be cultivated by training and observation.

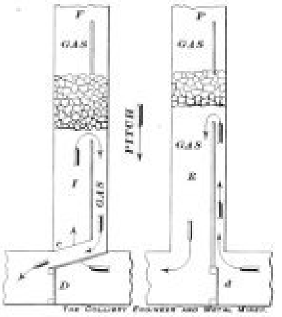

Fig. 124.

83. Underground Fires.—Many of the most brilliant feats in mining, however, have been the results of educational training, and indeed they could not have been carried out without knowledge, and to show the kind of culture the miner requires, let us notice some of these often occurring cases and take the teachings of Fig. 125 for a first example. Here we will see that at any rate, an elementary knowledge of the chemistry of gases, and the expansion of gases is required to deal with the conditions of the case, and to prove the accuracy of our statement, let us first explain the figure. We are supposed to have the coal on fire about the middle of a coal drift, and we are appointed to stopping it off, and we know by the painful experience of others that if the wrong stopping is built in first we are *sure* to have an explosion. It is therefore imperative that we should know what we are about, and for that to be so, let us notice that the locality of the fire is in the middle of the drift as at *H*, *H*, and that both the drifts, that is *A* and *B*, are different examples of treatment for the same drift, and that before the stoppings were built the air was moving from *B* to *R*, or from *F* to *X*, and, as has frequently happened, if the stopping *F* is first built to cut off the entry of fresh air, as in the case of the drift *A*, an explosion is sure to occur as the result of two causes: first, the large volume of inflammable gas driven off by the heat, and second, the expansion by heat of the air between the stopping at the intake end of the drift and the fire. The cause of the expansion of the air between the stopping and the fire, is the heated state of the rock of the roof and floor and the coal of the sides of the approach to the fire; and the immediate cause of the explosion is, the expanding air does not only mix with the gas, but it still further forces the mixture into the fire. When the stopping at the return end of the drift is built in first, as shown at *R*, an explosion cannot occur for two reasons: first, the air between the fire and *R* consists of the products of combustion that have become entirely inert, while the space in the drift between the fire and the incoming end becomes filled with dead gases and the gas given off in great volumes by the hot coal, and the result is, when the last stopping is built in, that is the one at the incoming end *F*, the whole drift is filled with gases that have excluded all fresh air, and therefore an explosion cannot now occur. Notice that the seat of the fire is at *H H*, and that when *F* is built first the fresh air between *F* and *H H*, or *E I*, supplies the oxygen for combustion, and that if *R* is built in first, not only the *R* but the *B* end becomes filled with gas free from any admixture with oxygen. The arrow at *B* indicates the outflow of gas from the fire, and the arrow in *A* indicates the course of the ventilation before any stoppings were built in.

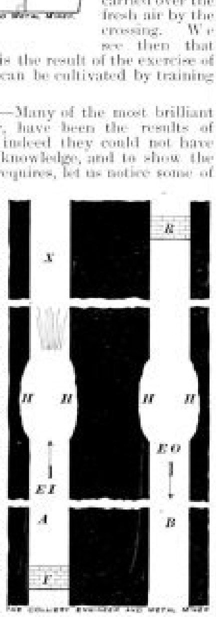

Fig. 125.

84. A Gob Fire in a Mine.—After these facts and principles have been considered we cannot fail to learn that some technical knowledge is required in mining, and it is the object of the "Easy Lessons" to aid in obtaining it. Fig. 126 teaches another lesson on underground fires, and here it has occurred in the gob, and as is generally the case the coal is supposed to be on fire, and from what has been said in relation to the former figure we might suppose that all we require to do is to "stopping off the fire" and it will die out, but our experience has proved that such a simple proceeding oftener fails than succeeds, and at first sight this seems a puzzle, for we would expect that a fire that was not supported with a continuous indraught of pure air would die out through lack of oxygen to support combustion, but our idea is that of a continuous stream of air, and it is true that there cannot be a continuous supply of oxygen to a fire that is stopped off, but where a large mass of fuel like coal or coke is in a state of incandescence and isolated from cooling influences, it will retain its heat for long periods, and the result is "the breathing of the gob" supplies the oxygen to continue the combustion, and the intermittent supplies of oxygen excite a corresponding intermittent activity of the fire, and it may, as it often does, continue for many years. It is not sufficient then that the gob is stopped off at *A*, *B*, *C* and *D*, because the gob will then inhale and exhale through fissures in the rock of the roof and floor and of the coal walls, and thus not only receive supplies of oxygen, but expel the inert products of combustion.

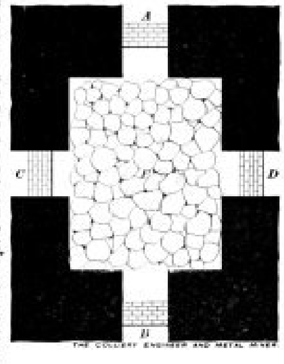

Fig. 126.

Not only are mine fires supported by the process of inhalation and exhalation, but the same active principle applies to fires in heaps of coals and cinders, and we have known large heaps of cinders to take fire many years after they were deposited.

85. Fires in Coal Heaps.—The writer knew a very interesting case at Mill Dam, South Shields, England, where an immense mass of furnace ash from a glass works had been deposited to level up a valley, and on the site many blocks of expensive houses and a theatre were built, and long after the property was completed, and drains were made, and gas and water pipes were laid, the mass of ashes and cinders was found to be on fire, and it continued to defy all attempts to extinguish it, until the whole of the houses and the theatre were destroyed.

Such examples of underground fires, that have smouldered for years, and yet have given no reason for alarm until a period of increased activity arrived, suggest to those that do not understand the "breathing of the gob" that the oxygen for combustion must be supplied by some cunning or mysterious process; but to us miners something more definite must be understood than the mere statement of vague terms, and therefore to unveil the true cause Fig. 127 is introduced.

86. The Breathing of a Gob.—The natural process is difficult to imitate because it furnishes a vast mass of incandescent matter that can retain its heat during the exhalation, to rekindle the fire at the period of inhalation; but by the use of the apparatus shown in the figure, the whole principle of action can be so far imitated as to leave little to be desired. But before explaining the action of the apparatus let us first explain how an underground fire breathes. First, then, inhalation is produced by the condensing of the gas that is in course of being cooled in the region of the fire, when the outside air rushes into the depression to restore the balance of pressure, and by the same act the inrushing oxygen rekindles the fire. The second phase of the matter is this, the renewed activity of the fire causes an evolution of gas, and the heat generated causes a considerable expansion of the products of combustion,

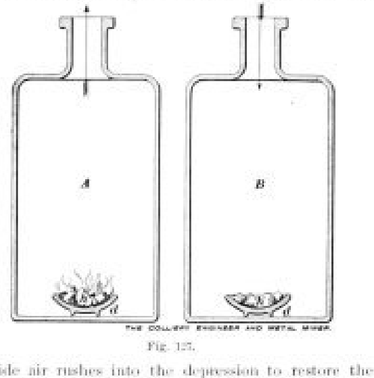

Fig. 127.

with the result that a large volume of the inert gas is expelled as an exhalation, and the remaining portion on cooling, shrinks and makes a depression for the succeeding inhalation. Now let us take the figure in hand, and first notice that two bottles are shown, but really they only illustrate opposite phases in the breathing, and it will now be understood that *A* shows the period of exhalation, as seen by the arrow, or really the period of expansion by heat, and *B* illustrates the period of inhalation, or the period of condensation by cooling; the fire is imitated by a piece of phosphorus lying in a saucer that rests on the bottom of the bottle, and the phosphorus is used as fuel because it rekindles at a low temperature on the admission of a minute trace of oxygen.

Now let us follow through a cycle or two the processes of inhalation and exhalation. First, then, fresh air has entered *A*, and on the free oxygen of this inhalation reaching the hot phosphorus, that substance bursts into flame and expands the air, and by this expansion the nitrogen is exhaled, and after all the oxygen is burnt off by the phosphorus, combustion ceases as in *B*, and then the remaining gases cool and contract, when fresh air is at once inhaled, as shown by the arrow in the neck of *B*; and so on, inhalation and exhalation occur in continued succession, until the phosphorus is all consumed. The bottle experiment furnishes a good illustration of the breathing of a gob, but we can better understand the matter when we consider the immense body of incandescent coal or cinder that retains the heat for rekindling the fire at each inhalation of a gob fire.

Underground fires in coal mines inhale through fissures in the roof and floor rocks, and through cracks, fissures and cleavage spaces in the coal barriers, and therefore it is seldom, indeed, that the breathing of the gob can be prevented.

(To be Continued.)

CHEMISTRY OF MINING.

Oil and Gas Lights—Oil-Gas Flames—Ideal Safety Lamps—Improved Safety Lamps—The Stephenson Lamp—The Jack Lamp.

83. Oil and Gas Lights.—From a physical and chemical point of view, the oil light is really a gas light and the wick is the gas generator, or the analogue of a gas retort in which the liquid oil is distilled or converted into vapor by the heat of the flame. In proof of this, a simple experiment may be tried with a small pipette about 6 inches long, and held by the hand at an angle of about 45 degrees of elevation, with its lower end inserted in the flame just over the upper end of the wick; gas will then ascend the tube, and can be lighted at the upper end and thus prove that the oil is not burning as a liquid, but as a gas.

The oil ascends the wick by capillary action and therefore, the velocity of combustion is limited by the rate at which the oil can ascend; and by the rapidity of the vaporization of the oil; and this being so, we can see that a thick glutinous oil will retard capillary action, and further, while it prevents the upflow by its thickness, it is an oil that burns languidly, and therefore the heat of the flame is not sufficient to generate the required volume of gas for a good flame. This is proved by the facts of experience, for when the wick is raised, the flame only enlarges for a moment or two, when the wick becomes encrusted with a shell of carbon, and then the volume of the flame becomes less than before.

The wick then furnishes a good guage of the value of an oil for the generation of light; and further, the facts now before us, suggest others of greater importance in relation to the miner's safety lamp, and of which we will treat further on, and for the present, let us sustain our conclusions so far by introducing Fig. 124.

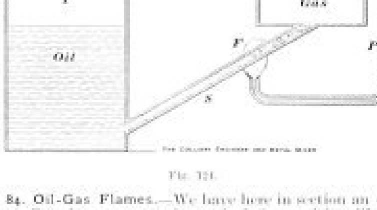

Fig. 124.

84. Oil-Gas Flames.—We have here in section an oil tank *T*, and a gas reservoir marked *Gas*, and it will be seen that the bottom of the reservoir is set level with the upper surface of the oil in the tank, and the two are connected by the sloping pipe *S*. A pipe *P* is seen to convey the gas from the reservoir to the flame at *F*, and the mode of action is as follows: The heat of the flame converts the oil in the upper portion of the pipe *S* into vapor, and while the gas continues at the temperature of vaporization, it flows through the pipe *P* to the flame.

We see then that some of the heat of the flame is utilized for the distillation of the oil, and therefore there is much in the physical and chemical action of this apparatus that has its analogue in the action observed in the common oil lamp, and yet there are two very distinctive differences; for example, the pipe *P* is not an analogue of the wick of an oil lamp, because the wick acts by capillary action that only applies to liquids, whereas the pipe *P* is a gas pipe and the vapor is forced from the reservoir to the flame by pressure. The second difference is a very interesting one, and it is this: The vapor of an oil such as is used in wick lamps only becomes a gas at a high and invariable temperature, and for illustration let us take the temperature of vaporization at 240° F, and we will find that just as steam condenses into liquid water the moment its temperature is reduced below 212° at the ordinary atmospheric pressure, so does the gas or vapor of the oil condense into liquid oil the moment its temperature is reduced below 240°F at atmospheric pressure, and it is for this reason that an apparatus like the one illustrated in the figure, could not be taken as a substitute for the wick of the oil lamp. The reservoir and gas pipe would have to be maintained at a high temperature to retain the oil as vapor, whereas the wick just exposes the liquid oil to the heat of the flame, at the very point where the gas is wanted, and the vapor is therefore generated without any waste of heat, by radiation. From what has been shown we see that if we wish to improve the miner's safety lamp, we must begin our studies by first mastering the principles of the physical and chemical action that takes place in burning oil and gas in a safety lamp.

85. Ideal Safety Lamps.—This brings us directly into the teeth of the question, and therefore to help to further elucidate the matter Fig. 125 is introduced, and to prevent complexity in the explanation one ideal lamp *F*, consists simply of an oil fountain and gauze cylinder, and the other *P C*, etc., consists of the oil fountain, gauze cylinder, and a bonnet, or shield, or close cylindrical shell. The *F* lamp is of the original Davy type, and it is here given as a useful lesson on what takes place when the Davy is exposed to a draught, or air current, charged with marsh gas. In such a situation the lamp is seen to be filled with flame *F*, for the current of air acts like a blast, and the quantity of air entering within the gauze is out of all proportion greater than what would simply enter as a normal draught to feed the flame. By the arrows the explosive air is seen to enter the lower half of the gauze shell, while the burnt air is seen to be leaving by the upper half, but in a swiftly-moving current, when the lamp is stationary, or when the lamp is moved in the hand say at six miles an hour, as when the man's hand is moving faster than his body, as the result of the swing of his arm, and when in addition to this six miles the current is moving to the carrier's face with a velocity of 15 feet per second, the lamp advancing against this current is subject to a blast, whose effect is that of a velocity of 15 + 8.8 = 23.8 feet per second; the blast of air therefore enters one side of the gauze and leaves by the other, with the result that the gauze on the lee side, or that on which the flame is blowing, becomes red hot, and at once "passes the flame through," because the volume of flame within the lamp, as the result of the breach provided by the *naked* gauze, is exceedingly greater than that of a "jacketed lamp," and among other reasons, this is one for the Davy lamp being "a good detector of gas." In the other lamp, at the left hand side of the figure, a Davy lamp is shown with the gauze covered with a close shell, on one side of which is a glass pane for the passage of light, but this is not shown in the section, and this is in principle what the English miners call "*the Davy in a can.*"

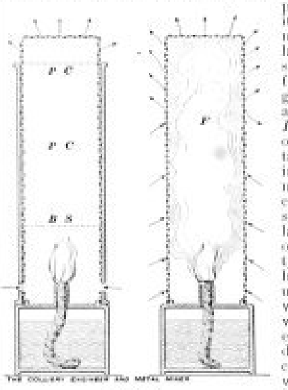

Fig. 125.

86. Improved Safety Lamps.—The safety of this lamp in a can or case is undoubted, so far as protection from fire damp is concerned, and the only objection to this encased lamp is that "it gives a bad light." It will be seen that no more than the normal volume of air necessary for the combustion of the oil enters this lamp, and at *B S* we have the limit of the combustion of the oil, as in the case of the Marsaut lamp, and above that line we have only *P C*, or the products of combustion. The true "*can*" does not fit the gauze so closely as does the shell in the figure, and further, the fresh air enters the can, at the top, instead of at the bottom, the result is the cold air sinks down the outside of the gauze to keep it cool, while the hot burnt air ascends to the cap within the gauze.

87. The Stephenson Lamp.—Stephenson had an experience that served him well in the invention and perfecting of his lamp; and his, one of the first lamps, was provided with a glass shell, shown by Fig. 126, in section at *G* and *G*. A glass cylinder was here set within the gauze, and the result was this inside close shell was a channel for the outflow of the products of combustion only, while fresh air was admitted through small hair-like holes situated in the bottom of the frame of the lamp, and the burnt air escaped by the cap of the gauze under the tile. In theory this was a good lamp, so far as the principle of action was concerned, but in practice it proved to be, when the glass cracked, a very dangerous one; because the gauze cylinder was of a relatively large diameter to admit the glass shell, and the result was with a broken glass it was in principle a Davy, with all the bad features of that lamp magnified. The air is seen to enter by the capillary holes at *A* and *A*, and to pass out of the cap *C* as shown by the arrows.

88. The Jack Lamp.—Fig. 127 is an illustration of the further development of the early improvements in the miner's safety lamp. Jack saw that in principle Stephenson was right, as have all succeeding improvers, in providing a closed shell as a protection against the rapid inrush of an explosive mixture into the lamp, and he also was aware of the dangers arising from the breaking of the inside glass cylinder, and therefore he improved the Stephenson lamp by reducing the diameter of the gauze cylinder and placing the glass shell on the outside, as shown in section under the letters *A* and *A*; and at *G* and *G* we have the poles that support the tile and keep the gauze and glass cylinders in position. Now looking at the various phases of the safety lamp retrospectively, it is very easy to discern that the Clanny lamp, one of the first introduced, which was coincident with the introduction of the Davy and the Stephenson, contained the essential principle of all the latest lamps,

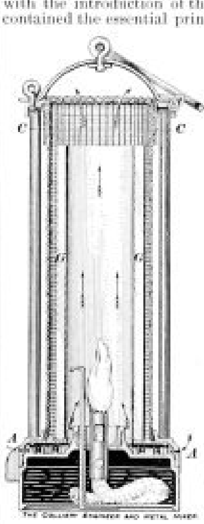

Fig. 126.

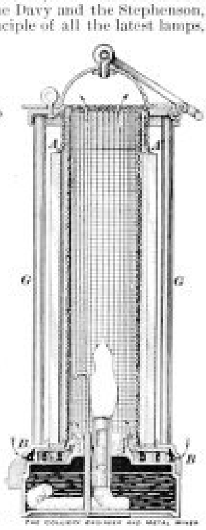

Fig. 127.

namely, the short glass cylinder for the transmission of light; and the Stephenson and the Jack lamp contained the other essential element of the best lamps in use, and that was the close shell, but in the improved lamps the glass shell is replaced with a metal one, and is now called the bonnet. We may therefore conclude correctly, that the latest and best lamps are a combination of the most essential principles found in the earliest examples of miner's safety lamps.

MINING MACHINERY.

Questions and Answers About Fans—The Dimensions of Centrifugal Fans—Velocities of Air Currents Into Depressions—The Areas of the Orifices of Intake and Discharge—Pressures Due to the Radial Columns—Quantities and Velocities of the Air Discharged—Calculations of the Working Efficiencies of Small and Large Fans—Calculations of the Useful Effect of Fans on the First and Second Motion.

103. The Dimensions of Centrifugal Fans.—This is the concluding lesson on the principles of action of the centrifugal ventilating fan, and it consists of questions and answers to elucidate the subjects that have been treated in relation to these machines.

QUES. 1. What should be the diameter of a centrifugal ventilating fan to obtain a quantity of 200,000 cubic feet of air per minute?

ANS. By the rule, divide the quantity by the constant number 200 and extract the square root of the quotient, and the result will be the diameter of the required fan in feet, as $\sqrt{\frac{200{,}000}{200}} = 31.62$.

QUES. 2. Suppose the velocity and other things to be the same as in the former question, What quantity would you expect to obtain with a fan 31.623 feet in diameter?

ANS. By a process the converse of that for finding the diameter, the quantity may be found, as $31.623^2 \times 200 = 200{,}000$ cubic feet of air per minute, the quantity required.

QUES. 3. What should be the diameter of a first motion, centrifugal fan to obtain a quantity of 80,000 cubic feet of air per minute?

ANS. $\sqrt{\frac{80{,}000}{200}} = 20$ feet, the diameter of the fan required.

QUES. 4. What quantity of air in cubic feet per minute should I obtain with a first motion fan 20 feet in diameter? The velocity and other things remaining as in the former question.

ANS. $20^2 \times 200 = 80{,}000$, the quantity of air required in cubic feet per minute.

QUES. 5. What should be the diameter of a fan on the first motion, to obtain a quantity of 125,000 cubic feet of air per minute?

ANS. $\sqrt{\frac{125{,}000}{200}} = 25$ feet, the diameter of the required fan.

QUES. 6. What quantity of air in cubic feet per minute, could be obtained with a fan 25 feet in diameter? The velocity and other things remaining the same as in the former question.

ANS. $25^2 \times 200 = 125{,}000$ cubic feet, the quantity required.

QUES. 7. What should be the radial length of the blades of a centrifugal fan, on the first motion, and constructed to give a high efficiency at a moderate speed, when the mine resistance is equal to 2 inches of water gauge?

Ans. By the rule given, there should be 7 inches in the radial length of the blades for every pound per square foot in the mine resistance, then $\frac{2\times5.2\times7}{12}=6.07$ feet, the radial length of the blades required.

Ques. 8. The radial length of the blades of a fan is 6.07 feet. What should be the mine resistance in pounds per square foot to run a fan on the first motion at a moderate speed?

Ans. The answer required is the converse of the former one, then $\frac{6.07\times12}{5.2\times7}=2$ inches of water gauge.

Ques. 9. What should be the radial length of the blades of a fan on the first motion, when 5 inches is allowed for every pound of mine resistance, which in this case is equal to 2.2 inches of water gauge?

Ans. $\frac{2.2\times5.2\times5}{12}=4.76$ feet, the length of the blades required.

Ques. 10. What should be the mine resistance for a fan in which the radial length of the blades is 4.76 feet, and 5 inches is allowed in this length for every pound of mine resistance?

Ans. $\frac{4.7666\times12}{5.2\times5}=2.2$ inches of water gauge.

Ques. 11. Two centrifugal ventilating fans on the first motion, are equal in diameter, and are intended to produce equal quantities of air in cubic feet per minute, but the radial length of the blades in A is such that there is an allowance of 7 inches in the radial length, per pound of mine resistance, whereas, in B the allowance is only 5 inches; and taking the speed of A at 1, what should be the speed of B, if A makes 70 revolutions per minute?

Ans. As the pressures vary directly as the radial lengths of the fan blades multiplied by the squares of the velocities, let L be the greatest radial length, and l the least, and let v be the given velocity of A, and V the sought for velocity of B, then $\frac{Lv^2}{l}=V^2$ or $\sqrt{\frac{Lv^2}{l}}=V$ as $\sqrt{\frac{L\times70^2}{l}}=82.825$, the speed of the fan B in revolutions per minute, to produce the same quantity of air in cubic feet per minute as A.

Ques. 12. In two fans, A and B, the radial lengths of the blades and other things are equal, except the diameters and peripheral speeds: Now, if A runs at 80 revolutions per minute and is 24 feet in diameter, what should be the speed of B to produce the same quantity as A, B's diameter being only 20 feet?

Ans. The speeds of A and B must be inversely as their diameters, then if A's speed is 80 revolutions B's speed will be $\frac{24\times80}{20}=96$ revolutions per minute, to obtain the same quantity of air in cubic feet per minute as that of A.

Ques. 13. What should be the area of the port or ports of entry, for a fan exhausting from a mine a quantity of 200,000 cubic feet of air per minute?

Ans. The best results are obtained when the area is found by dividing the quantity by the constant number, 1,300, or $\frac{Q}{1,300}=\frac{200,000}{1,300}=153.8$ square feet, the area of the port or ports of entry required.

Ques. 14. The area of the ports of entry of a fan is equal to 100 square feet, what then should be the maximum quantity produced by it to obtain the best useful effect?

Ans. Q is equal to $1,300\times100$, or let A = the area, and C the constant, then $Q=AC$, as $1,300\times100=130,000$ cubic feet of air per minute, the quantity required.

Ques. 15. A ventilating fan admits air at both sides, and the diameter of each port of entry is 8 feet, what, then, is the joint area of the two ports?

Ans. The joint area of the two ports of entry will be; $8^2\times.7854\times2=8\times8\times.7854\times2=100.5312$ square feet.

Ques. 16. As the throat of the fan should be equal in area, to the joint areas of the ports of entry; what should be the length of the throat, or breadth of the fan blades?

Ans. The length of the conceivable surface of the throat cylinder, or what is the same, the breadth of the fan blades, can be found by dividing the area of the ports of entry by the circumference of the throat, as $\frac{100.5312}{8\times3.1416}=4$ feet, the length of the throat, or breadth of the fan blades required.

Ques. 17. What should be the area of the port or ports of discharge of a fan producing 150,000 cubic feet of air per minute?

Ans. If the quantity required be Q, and the area required be A, and the constant number be C, then $Q=AC$, or $\frac{Q}{C}=A$, as $\frac{150,000}{2,600}=57.69$ square feet, the area of the port of discharge required, being half that of the port of entry, or C for the port of entry being 1,300, C for the area of discharge is 2,600.

Ques. 18. Suppose that the port of discharge for the last question had been 30 instead of 57.69 square feet, what increased velocity would be required by the fan, to maintain the outflow of the same quantity, 150,000; the mine resistance being 10 pounds per square foot?

Ans. Taking the *vena contracta* at .62, the velocity in the former case, in feet per second, would be $\frac{150,000}{57.69\times.62\times60}=69.895$, and this would require a pressure of $\frac{69.895^2\times2,120}{1,800,000}=\frac{4,885.3\times2120}{1,800,000}=5.75$ pounds pressure per square foot, and as the pressures vary as the squares of the velocities, $\left(\frac{57.69}{30}\right)^2\times5.75=21.3$ pounds per square foot, the pressure required for the reduced area.

Now to 21.3, and to 5.75 add the mine resistance 10, as, $21.3+10=31.3$, and $5.75+10=15.75$, and we can at once determine the increased velocity of the fan due to the reduced area of discharge, for the velocities vary as the square roots of the pressures, then the velocity required is, if the former velocity was 1, $\sqrt{\frac{31.3}{15.75}}=1.4$, or, if the revolutions in the first case were 70 per minute, in the latter they would be $1.4\times70=98$ revolutions per minute.

104. Velocities of Air Currents Into Depressions.—Ques. 19. At what velocity will air pass through an orifice into a depression, where the pressure is 5 pounds per square foot below that of the atmosphere.

Ans. As the depression in a fan does not affect this value, we only have the 5 pounds to consider, and as air is elastic, the expression is, $\sqrt{\frac{5\times1,800,000}{(2,120+5)}}=\sqrt{\frac{5\times1,800,000}{2,125}}=65.08$ feet per second, the velocity required.

Ques. 20. What is the velocity and mean quantity of air passing through an orifice of 50 square feet, into a depression of 20 pounds per square foot below the pressure of the atmosphere?

Ans. The velocity per second of elastic air rushing into a depression 20 pounds per square foot below the pressure of the atmosphere will be $\sqrt{\frac{20\times1,800,000}{(2,120+20)}}=\sqrt{\frac{20\times1,800,000}{2,140}}=129.7$ feet, the velocity per second, or $129.7\times60=7,782$ feet per minute. Taking the *vena contracta* at .62 the quantity required will be $7,782\times50\times.62=241,242$ cubic feet of air per minute.

Ques. 21. What should be the area of an orifice for the admission of 180,000 cubic feet of air per minute, when the air is flowing into a depression where the pressure is 7 pounds per square foot below the pressure of the atmosphere?

Ans. The velocity of the inflowing air per second will be equal to $\sqrt{\frac{7\times1,800,000}{(2,120+7)}}=\sqrt{\frac{7\times1,800,000}{2,127}}=76.967$ feet per second, or, $76.967\times60=4,618$ feet per minute and taking the *vena contracta* at .62, the area of the orifice in square feet will be equal to $\frac{180,000}{4,618\times.62}=62.86$.

Ques. 22. The smallest port in an exhausting fan, is that of discharge, and it is equal to 45 square feet. The total pressure due to the motive column is equal to 14.5 pounds per square foot of section:

The mine resistance is equal to 9 pounds per square foot of section. What then is the quantity of air in cubic feet per minute passing out of the fan?

Ans. Here the expression $\sqrt{\frac{(T-M)\times1,800,000}{(2,130+M^2)}}=v$ meets the requirements of the case.

Then $\sqrt{\frac{(14.5-9)\times1,800,000}{(2,130+9^2)}}=v=\sqrt{\frac{5.5\times1,800,000}{2,211}}=67$, nearly, = the velocity of discharge in feet per second, and taking the *vena contracta* at .62 the quantity of air discharged by the fan in cubic feet per minute will be, as, $67\times60\times.62\times45=112,158$ cubic feet.

Ques. 23. The calculated total pressure, due to an exhausting fan, is found to be 18 pounds per square foot of section of the motive column; and the mine resistance is found to be 11 pounds per square foot of section, at the top of the upcast shaft; the smallest orifice is found to be the throat of the fan, that is 52 square feet in area: What, then, is the quantity of air exhausted by this fan in cubic feet per minute?

Ans. We will find the velocity of the air passing through the throat of the fan in feet per second, by the expression $\sqrt{\frac{(T-M)\times1,800,000}{(2,130+M^2)}}=\sqrt{\frac{7\times1,800,000}{2,251}}=74.82$ feet. The quantity per minute will therefore be, if we take the *vena contracta* at .62,

$$74.82\times60\times.62\times52=144,731.6 \text{ cubic feet.}$$

Ques. 24. The calculated total pressure for a blowing fan is found to be 14 pounds per square foot of the motive column, and the mine resistance, as measured with the water gauge is found to be 1.4 inches. The smallest orifice is the port of entry, whose *mean* area is 57 square feet, what, then, is the quantity of air in cubic feet per minute, blown into the mine with this fan?

Ans. The following expression is used to find the velocity of the air in feet per second through the smallest orifice of a blowing fan: $\sqrt{\frac{(T-M)\times1,800,000}{(2,130+M)}}=\sqrt{\frac{(14-7.28)\times1,800,000}{(2,130+7.28)}}=\sqrt{\frac{6.72\times1,800,000}{2,137.28}}=75.23$ feet, and the quantity of air in cubic feet per minute blown into the mine with this fan will therefore be, if the *vena contracta* is taken at .62, as $75.23\times60\times.62\times57=159,517.7$ cubic feet.

Ques. 25. The orifice of discharge has a smaller area than the other ports of a blowing fan, and it is equal to 49 square feet. The quantity the fan blows is equal to 150,000 cubic feet of air per minute, what, then, is the velocity of the air in feet per second out of the orifice, when the *vena contracta* is taken at .62?

Ans. $\frac{150,000}{.62\times49}$ is equal to the velocity per minute, and, therefore, $\frac{150,000}{.62\times49\times60}=82.29$ is equal to the velocity of the air in feet per second out of the orifice of discharge of a blowing fan.

Ques. 26. If the orifice of discharge in a blowing fan is the smallest, and has a mean area of 53 square feet; let the quantity blown be 160,000 thousands of cubic feet of air per minute, and let the mine resistance be equal to 1.8 inches of water gauge: What, then, will be the total pressure under these conditions?

Ans. Let us first find the velocity in feet per second by making the *vena contracta* .62, as, $\frac{160,000}{60\times53\times.62}=81.15$. As the pressures vary as the squares of the velocities, it follows that the pressure blowing the air out of the fan will be proportionate to $\frac{81.15^2\times(2130+9.36)}{1,800,000}=\frac{6,585.3\times2,139.36}{1,800,000}=7.827$ pounds per square foot, and the total pressure that "blows," and overcomes the mine resistance will, therefore, be $7.827+(1.8\times5.2)=7.827+9.36=17.187$ pounds pressure per square foot of the radial motive column.

Ques. 27. The ventilation due to an exhausting fan is equal to 190,000 cubic feet of air per minute; the mine resistance is equal to 1 inch of water gauge; the area of the smallest port, is the orifice of discharge, and it is equal to a mean area of 60 square feet. Now take the *vena contracta* at .62, and find the total pressure due to the centrifugal force produced by the rotation of the fan.

Ans. First find the velocity of the air out of the orifice of discharge, as follows, $\frac{190,000}{60\times.62\times60}=85.12$ feet per second, and as the pressures vary as the squares of the velocities, it follows, that the pressure discharging the air from the fan can be found as follows: $\frac{85.12^2\times(2,130+5.2^2)}{1,800,000}=\frac{7,245.41\times2,157}{1,800,000}=8.68$ = the pounds pressure per square foot required for blowing out; then, $8.68+5.2=13.88$ pounds, is the total pressure per square foot of section due to the centrifugal force produced by the rotation of the fan.

Ques. 28. A centrifugal exhausting fan is 24 feet in diameter; the radial length of the blades is 8 feet. What, then, is the mean velocity of the radial air column when the fan is running at 80 revolutions per minute?

Ans. Practically, the radius of gyration is 8 feet in length; half the length of the blades being 4 feet and the radius of the orifice of entry being 4 feet also, or $4+4=8$ feet. The mean velocity then of the radial column in feet per second, is as follows:

$$\frac{8\times2\times3.1416\times80}{60}=67.02 \text{ feet.}$$

Ques. 29. The diameter of a fan is 30 feet; the radial length of the blades is 8 feet. What, then, is the practical length of the radius of gyration?

Ans. To find the practical length of the radius of gyration, subtract the radial length of the blades from the diameter of the fan, and half the difference is the length of the radius of gyration, as $\frac{(30-8)}{2}=11$ feet, or the length of the radius of gyration.

Ques. 30. The radial length of the blades of a fan is 9 feet, what then is the weight of this motive column of air, that is taken as W in making fan calculations?

Ans. The average weight of a cubic foot of air is .0766, then $W=.0766\times9=.6894$ of a pound.

Ques. 31. Find the value of W in four cases in which the radial columns are 4, 5, 6 and 7 feet in length, respectively?

Ans. $W_1=.0766\times4=.3064$ in first case.
$W_2=.0766\times5=.3830$
$W_3=.0766\times6=.4596$
$W_4=.0766\times7=.5362$.

Ques. 32. An exhausting fan is 24 feet in diameter; the radial length of the blades is 8 feet; the angular velocity is 75 revolutions per minute. What, then, is the velocity of the center of gyration in feet per second?

Ans. The diameter of gyration is $24-8=16$ feet, and, therefore, the velocity required in feet per second is $\frac{16\times3.1416\times75}{60}=62.832$ feet.

Ques. 33. A blowing fan is 20 feet in diameter; the radial length of the blades is 6 feet; the angular velocity is 92 revolutions per minute. What, then, is the velocity of the center of gyration in feet per second?

Ans. The diameter of gyration is $20-6=14$ feet, and, therefore, the velocity of the center of gyration in feet per second, is as follows: $\frac{14\times3.1416\times92}{60}=67.43968$ feet.

Ques. 34. The velocity of the center of gyration of the radial column of air in a fan is 70 feet per second; the length of the blades is 7 feet. What then is the value of the centrifugal force, expressed as pressure per square foot?

Ans. The following equation expresses the value sought for, and is known in these examples as T.

$\frac{v^2W}{3.1416g}=T$, then, $\frac{70\times70\times7\times.0766}{3.1416\times32.16}=26$ pounds; or T, the total pressure, that includes the mine resistance and the depression produced in the fan, is equal to 26 pounds pressure per square foot of the radial motive column.

QUES. 35. What is the speed of the periphery of a fan 24 feet in diameter, when the radial length of the blades is 8 feet, and the center of gyration has a velocity of 65 feet per second?

ANS. First find the diameter of gyration, as 24 − 8 = 16 feet, and as circumferences are in the same proportion to each other as their diameters, it follows that the speed of a point in the periphery of the fan, must be to that of the center of gyration, as 24 is to 16 or $\frac{24}{16} \times 65 = 97.5$ feet per second, or 97.5 × 60 = 5,850 feet per minute, is the speed of a point in the periphery of the fan.

QUES. 36. A ventilating fan is 18 feet in diameter; the radial length of the blades is 5 feet; the angular velocity of the fan is 85 revolutions per minute. What then is the value of the centrifugal force expressed in pounds pressure per square foot of radial motive column.

ANS. The diameter of gyration will be as 18 − 5 = 13 feet, and, therefore, the velocity of the center of gyration in feet per second is equal to $\frac{13 \times 3.1416 \times 85}{60} =$ 57.8578 feet. T will then be equal to $\frac{W v^2}{3.1416 g}$ = T = $\frac{.0766 \times 5 \times 57.8578^2}{3.1416 \times 32.16}$ = 12.69 pounds, the total pressure required.

QUES. 37. An exhausting fan is 25 feet in diameter; the radial length of the blades is 7 feet; the mine resistance is equal to 3.2 inches of water gauge; the angular velocity of the fan is equal to 78 revolutions per minute. What, then, is the velocity in feet per second of the air thrown off by the fan, the orifice of discharge being the smallest?

ANS. The diameter of gyration will be 25 − 7 = 18 feet, and the velocity of the center of gyration in feet per second will be $\frac{18 \times 3.1416 \times 78}{60} =$ 73.514 feet. Now T will be equal to $\frac{v^2 W}{3.1416 g} = \frac{73.514^2 \times 7 \times .0766}{3.1416 \times 32.16} =$ 28.68 pounds. E, the pressure of discharge will then be equal to 28.68 − (3.2 × 5.2) = 28.68 − 16.64 = 12.04 pounds per square foot of section of orifice. Therefore, the velocity of discharge will be equal to $\sqrt{\frac{(T-M) \times 1,800,000}{(2130+M^2)}} = \sqrt{\frac{12.04 \times 1,800,000}{2406.8896}} =$ 94.89 feet per second, the required velocity of discharge.

QUES. 38. An exhausting fan is 26 feet in diameter; the radial length of the blades is 8 feet; the angular velocity is equal to 72 revolutions per minute; the mine resistance is equal to 2.7 inches of water gauge; the orifice of discharge has an area of 52 square feet, and it is the smallest port. What, then, should be the quantity of air in cubic feet per minute thrown off by this fan?

ANS. The diameter of gyration will be equal to 26 − 8 = 18 feet; the velocity of the center of gyration will be equal to, in feet per second, $\frac{18 \times 3.1416 \times 72}{60} =$ 67.8585 feet; T will be equal to $\frac{v^2 W}{3.1416 g} = \frac{67.8585^2 \times 8 \times .0766}{3.1416 \times 32.16} =$ 27.92 pounds pressure per square foot of the area of the orifice of discharge, and the velocity of the outflow will therefore be equal to $\sqrt{\frac{(T-M) \times 1,800,000}{(2,130+M^2)}} = v$ or this will be equal to $\sqrt{\frac{13.88 \times 1,800,000}{2,327.12}} =$ 103.6 feet per second.

The quantity then of air discharged from the fan in cubic feet per minute must be, when the *vena contracta* is taken at .62, equal to 103.6 × 60 × 52 × .62 = 200,403.84 cubic feet.

QUES. 39. A blowing fan is 21 feet in diameter; the radial length of the blades is 6 feet; the angular velocity is equal to 84 revolutions per minute; the mine resistance is equal to 2.4 inches of water gauge, and the orifice of discharge is equal to an area of 40 square feet, and if the *vena contracta* is taken at .62 what quantity of air in cubic feet will this fan blow into the mine per minute?

ANS. The diameter of gyration will be equal to 21 − 6 = 15 feet; the velocity of the center of gyration in feet per second will be equal to $\frac{15 \times 3.1416 \times 84}{60} =$ 65.97 feet, and T will be equal to $\frac{v^2 W}{3.1416 g} = \frac{65.97^2 \times 6 \times .0766}{3.1416 \times 32.16} =$ 19.79 pounds per square foot of area of the orifice of discharge; the velocity of the air discharged will be as $\sqrt{\frac{(T-M) \times 1,800,000}{(2,130+M)}} = \sqrt{\frac{7.31 \times 1,800,000}{2,142.48}} =$ 78.36 feet per second. The quantity will therefore be 78.36 × 60 × 40 × .62 = 116,599.68 cubic feet of air per minute forced into the mine with a blowing fan.

QUES. 40. An exhausting fan is on the second motion and runs with an angular velocity of 140 revolutions per minute; the diameter of this fan is 12 feet; the radial length of the blades is 3 feet, and the port of discharge is the smallest and has an area of 20 square feet, and the mine resistance is equal to 1.1 inches of water gauge: What, then, is the quantity of air in cubic feet per minute exhausted by this fan?

ANS. The diameter of gyration will be equal to 12 − 3 = 9 feet; the velocity of the center of gyration in feet per second will be equal to $\frac{9 \times 3.1416 \times 140}{60} =$ 65.97 feet. T, or the total of the centrifugal force due to the radial column, will be equal to $\frac{65.97^2 \times 3 \times .0766}{3.1416 \times 32.16} =$ 9.898 pounds per square foot of motive column. The velocity of the air discharged will be equal to $\sqrt{\frac{(T-M) \times 1,800,000}{(2,130+M^2)}} = \sqrt{\frac{4.178 \times 1,800,000}{2,162.71}} =$ 58.969 feet per second, and the quantity sought for must, therefore, be equal to 58.969 × 60 × 12 × .62 = 26,323.87 cubic feet of air per minute.

QUES. 41. A blowing fan is on the second motion, and runs with an angular velocity of 200 revolutions per minute; the diameter of the fan is 14 feet, and the radial length of the blades is 3.5 feet; the port of discharge is the smallest, and has an area of 40 square feet; and the mine resistance is equal to 2.5 inches of water gauge. What, then, is the quantity this fan is blowing in cubic feet per minute?

ANS. The diameter of gyration will be 14 − 3.5 = 10.5 feet; the velocity of the center of gyration will be equal to $\frac{10.5 \times 3.1416 \times 200}{60} =$ 109.95 feet per second, and T, the pressure due to the centrifugal force of the radial column will be equal to $\frac{v^2 W}{3.1416 g} = \frac{109.95^2 \times 3.5 \times .0766}{3.1416 \times 32.16} =$ 32.08 pounds per square foot of the area of discharge.

The velocity of the outflowing air will be equal to $\sqrt{\frac{(T-M) \times 1,800,000}{(2,130+M)}} = \sqrt{\frac{19.08 \times 1,800,000}{2,143}} =$ 126.6 feet per second, and we can now determine the value of the required quantity as follows: 126.6 × 60 × 40 × .62 = 188,380.8 cubic feet of air per minute blown into the mine with this fan.

QUES. 42. A centrifugal exhausting fan is 12 feet in diameter; the radial length of the blades is 3 feet; the fan is on the second motion and runs with an angular velocity of 300 revolutions per minute; the mine resistance is equal to 2.6 inches of water gauge; the port of discharge is the smallest, and is 30 square feet in area. What quantity of air will this fan exhaust from the mine, in cubic feet per minute?

ANS. The diameter of gyration will be equal to 12 − 3 = 9 feet; the velocity of the center of gyration will be equal to $\frac{9 \times 3.1416 \times 300}{60} =$ 141.372 feet per second and T, the pressure of the radial column, will be equal to $\frac{v^2 W}{3.1416 g} = \frac{141.372^2 \times 3 \times .0766}{3.1416 \times 32.16} =$ 45.45 pounds per square foot of area. The velocity of the air thrown off by the fan will be equal to $\sqrt{\frac{(T-M) \times 1,800,000}{(2,130+M^2)}} = \sqrt{\frac{31.93 \times 1,800,000}{2,312.79}} =$ 157.64 feet per second, and the quantity will, therefore, be equal to 157.64 × 60 × 30 × .62 = 175,926.25 cubic feet of air per minute.

(*To be Continued.*)

METHODS OF MINING IN BUTTE.

There is no question but that mining, as practiced in the Butte district, is on a most scientific scale and is not surpassed in any part of the world. Mining men and corporations from all parts of the world send their experts here to study and obtain information respecting the development of large ore bodies in an economical manner, and also to inquire into the systems of hoisting, pumping, timbering, etc., as well as the treatment of ores.

The development of the Butte mines has entirely been accomplished by shafts, these being, with probably two exceptions, vertical—the exceptions being the Gagnon and Stewart. The system of shafts are of one, two and three compartments; a large majority of them being two, while the largest mines in the district use the three-compartment. One of these is used for manway and pumps, while the other two are used for hoisting—one cage is lowered and the other raised at the same time. Shafts vary in size from 5x9 feet to 5x20 feet in the clear, and are generally timbered with the ordinary square-sets, and lagged with two and three-inch planks. These timbers vary from 8x8 to 12x12 inches, and are framed on the surface by machinery especially made for this purpose. In the Gagnon mine round-sets are used with good success.

The types of "gallows frames" in vogue are either the vertical—those with two slanting timbers, or those with four uprights, and corresponding braces. The Anaconda and Syndicate and other large mines prefer the latter as being more especially adapted to rapid and heavy hoisting. These average about sixty feet in height.

The hoisting engines vary greatly in size, being from 12x00 to 20x60 inches. The large hoist at the Anaconda is one of the old-fashioned type. The one that has just been erected at the Green Mountain has a pair of 28x72-inch cylinders, and so far is the largest one erected in the district, and is designed to hoist three cars of ore on each of the two triple-decked cages—the first of the kind in the camp. A new hoisting engine is now being built by the Union Iron Works of San Francisco for the original Anaconda, and it is hoped to have the same in operation early next spring. This will greatly exceed that of the Green Mountain as to capacity. Each cage will be operated by two pairs of compound vertical engines and operating beams, which rotate the shaft. Both the high and low pressure cylinders will have a stroke of seventy-two inches; the former being twenty-six inches in diameter and the latter forty-six. The two reels will wind up nearly 5,000 feet of steel cable ⅝x8 inches. The clutches will be of the friction type, which with the brakes and reversing gear, will be operated by steam.

In the incline shafts at the Gagnon and Stewart mines cages or skips are used. When hoisted to the surface they are automatically dumped into the ore bins or cars.

Nearly all the important mines are equipped with air compressing plants, and machine drills are numerous. Several of the leading companies rely to a great extent in prospecting new ground on the Diamond core drill, and the occurrence of this most useful implement is daily becoming more prevalent.

For pumping water from the mines, the Knowles pump is in the lead. There are but very few mines now using the Cornish pump. A large Riedler duplex pump has lately been put in the Silver Bow mine at the 1,000-foot level which is estimated to pump 1,000 gallons of water per minute from this level.—*Western Mining World.*

Wire Rope Transportation.

A new and attractive card of the Trenton Iron Co., which appears in this column is worthy the attention of our readers. This company enjoys an enviable reputation as manufacturers of wire and wire ropes of all kinds, wire rope tramways, cable hoists, and haulage and coal equipments for the transportation of materials.

Mr. Abram S. Hewitt, of national reputation, is President of the company, and Mr. E. Gybbon Spilsbury, an engineer whose name is familiar to every technical man as one of the leading engineers of the world, is Managing Director of the company. The connection of these gentlemen with the company is a guarantee of the quality of the goods turned out.

A couple of years ago we called attention to a blue book on Wire Rope Transportation issued by this company which was sent free to all mine owners and mine managers on application. The book is a very handsomely illustrated volume, bound in cloth and contains first-class illustrated articles on Wire Rope Transportation, Wire Rope Haulage and Wire Rope Transmission. In fact it is one of the best publications extant on these subjects. It is more of a text-book than an advertisement. Any of our readers who did not receive a copy of the last issue of this book will be highly gratified if they send to the Trenton Iron Company, Trenton, N. J., for a copy of the new issue. We have never yet called attention to a book of greater value to mine owners and mine managers. Besides manufacturing the materials, etc., we mention, the Trenton Iron Company make a large number of specialties in wire goods, and the evidence of their superior quality is in the numerous awards allowed them at the Columbian Exposition, at Chicago, where their display was certainly a magnificent one. Among the recent productions of this company is a new grade of heat resisting wire for electric heaters which is meeting with great favor. Other specialties are the Patent Lock Wire Rope, Bleichert Patent Wire Rope Tramways, and a Patent Bale Tie known to the trade as the Anchor Tie.

Some of these specialties are not of special interest to mine managers and mine officials, but the book we mention is, and the description of wire rope tramways, cable hoists and conveyors, and the application of wire rope to mine haulage are of such a nature that the mining engineer or mine manager who does not possess a copy misses a valuable publication from his technical library.

A Louisiana Sulphur Mine.

The Standard Oil Co., has finally solved the problem of winning the curious and valuable sulphur deposit in Calcasieu parish, Louisiana.

For thirty-five years company after company has experimented with this deposit of sulphur, which is probably the largest in the country, and is valued at from $30,000,000 to $100,000,000. There was no doubt about the sulphur being there, but unfortunately between it and the surface lay an immense quicksand, which could not be removed, excavated, or bored through. There seemed to be no way of man reaching the sulphur and getting it up. A small town, Sulphur City, has grown up in the neighborhood of the mines, at which lived the operatives engaged in trying to solve the problem. As the expenses of these employes had to be paid, and as not a pound of sulphur was obtained, the several companies organized to mine it went one after another into bankruptcy, until the property fell, a short time ago, into the hands of the great Standard Oil Company.

Long before the discovery of petroleum in Pennsylvania a party of hunters stumbled on a petroleum spring in Calcasieu. The Louisiana Petroleum Company was organized to bore for it, and while boring discovered that side by side with the oil was one of the most valuable deposits of nearly pure sulphur in the world. The sulphur was 400 feet below the surface and extended below, 800 feet further. There was no doubt or question about this, but, unfortunately, just above the sulphur was a quicksand 160 feet thick. One effort after the other to reach the sulphur failed. After several deaths the American Sulphur Company gave up the enterprise. Then a Belgian engineer undertook the work and endeavored to neutralize the quicksand by freezing it solid and boring it through (Poetsch process) and erected valuable refrigerating machinery for that purpose, but the quicksand would not stay frozen and that system of mining had to be abandoned.

Recently the Standard Oil Company obtained control of the property. It set about mining in a fashion the very opposite to that of the Belgian engineer. Instead of using freezing as the means of getting at the sulphur, it is trying heat. Superheated water is forced through ten-inch cased borehole on the sulphur, melting it. The liquid sulphur water is then pumped up. A little exposure to the air evaporates the water and leaves almost pure sulphur. The experiment has been successful beyond expectations.

MISCELLANEOUS.

PHENOMENA OF THE HAIR.

A fact not generally recognized, and the importance of which is woefully misunderstood by the majority of those who have looked into the matter, is the old truth that the hair is the barometer of a person's health and character.

Before introducing examples it will be necessary to explain the nature and composition of the hair. The hair consists of a root, a shaft, and a tip, the latter two being the projecting parts. Its substance is composed of a horny material containing the pigment granules, which are developed in the root, and the color of which depends on the presence of a peculiar oil—sepia tint in dark, blood red in red, yellowish in fair hair. While it was generally admitted that the hair of all mammalia had nerve connection, a similar state of affairs has been denied with reference to human hair until quite recently. The past lack of knowledge accounts for the skepticism of the modern physiologists above mentioned. Their argument was logical: If nerve activity did not reach the hair root, it could not affect it.

Let us settle one more point, the cause of gray hair in advanced life. The grayness commences at the hair bulb, where the cells are produced, and rises upward to the tip. It is caused by a deficiency and the degeneration respectively of the pigment matter. The coloring stuff either gives out or retrogrades. The chemist can perform the same for you in an incredibly short time by simply soaking your raven or auburn locks removed from the head in alcohol or ether.

Dr. Landois of the Greifswald Clinic had a patient suffering from delirium tremens, who saw rats and other animals constantly running about him. He was extremely nervous, and when, on the fourth night after his arrival in the institute, one of the physicians entered the ward suddenly, he became so terrified that he wrapped himself up in his blanket, while his teeth chattered and his limbs trembled. Next morning the patients and medical attendants observed a great change in the appearance of the man. Three-fourths of his hair and beard had become gray. The celebrated Dr. Virchow, among other authorities, investigated the case, and gave it as his opinion that degeneration of the pigment matter had nothing to do with the change.

The French physician, Raymond, had a female patient suffering from neuralgia. The lady's hair was jet black. After an especially bad attack of pain the hair took on a reddish hue, and after some hours faded into gray. The change occurred within a space of five hours.

Several medical reports set forth that patients suffering from disease of the nerves in the head became gray at the very spots where pains manifested themselves. This change, in the majority of cases, took place slowly; in some cases it occurred over night.

A young man, 18 years old, serving in the German army as an aspirant for a Lieutenantship, had been discovered in the act of hazard playing by his chief. He feared to be dishonorably dismissed from his regiment and spent twenty days in dreadful anticipations. When finally his case was passed on by his Colonel, that gentleman decided not to punish the young fellow on condition that he promised never to touch a card. After it was all over I cut a bunch of hair from the culprit's head to subject it to a microscopical investigation.

In this connection it should be stated that the growth of hair allows of measurement day by day. At an average young people's hair grows at the rate of fifteen lines (twelve lines make one inch) per month, but there are exceptions. My young friend's hair, according to previous investigations, grew only at the rate of one-fourth of a line per day. Taking this for the basis of my examination, it was easy to determine on what particular days certain portions of the hair I cut from his head had formed. I found that, beginning with the particles formed on July 5, and terminating with the formations of July 24, the hair had changed from brown to reddish and light bluish tints, increasing in intensity until under the microscope it appeared almost a yellowish white.

Recourse to the young fellow's diary showed that during that period he had gambled, losing steadily. Consequently his nervous excitement grew apace. On the 24th it reached its height, when the rascal found himself vis-a-vis of Nemesis personified by his superior officer. After that followed a period of quiet resignation, during which time the hair formations assumed their natural color, but as the day of judgment drew near, in the second week of August, the tint changed again from brown to brown yellow and bluish green. The inference is obvious.

A gentleman of my acquaintance received on October 16 last year news that his only son was suffering with a fatal malady. On November 4 the patient was declared to be out of danger. Five days later I cut a bunch of hair from my friend's head, and, after conducting preliminary investigations similar to those in the case of the young soldier, I let the microscope tell the story. The formations from the roots upward covering a period of five days, were entirely normal; those formed between October 16 and November 4 exhibited the following tints:

Black blue turned red, red turned yellowish brown, yellowish brown, blood orange, blood orange a light yellow.

I also discovered another phenomenon in connection with this case, as well as with others that have come under my observation. The particle of hair grown on the day when the individual experienced a sudden shock—at the news of a son's fatal illness, for instance—seemed to be bent, so as to occasion a flaw in it, and at the concave part of that impression I found a number of infinitesimal corpuscles, apparently parts of the hair root. That shows the tremendous force which the nerves and muscles exercise over the hair, a symptom, by the way, which the average individual finds exemplified in the sensation commonly called "goose flesh" or goose skin. It is endured as a consequence of sudden fright or terror. The skin of the head for the moment loses its smoothness, the hair roots elevate, the hair itself becomes rigid, the color of the skin is pale. Medical science explains this phenomena as follows: The hair contains certain muscular fibre cells, which arise in the upper part of the corium. As each hair enters the skin obliquely, forming an acute angle with the surface, and as the muscle lies in the corresponding obtuse angle, its contraction erects the hair, that is, makes it stand up.

The microscope does not explain the last-mentioned phenomena; it shows, however, the nature of the causes that make the hair appear white as the consequence of fear, distress or any strong mental excitement. As already stated, the sensation is apparently due to degeneration of the pigment matter. According to my own investigations it is occasioned by air bubbles arising in the shaft of the hair, and completely enveloping the color particles. How this process comes about science has not yet discovered. It is an open question whether the air is admitted from outside or whether the elastic fluid is the result of decomposition in the interior of the hair shaft or roots.

Another explanation may be mentioned here which says the process may result from the throwing off of some fluid or acid that chemically destroys the coloring matter.

Though our knowledge of the barometer qualities of the hair is yet crude and unfinished, its practical application, even at this early state of medical inquiry, promises advantageous results, for it furnishes not only direct proofs of the existence of mental and physical infirmities, but also, indirectly, denotes a person's healthy condition.—*Condensed from St. Louis Globe-Democrat.*

ELEPHANT WORKERS IN RANGOON.

We had seen many elephants during our Indian journey, and in a variety of occupations, from the temple elephants engaged in their solemn and sleepy processions to the huge and well-groomed animals belonging to the artillery batteries at Quetta and Peshawur on the Afghan frontier, and we had listened to not a few tales of what they could do, sometimes with just a shade of incredulity.

There are about a dozen elephants employed in the work of the yard, and all of these but one are males. This may and probably does, arise from the fact that the males are usually larger and stronger than the female elephants, but, judging from the specimen we saw, it cannot be from any superiority of intelligence on the part of the male animal. The solitary female worker, indeed, is a veritable maid-of-all-work about the yard, and no kind of work appears to come amiss to her. At one time she may be seen holding a log up to the saw when at work, either endwise or across, as occasion may require; at another she is dragging the slabs away with the end of her trunk, and piling them in heaps with all the regularity and skill of the most neat-handed workman; at a third she is making a stack of the sawn boards, or sweeping the sawdust from the mill-house floor with a gigantic broom. The meaning of the whistle to knock off work is not better known to any workman on the place than to her, and it is no easy matter to induce her to do a single trunk's turn when the signal has once sounded.

The log, once piloted to shore, will, at the word of command if not of a greater weight than about a ton and a half, be prized up by the animal's tusk, and then grasped with the trunk carefully and exactly in the middle, and carried to the spot where it is wanted. Arrived at the heap of logs in the yard, he will place one end on the ground and the other on the heap, and then proceed with the most systematic care to push it up and adjust it with the point of his tusks.

You cannot overload an elephant, however, for the animal will at once refuse any load which he considers beyond his strength, and there is practically no appeal from the elephant's opinion on such a question. In case of a log being brought ashore which seems to be too large and heavy for a single elephant, a second is called to his assistance, and the two animals proceed quietly to pick it up by the extreme ends and carry it to the required heap, where they deposit it with the utmost care, even examining it critically to see that it is perfectly in line with the rest of the stack. For this and all other nice processes of adjustment the point of the trunk is the instrument used.

It has been said that an elephant can do everything but speak; and, indeed, we were often disposed to doubt whether there was even this exception. Whatever emotion one of these animals feels he seems ready to express in sound, and so various are the modulations of his voice and so ready their sympathy and apparent comprehension of one another, that we could hardly doubt that the impression that elephants cannot speak was due rather to our ignorance than to their want of the power of making themselves understood. The elephant is very liable to sunstroke, especially when working in the water, and even on shore he is generally furnished with a cover for his head during the hours of the greatest heat. A good elephant is of such value that his health is not to be risked lightly, and, indeed, after we had seen what they could do, we were inclined to go further, and say that a well-trained elephant is absolutely invaluable for heavy labor in a climate such as that in which he finds his natural home.—*From Harpers Weekly.*

TREATMENT FOR ELECTRIC SHOCK.

Some time since, the Paris Academy of Medicine were commissioned by the Minister of Public Works to find if possible some method for saving the lives of persons affected by electric shock.

The professional gentlemen were especially demanded to recommend a method that was at once simple and capable of execution at a moment's notice and by any intelligent person on hand. The Academy selected a committee of electrical experts to report on the case, and the committee began its labors under the Presidency of Dr. A. D'Arsonval, well known on the other side of the ocean as an authority in all matters connected with electricity.

After a careful investigation the committee made a report. In it Dr. D'Arsonval first explains that electricity occasions death of two different sorts: (1) By the disruptive and electrolytic efforts of the discharge, causing injury or destruction of the tissues. This death is final. (2) By arrest of respiration and syncope caused by excitement of the nerve centres. In the latter case there are no material injuries, and death is merely apparent. In both cases the shock may be of the nature termed "heavy." "Heavy shocks" have heretofore been generally considered "sure death," on the supposition that the current produces a contraction of the arteries through its influence on the nervous system, and that this causes an overpowering impediment to the flow of the blood which the heart is unable to overcome. But this is true only if the victim is left unaided for a considerable time, or if his would-be rescuers cease their efforts at too early a period.

"The writer," continues Dr. D'Arsonval, "has always maintained that even the victims of very heavy shocks—as long as the tissues are not destroyed—may be resuscitated by means of artificial respiration. I learned this fact by numerous experiments, and the report of a typical accident in which my method was successfully tried confirmed all I ever entertained for it."

He then quotes instances in which in one case a man was accidently subjected to a current of 4,500 volts for six or seven minutes and was resuscitated, and in another case to 3,000 volts and by the application of the methods recommended his life was saved. The following are the recommendations of Dr. D'Arsonval and the commission:

"My formula for reviving the victims of electric shock is this: A person so disabled should be treated like one drowned. These are the directive rules, which not only workmen in electrical industries but every citizen and every friend of humanity should know by heart:

"Above all, break the contact with the conductors. If the current can be instantly cut off, so much the better. If not, lose no time by telephoning or sending, but apply yourself directly to the body that must be removed.

"In doing so touch not the victim on face or hands, or any naked part of his body. You may try to lift him up by the coat-tails, or after throwing a blanket or coat around him. Mind, they must be dry. Also remember that dry wood is a non-conductor. You may use a stick to draw the body over to one side, or to hold back a live wire. To lift the victim off a cross-bar pass a piece of lumber under his heels and raise him up. The same should be done if the body is in contact with the ground. His feet should be raised from the earth immediately. Any piece of wood, or furniture, or cloth will do.

"The body should be carried into the open or a room where air has free access. All not directly engaged in the work of rescue should be instantly dismissed from the place. The body must be placed upon the back after the shirt and collar have been loosened. Raise the shoulders and let the head fall back.

"Then begin the work of restoring respiration; that is, seize both arms and draw them energetically over the head, bringing them nearly together and holding them in that position for a couple of seconds. These movements having expanded the chest and pressed air into the lungs, carry the arms down to the sides and front of the chest, doubling them up at the elbows, in order to expel the air from the lungs. Continue in this for at least an hour, unless respiration sets in before.

"A second samaritan should at the same time seize the tongue of the victim—it is well to protect one's finger with a piece of cloth or glove for this process—and draw it out while the arms are extended over the head, allowing it to recede when the arms are pressed against the sides of the breast. Both these manœuvres should be carried on with as little interruption as possible. Twenty times per minute is not too much.

"If the victim shows a tendency to clinch his teeth, keep them apart by placing a piece of wood or anything handy between them.

"It is also advised to rub the body with brushes, brooms and cloth, in order to promote the circulation of the blood.

"Do not administer stimulants unless a medical person pronounces it safe to do so. When possible procure a tank of oxygen gas from the nearest drug store, and after improvising a cone, place the tube over the mouth and nose while the gas is issuing. It is a powerful stimulant to the heart's action under certain conditions, and will aid respiration."

AMERICAN COMFORT AND LUXURY.

New York still leads the vulgar race with the most costly art-gallery bar-room, but the other cities boast what their saloon *habitues* would call "close seconds." Buffalo has such a palace, and whereas New York has long had a bar-room with silver dollars let into the floor, Chicago led with the idea, and has five times as many dollars in the floor of the greatest and finest barber shop in Christendom. And Denver prides itself upon a saloon whose floor is studded with twenty-dollar gold coins.

There is no candy and soda water shop in America to equal one in Chicago, whose walls are coated with looking glass cut to gleam like jewels. We pride ourselves upon our railway depot, but Philadelphia has two fine ones—the Pennsylvania and the Reading—and St. Louis' Union depot and the Illinois Central Railway depot in Chicago are splendid stations. San Francisco has swimming baths that no other city parallels, and that city and New Orleans and Galveston have refreshing water-side resorts within their boundaries the like of which the people of other cities are put to trouble, expense, and travel to get at. Chicago has a jewelry store second only to Tiffany's, and approached in only two other American cities—Cleveland and San Francisco. St. Louis has two jewelry stores nearly as fine. The most ambitious shop for the sale of bric-a-brac, outside of New York, is in Cleveland, and no city on the continent has such a book store as McClurg's in Chicago. Pittsburg has one of the finest and most modern theatres in the world, wherein the actors are cared for as they are nowhere else while at work. The best theatres of Chicago are of the first class, and St. Paul, Milwaukee, Cleveland and Denver have each at least one theatre that is finer than some noted ones on Broadway.

Many cities now display tall buildings, but the only dizzy ones—"sky scrapers," as the firemen call them—are in the only two cities in which there are need and excuse for them. Those cities are New York and Chicago, in both of which, for different reasons, the business districts are cramped. As for the club houses of the country, there are none of the conventional types here or in London that are of a higher grade than three in Chicago—the Chicago, the Chicago Athletic and the Union League. There are few clubs in cities of the same size of the East that have better headquarters than the Detroit, Minneapolis, Pacific Union and Bohemian of San Francisco, and the Boston club of New Orleans. The Jewish club of Cleveland should go in the same category. The *Garten Verein*, or Garden club, of Galveston, is a unique institution, delightful beyond any form or variation of the country club in America. The modern plan of putting the kitchens in the tops of buildings has been adopted in certain clubs and hotels in many cities, even of the size of Milwaukee and still smaller Duluth. In their concessions to the women and their quarters for them the Western clubs are far more progressive than most of ours in the East. A large, costly, and attractive "arcade," or interior court of shops, in the business centre of Cleveland, is said to be the finest except one that is in southern Europe. The public parks which Chicago already possesses, and those that are in various stages of development in St. Louis, Milwaukee, Minneapolis and San Francisco, are among the noblest works of our people. Noble splendid residence streets are among the possessions of Cleveland, Minneapolis, St. Louis, San Francisco, Detroit and New Orleans. The finest ones of the semi-parkway type are in Buffalo, St. Paul and Milwaukee.—*From Harper's Weekly.*

WARM FEET.

You will never be in good health and never do your best work if your feet are constantly cold. Grave diseases of the throat and lungs are caused by cold feet alone, and these troubles are always aggravated by a frigid condition of the lower extremities. If proper footwear does not give relief, consult a physician, for the chances are the system is "run down" and radical measures are necessary. In nine cases out of ten, however, the foot covering is to blame, either because of its shape or its material. Save in warm weather, and for low-cut shoes, leather, as ordinarily prepared, has serious objections. It lacks two prime qualities—porosity and capacity for absorption—being in this respect too much like rubber. No foot can remain either comfortable or healthy if kept in a perpetual bath of its own emanations and excretions. Leather, especially that of the more porous varieties, may be tolerated for the outside, but for cold weather it should always be lined with woolen cloth, or, better, with wool felt. In fact, for all cold climates, and for winter wear in all climates where there is any winter, a footgear made from all-wool felt approaches the ideal. According to modern notions, any illness in one part of the body may be occasioned by some irritating cause far removed from the seat of the trouble. Just how this is cannot always be clearly explained, but that such connection does sometimes exist is beyond dispute. In the matter under discussion, if the nerves of the whole body are irritated by a tight shoe, or the extreme coldness of the extremities makes extra demand upon the blood supply, there is neither nerve force nor blood enough left for other functions.—*From the Vocalist.*

LAUNDERED AIR.

A plan for cleaning the air to be used for ventilating purposes, which furnishes to the offices absolutely pure instead of the usual dust, soot and germ laden air of crowded cities, has been put in operation at the offices of the Chicago Telephone Company.

This system, so far as known, is not in operation elsewhere in this country, and its remarkable success is attracting much attention from architects and manufacturers. It has suggested an innovation in the construction of the big office buildings which may lead to a revolution in heating and ventilating systems.

In its workings the system, which has been recently perfected by A. V. Abbott, Chief Engineer of the Chicago Telephone Company, resembles nothing more closely than a laundry. The air breathed by the little army of young women on the top floor of the building is first washed, then dried, then heated or cooled, as the case demands, and finally, to carry out the comparison, it is pressed. The washing removes a wagon load of soot and dust and disease germs, the mere sight of which is enough to arouse wonder in the average man's mind how he lives in the climate of Chicago.

The drying removes every trace of moisture, the heating or cooling brings the air to just the right temperature, and the compression follows as a natural consequence of the introduction of several thousand cubic feet of air every minute into a big room almost hermetically sealed.

It was to overcome conditions which seriously impaired the efficiency of the telephone company's service that the present system of ventilation was devised. The delicate apparatus of the huge switchboard was in a constant state of disorder, owing to the dust and soot that entered the room. Subscribers were continually complaining that their telephones were out of order, as many as 400 complaints being on file in General Manager Hibbard's office at once.

The trouble was not in the telephones, but in the operating room. In this room, 40 by 90 feet, is a switchboard in which are 100,000 little holes, each hole representing four wires. When a subscriber asks for a connection with some other subscriber, the operator pushes a brass plug into one of the holes, which raises a delicate spring known as a "jack." The presence of a speck of dust or soot on one of these "jacks" renders a connection impossible, and then the subscriber complains.

Pure, fresh air, always of the same temperature, now makes the operating room about the most desirable place to work in Chicago. Down in the basement of the building is a big rotary fan that sucks in the air which the ordinary citizen is obliged to breathe. As the current enters the basement through a huge tube it passes into a tightly closed chamber in which a rainstorm is constantly raging. This condition is effected by three rows of small nozzles or atomizers, which discharge a perfect cloud of spray and remove every particle of dirt from the air. The dirt passes off into a well, while the air is whirled through a battery of spiral tubes. The twisting motion of centrifugal force removes the last trace of moisture from the air, and it then passes into another chamber, where it is heated in the winter or cooled with ice in the summer. Then the current is directed upward through a shaft that leads to the top floor of the building and into the operating room.

Every window in the operating room is tightly closed and sealed around the edges, while double doors make it necessary for one to enter the room through what constitutes an air-locked passage. The supply is forced through vents, or registers, opening through the ceiling from a tube that runs around the room. It is compressed air, although its density is so slight as to be almost inappreciable. Every three minutes the air is completely changed, the supply being calculated at 10,000 cubic feet a minute. It leaves the room through outlets fixed in each window, that are provided with delicately adjusted valves opening outward. These outlet tubes take in the air from near the floor, the current being strong enough to draw a piece of paper through the tube and throw it outside. As the valves open outward, there is no chance for the introduction of foul air from the street.

A self-recording thermometer in the operating room tells the story of the success of the system in unmistakable language. Yesterday the instrument showed an almost perfect circle the record of a month's temperature. One or two little jogs in the red tracing showed a variation, at no time exceeding two degrees, a record equal to that of the most carefully regulated hospital. This perfection is attained by a thermostat arranged to keep the air at an even temperature. During the heated season last September, when the mercury was marking 95 degrees every day, the use of five tons of ice daily in the basement of the building reduced the temperature of the operating room to 75 and 80 degrees. Mr. Hibbins estimates that the monthly expense of operating the system is not over $100.—*Chicago Times-Herald.*

THE SEASON OF SHOOTING STARS.

The months of August and November are those in which the so-called shooting stars are most abundant; but they may be seen any night in the year, when the sky is clear, darting out of space across the heavens and vanishing almost before the eye can catch a glimpse of them. It is during August and November that the earth in its course passes through the pathway of the principal meteor streams; but the aerolites are always falling onto the earth, and it is estimated that 400 millions of these fragments are hurled at our globe every 24 hours. Occasionally, these come down in large masses, and there is at the Natural History Museum at South Kensington a mass of meteoric iron weighing 1,400 lbs. It is, however, only a portion of a much larger mass that fell in South America, while on the Continent much greater masses have been found and preserved. But no record exists of anyone having ever been injured by these falling bodies, a fact which is remarkable, considering the size and density of many of them. The reason why the meteorites do no injury to the earth is that the atmosphere by which this globe is surrounded protects us. This may appear strange; but it is not so remarkable. If the heaviest shot we could fire with the most powerful projectile yet made were fired into the ocean, the animals living at the bottom would be completely uninjured by it, for the reason that the mass of water would break the force of the projectile. What the water is to the animal inhabiting the ocean bed the surrounding atmosphere is to the people on the earth. The rush of the aerolites through the atmosphere at a velocity of from 30 to 40 miles per second causes a friction that sets them ablaze, and they are reduced to powder. All over the world this powder is spread, in the deepest valleys, on the loftiest mountains, in the bottom of the sea, and on the plains. It is but rarely that fragments of any size reach the earth; but were it not for our atmosphere, life on this globe would be impossible, owing to the ceaseless shower of stone and iron which is ever being poured upon us from space.

What are called shooting stars, as all with the most elementary knowledge of astronomy are aware, are no more stars than are the Aurora Borealis. Each star is itself a sun, the smallest being in all probability much larger than our own sun, and a million times bigger than the globe we inhabit. So far distant from us are these remote worlds, that if the nearest of them left its orbit and began to rush across the sky to-morrow, we should not see it start for several years to come, and it would take millions of years, traveling all the while thousands of times more rapidly than a cannon shot, to reach the earth. The objects that flash across the heavens are merely solid fragments of stone and iron, revolving in swarms around the sun in well defined orbits at from 30 to 40 miles per second. In olden times it was natural enough for people to speak of them as shooting stars; but there is no longer any excuse for the misnomer. There is one large meteoric stream which takes 33 years to travel round the sun in a kind of egg-shaped orbit, the sun, or focus, being situated near one extremity of the egg. The stream is upwards of 200,000 miles broad, and although traveling at the velocity previously mentioned, it requires fourteen months for it to pass any given point. It was in 1866 that the earth last passed through this rich meteoric region, and on that occasion one observer at Greenwich counted no less than 8,000 of these transient visitants. In four years time, the earth will again pass through the course of this mighty army of meteors, and on the 13th and 14th of November, 1899, we shall be right in the thick of the stream. If it is night time with us when the earth dives into it, meteors by tens of thousands will be visible during the five hours passage. But if it be daylight with us, it will be night in other portions of the world, and there are certain to be multitudes in all quarters of the globe on the look-out for the brilliant spectacle. If these aerolites were really "shooting stars," and fell upon this earth, any one of them would completely overlap this globe and crush down the mightiest buildings raised by the hand of man, break to powder the towering mountains, and by the sheer force of impact fuse the whole into a molten mass. It is quite bad enough to have large masses of iron hurled at us from space; cut if the stars left their courses and fell upon us, the first that reached this planet would annihilate the world.—*Newcastle, Eng., Chronicle.*

CHANGE OF SCENE AT HOME.

A change of air and scene is often prescribed for invalids. In many cases it is a wise prescription, but in others the journey entails expense which cannot be borne without great sacrifice, and means for the sufferer an unhappy isolation among strangers, and a deprivation of the home comforts and care which are so necessary to a sick person's peace and well-being. Homesick and disheartened, the invalid returns from his sojourn among strange scenes not benefitted by the change, and alas! his return is too often but a coming home to die.

Happily it is possible to secure many of the advantages of a change without incurring the disadvantages just described. In other words, a real change may often be secured without sending the patient away from home.

For one thing, his room may be changed to the most cheery and sunshiny in the house. And here, with a little attention an almost daily sunbath may be obtained, a sunbath quite as good as would be afforded at the fine sanitariums in foreign lands or in this country.

Well wrapped from cold and draughts, the patient can sit on the lawn or the piazza, or in the open field or pasture, and breathe the life-giving air. Walks and rides, which need only to be planned for, will aid in the good work. Open windows and open doors, with a fire when needed, will in many instances afford a most salubrious change of air after the close, stuffy rooms in which sick people are prone to spend their time.

A friend,—perhaps a former schoolmate,—where a nurse is out of the question, may be glad to pay the invalid a visit, making himself a cheerful companion, always ready to amuse, to read aloud, to play games, and in general to keep away the "blues."

These few hints will suggest some of the changes that can be wrought at home to aid in restoring the invalid to health, changes which may be effected at small cost of money or convenience.

And after all, if the sufferer fails to find the health hoped for, it is at least a comfort that his last days should be spent at home, sheltered by love and care, and not among strangers, homesick and wretched.—*Youths' Companion.*

THE MARVELLOUS NEW LIGHT.

Great progress has already been made with Prof. Rontgen's wonderful discovery of a new light, if that be a proper description of it, which penetrates many solids, among them aluminum, as if they were glass. Prof. Klupathy of the Pesth University has obtained even greater success in photographing concealed objects. He also varied the experiments by enclosing objects to be photographed in a variety of coverings. It has been ascertained that the light from Crooke's tube penetrates not only organic matter, but also one metal, aluminum. Prof. Rontgen has sent rays of the new chemical light through aluminum plates an inch thick, and they went as clean through as if the substance had been glass. The same was the case with two sets of books, including many volumes; these he placed between a Crooke's tube and an ordinary compass. Behind them was a wooden case with dry plate, and the result was as complete a photograph of the compass as is possible.

All the professor's experiments have been successfully repeated in London this week, and many of them were shown at the meeting of the Camera Club on Thursday. It proves that the strange medium which produces images of hidden objects on a photograph plate is not light at all. It is equally incorrect to describe it as electricity. It is some force or influence produced by Crooke's tube when excited in a peculiar manner, but it is not the visible light or glow which comes from the tube. That visible light has the same qualities as an ordinary light. The invisible new medium has not the same qualities. For instance, it will not penetrate clear glass. It will penetrate ground glass, though more feebly than wood and other organic matter. Aluminum is far more transparent than glass. Even copper is less opaque than glass.

Mr. Swinton, the well-known electrical engineer, showed a large collection of these strange photographs which had been taken to the Camera Club. He employed a half horse power electric current, and passing it through an induction coil, loaded ten Leyden jars. The discharge from them was passed through a second induction coil by a secondary system by which Crooke's tube was excited. He said that he had only succeeded in this way, and had failed with Crooke's tubes excited by an ordinary induction coil.

He showed pictures of the skeleton of a living human hand, a purse containing coins in which only the coins and the metal clasp of the purse were reproduced, and other objects.

The method of procedure was simply to place the object to be photographed between Crooke's tube and the usual wooden case containing the sensitive plate in which the negative is placed when carried to and from the camera. The slide is not removed, and an exposure of from four to twenty minutes is required.

It is perhaps no photograph in the ordinary sense, because no lenses are used. It is not a negative, but a positive plate that is obtained.—*N. Y. Sun.*

LIGHT AND DISEASE.

Two objections are commonly brought against the disinfectants recommended for general use; they are expensive and cannot be used promiscuously without more or less damage. It will be welcome news, therefore, that investigations are now going on, looking to some practical application of the well-known disinfecting properties of light.

Various species of microbes have been examined to ascertain their power of resistance to the sun's rays. For instance Koch has shown that the germ of consumption can withstand the solar rays for only a short time. Cholera germs are easily rendered inert under the influence of direct sunlight, and other germs are susceptible, in varying degrees, to the same influence.

Experiments have been made upon fabrics and manufactured articles of household use, like furniture, by first impregnating them with germs and afterward exposing them to the direct action of the sunlight. It is found that while the sun's rays have a distinct action upon the upper layers of stuff, the disinfecting process is somewhat retarded in the lower or deeper layers. Objects of a dark color are but little affected.

Investigators report that direct solar light kills in from one to two hours any germs of typhoid fever which may be present in water. Even diffused light exerts an appreciable effect in purifying water. In fairly clear water the effect has been known to be exerted at a depth of more than six feet.

In bodies of water exposed to the rays of the sun a minimum of germs is found in the early evening and night hours, and as might have been expected, a maximum of the same germs is found in the early part of the day.

A study of the action of artificial light upon disease has revealed the fact that nearly every germ develops in some one or two particular rays of the spectrum. For instance, typhoid germs multiply rapidly in orange, deep red, or deep violet rays, while they cease to develop in green, blue, or pale violet rays.

This corresponds in some degree to facts elicited by a study of the action of artificial light upon plant-life in general, of which latter facts growers have taken advantage to produce wonderful results.

Of all forms of artificial light the arc-electric seems to promise greatest results to experimenters on this interesting subject, but it is probable that nothing can equal the direct rays of the sun itself.

That the sun does exert an important influence as a disinfectant—and this not merely because of its warmth or drying power—is not to be disputed.—*Youth's Companion.*

ELECTRICITY FOR HIGH-SPEED RAILROAD TRAINS.

If we wish to obtain higher speeds on railroads we must employ more power in proportion to weight than we now have at our disposal with the modern steam-driven locomotive. In order to greatly increase the power, it is necessary that the source of energy should be stationary and the energy transmitted to the moving train, and the only practical way of accomplishing this on a large scale is by employing electricity. An electric engine may be made to develop almost any amount of power, and still be well within the weight and bulk of an ordinary locomotive. In regard to the question of supplying a long road with a powerful high-tension current, I would say that when trains are propelled by steam it is necessary to employ a large number of separate steam engines. Why, then, should there be any objection to using a large number of steam for an electrical railroad? It certainly costs no more to run a stationary engine than a locomotive engine, and the engines for supplying the current could be placed at regular intervals along the line. The tension of the current might be, say, from 2,000 to 5,000 volts. The main conductors should be thoroughly insulated and protected from atmospheric influences. The actual rubbing surface, transmitting the current to the moving train, should be in relatively short sections, and connected to the main conductor only while the train is actually passing, the latter being provided with suitable apparatus for switching the current in ahead of the train and cutting it out after the train had passed. In this manner there would be very little loss of current, even if at a very high tension, and nearly all danger of accidents would be avoided.

With the present steam engines it is necessary to use the very best quality of coal, costing at least twice as much per ton as the cheap coal. A locomotive steam engine has, of necessity, to be a high-pressure, non-condensing engine, and the exhaust steam has to be discharged against considerably more than an atmosphere of pressure, because it has to be employed for inducing the draught. Moreover, for reasons before stated, a locomotive engine must be limited in size.

A stationary engine, however, may be made of any size. It may be a compound condensing, or a triple expansion engine. Large boilers may be employed, having a very large heating surface in proportion to the coal consumed; and the grate surface may be of any size, so that a very cheap coal may be employed. In this manner the cost of developing a given horse-power costs 60 per cent. less than it does on the locomotive.—*Hiram S. Maxim in Cassier's Magazine for January.*

TO RIDE IN A CROWDED CAR.

The following instructions in regard to how to stand successfully in a crowded street car were given in *The American Jewess* for the benefit of women, but from the gymnastic exhibitions we often see given by people of all ages and sexes they should be interesting to all. They are:

Always face the sides of the car, never the front or rear. When the car starts, lean slightly in direction in which it is going. When the car is about to stop lean toward the rear. Plant your feet as far apart as you comfortably can. When a car turns a corner incline the body toward the inside curve of the rails, and when feasible grasp the strap on the side of the car over this inside curve, thus reducing the strain to a minimum. Non-observance of this particular rule is the cause of the frantic clutches and involuntary displays of affection which the standers sometimes bestow upon those seated.

The philosophy of such rules is as follows: You lean toward the direction of the starting car, so that your body, which does not acquire the forward motion simultaneously with the car, shall, so to speak, not be left behind. The starting of the car restores the body to its usual erect posture. You lean toward the rear when the car stops to counteract the forward momentum acquired by the body while the car was in motion. In rounding a curve you lean toward the inside rail to counteract the centrifugal force which tends to throw objects from the centre. But the main thing for you to remember is: Always face the sides of the car. These rules are particularly applicable to cable cars, which rarely fail to start or stop with a jerk.

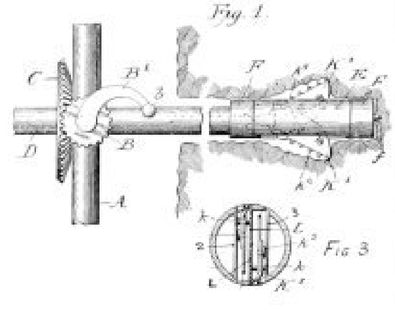
When alighting from the car place the left hand on the brass rod provided for the purpose (I assume that you alight on the railless side) and face the front of the car. Even if the car is still in motion, you are then safe. As for boarding moving cars, I should advise you to wait until your garb is better adapted for higher gymnastics.

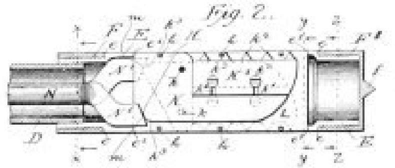
In case these rules prove beneficial the women may thank me. Should they be deficient, why, there's the man.

NEW INVENTIONS.

MINING REAMER.

No. 549,771. R. H. ELLIOTT AND J. B. CARRINGTON, BIRMINGHAM, ALA. *Patented Nov. 12th, 1895.* Fig. 1 shows the reamer in operation, enlarging a drilled hole, to make a pocket for powder. Fig. 2 is a section through the reamer, drawn on a larger scale; and Fig. 3 is a cross-section of the same on the line *y, y.* The body of the tool is made in halves which are held together at the ends by the cap F^1 and the band *E.* The end cap is provided with a conical point, on which the reamer turns when in use. The middle partition plate *L*, is firmly

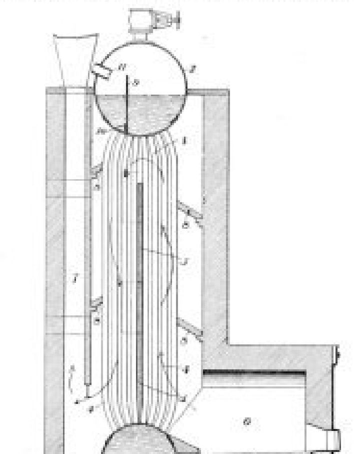




secured to both halves of the shell, and smaller plates 2 and 3, are fastened on each side of it. These plates provide bearings for the fulcrum pins *k*, upon which the cutters are hinged. Each cutter is provided with a removable toothed plate K^1 which can be adjusted by means of the screws k^2. A central rod *N*, having forked ends N^1, is used for driving the cutters outward. The ends N^1, bear upon the heels of the cutters at *a* and compel them to move outward equally. The tool is mounted and operated like an ordinary boring machine, as shown in Fig. 1.

STEAM BOILER.

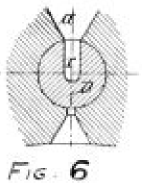
No. 548,455. JAMES PIERPOINT, PITTSBURGH, PENN'A. *Patented Oct. 22nd, 1895.* In the drawing, 2 represents the upper steam and water drum, 3 the mud-drum, and 4 the set of tubes connecting the same. Between the central rows is placed the fire-brick partition 5, which extends from the mud-drum upwardly to a point near the steam drum. 6 is the furnace, from whence the gases pass upwardly among the front rows of tubes, then descend among the rear rows, and thence ascend through the outlet flue 7. Deflecting plates 8 are employed to hold the gases in contact with the tubes, thus insuring the abstraction of heat thereby. In the steam and water drum there is a baffle-plate 9, which extends be-

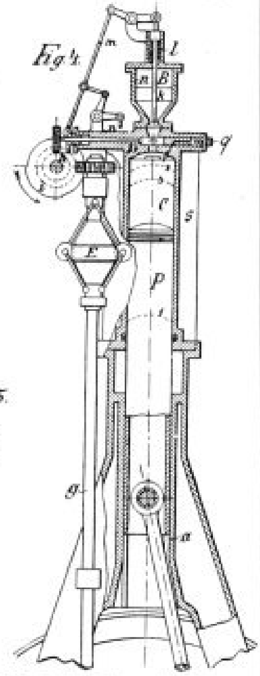


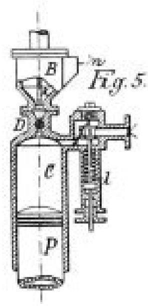
tween the tube ends to a point above the water level. The feed-water entering through the pipe 11 on the left hand side of the plate is prevented thereby from mingling with the hotter water rising through the tubes nearer the furnace, but descends through the rear rows in a less violent manner than in the main circuit, from which it is cut off by the baffle-plate, thereby giving a much better deposition of sediment. The heat of the gases is fully extracted on account of the lower temperature of the rear tubes down which the feed-water passes, while a violent circulation takes place between the front rows and these rear rows which are not cut off by the baffle-plate.

HEAT ENGINE.

No. 542,846. RUDOLF DIESEL, BERLIN, GERMANY. *Patented July 16th, 1895.* Fig. 4 is a section of the cylinder and attached working parts; Fig. 5 is a section taken at right angles to Fig. 4, and Fig. 6 is a section of the feeding valve, on a larger scale. This engine is designed to use finely ground coal, for the direct production of power, in the cylinder of the engine. Instead of burning the fuel under a boiler, as in the steam engine, or making it into gas with which to run a gas engine, the pulverized fuel is fed directly from the hopper *B*, into the top end of the cylinder, through the valve *D.* This valve is a cylindrical plug, having a pocket *c*, cut into one side, and it is revolved once in each two revolutions of the engine, by suitable gearing. When the pocket turns upward the ground coal fills the space, and as the valve revolves, the charge of coal drops into the top of the cylinder. At that instant, the piston or plunger *P*, has risen nearly to the top of its stroke, and the air in the cylinder has been compressed to such a degree that its temperature has risen above the burning point



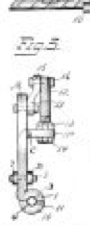




of the coal. The coal is ignited, but its combustion is controlled by the admission of air through the valve *g.* The combustion continues to about one-fourth or one-third stroke, and serves to partly maintain the pressure upon the piston, although the temperature within the cylinder actually falls. After the combustion ceases, the hot gases expand without transfer of heat, down to or even below atmospheric pressure. The gases are thus cooled by expansion, to such an extent that no artificial cooling arrangements, water jackets, etc. are needed. The range of temperature throughout each stroke is very great, and it is claimed therefore, that the economy is greater than in any other form of heat engine. The ashes being suspended in a finely divided state in the whirling gases, are blown out with them into the exhaust. The valve gear and arrangement of power cylinders and air pumps, are similar to those in ordinary gas engines.

CABLE GRIP.

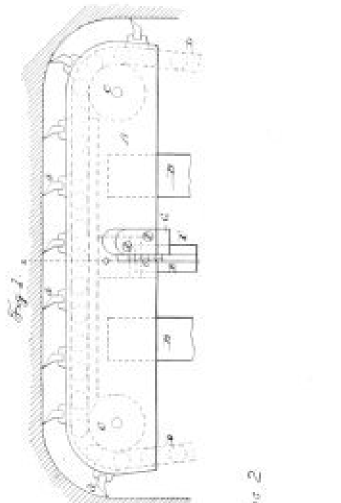
No. 549,893. R. F. BENNETT AND M. L. GEORGE, COAL CREEK, TENN. *Patented Nov. 19th, 1895.* Fig. 1 is a side view of the grip; Fig. 3 is an end view of the same, and Fig. 4 shows the application of the grip to a mine car. The grip is composed mainly of the bow *A*, which has curved lugs 1 and 2, and the hook *C.* The lever *D*, is pivoted to *A*, as shown in Fig. 3, and its upturned end is connected to *C* by an eye bolt 12. By adjusting the nuts 13 and 14, the tension of the grip upon the cable

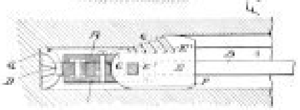


can be regulated as desired. The grip is supported by a rigid draw bar *B*, which is so connected to the car as to prevent it from falling low enough to foul the track, or from turning over. The draw bar being rigid, the cars cannot run over it when descending a grade. Thus, all rope riders are dispensed with. Two grips may be used, one at each end of a train, thus, making the connection of the cars to the cable entirely certain and safe.

MINING MACHINE.

No. 548,970. HENRY B. DIERDORFF, COLUMBUS, OHIO. *Patented Oct. 29th, 1895.* This device is designed to steady and guide the cutting head of machines which employ horizontal cutting chains for undercutting coal. It consists mainly of a saw-toothed cutter *E*, which is attached to the head plates *A.* Each tooth is higher than the one next in front, and takes but a small kerf, (about one-eighth of an inch) so that compara-

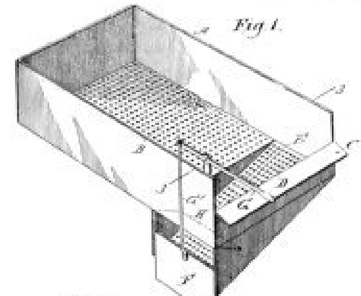


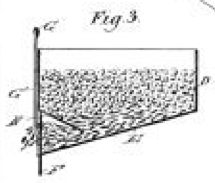


tively little force is required to drive it forward, as the cutter head advances. The cutter is made usually but ¼ inch thick and cuts a kerf ¾ inch high. This is found to be sufficient to properly guide the machine. The lower edge of the cutter is provided with a wide flange, which forms a shoe and thus supports the cutter head, and prevents it from sagging.

JIG BOX.

No. 548,665. WILLIAM O. LENTZ, MAUCH CHUNK, PENN'A. *Patented Oct. 29th, 1895.* Fig. 1 is a perspective view of the box; and Fig. 3 is a cross section through the slate box, on the line 3, 3. This pan is adapted to work with plunger jigs, in which the box is stationary and the water is moved, or with shaking jigs which vibrate the box in standing water. The lower end of the box is made into a slate pocket *E* hav-

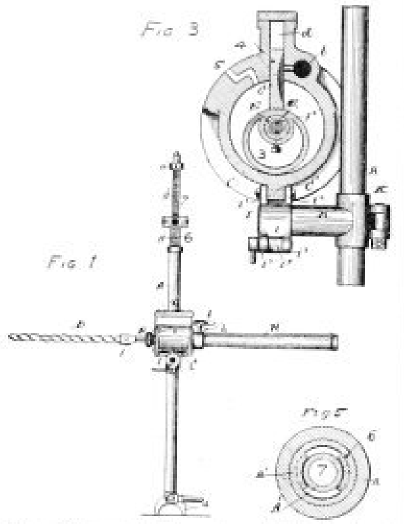




ing an inclined bottom as shown. A guard plate *H* prevents the contents from escaping too freely toward the gate *F.* In operation, the coal works to the top and flows over the lip or flange *C*, while the slate goes to the bottom and slides down past the edge of the guard plate *H*, to the gate *F.* This gate can be adjusted so as to secure a constant discharge of the slate over it thus permitting the jig to work continuously for any length of time.

COAL DRILL.

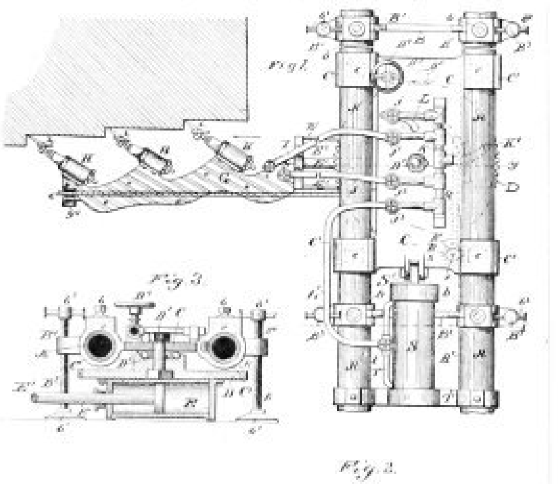
No. 551,139. EDWARD S. MCKINLAY, DENVER, COLO. *Patented Dec. 10th, 1895.* Fig. 1 is a side view of the machine ready for work; Fig. 3 is a cross-section of the motor on a larger scale; and Fig. 5 is a cross-section of the post. The motor is a rotary engine, and it is driven by steam or compressed air. The cylinder *C*, is divided by a partition into two chambers, in each of which there is a rotating piston 3, and a reciprocating plate 4. The pistons 3, are secured to the hollow shaft *E*, one opposite the other, so that the driving motion shall be nearly uniform. The shaft *E*, is provided with suitable feathers which engage grooves in the drill rod *R*, or is made to fit directly upon the spirals of the auger. In the latter case the machine may be operated very close to the face. Steam or air enters the motor at E', and exhausts at 5. The rear end of the auger, or drill rod is attached by a swivel joint to a piston, which moves within the feed cylinder *H*. Air or steam pressure is used to feed the auger into the cut. The post is made in three parts. The rod 7, is screwed into a long nut 6. The threads on the rod, and in the nut, are cut away, as shown in Fig. 5. In the position shown, the rod may slide in or out freely, and by turning it through one quarter of a revolution its threads are made to engage the threads of the nut. The post is then tightened in place by turning the nut 6. The outside of the nut is threaded into



the top of the post *A*. The motor and drilling mechanism are mounted upon a knee *I*, which may be clamped at any point upon the post *A*, by means of a clamp *K*.

MINING MACHINE.

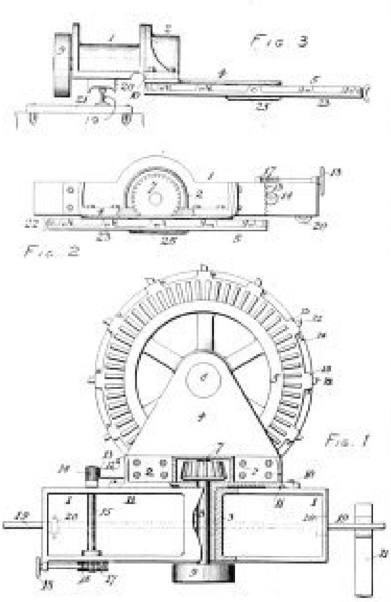
No. 550,896. Edward S. McKinlay, Denver, Colo. *Patented Dec. 3rd, 1895.* Fig. 1 is a top view of the machine; Fig. 2 is a sectional end view; and Fig. 3 is a cross section on the line *x*, *x*, of Fig. 1. The cutting mechanism which is employed in this machine consists of a number of small independent chiseling machines *H*, which are driven by compressed air, and are rigidly mounted on an arm *G*. This arm is attached to the machine by a center pin B^6, and it can be



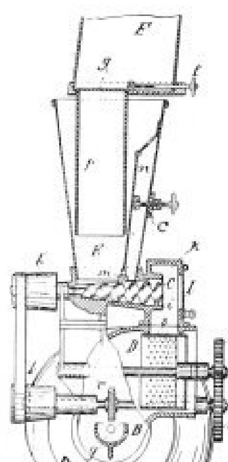
swung around through a considerable angle by means of the gear *D*, worm D^2, and hand wheel D^3. It is mounted upon a sliding frame which passes around each side of the cylinder *E*. By admitting air into the rear end of the cylinder the arm *G* is moved bodily forward, at right angles to the face of the coal. The cutting apparatus is mounted upon a slide or cross head *C*, which is movable upon the main frame bars *A*, *A*. It is attached to the piston rod of the feed cylinder *S*. When the arm *G* is pushed out to its furthest extent, it automatically reverses the valves upon the cylinder *E*, and it is at once drawn back. As it reaches the inner end of its travel, it trips a pawl *Q*, and thus releases the ratchet wheel *R*, and permits it to turn forward one tooth. The ratchet wheel is attached to the feed pinion R^1 which engages the rack R^2 upon the rear bar of the main frame. As soon as the ratchet is released, the pressure in the cylinder *S* drives the crosshead forward one step, and thus moves the arm *G* along, in a direction parallel to the face. The cutting cylinders *H*, are provided with long heavy pistons which have a very short stroke. Each piston rod carries a gang of chisels *N*, as shown, and the strokes are made with great rapidity. The chips are removed by means of the chain *c*.

CUTTER WHEELS FOR MINING MACHINES.

No. 550,944. William J. E. Carr, Leavenworth, Kansas. *Patented Dec. 10th, 1895.* Fig. 1 is a top view of the wheel and its mountings; Fig. 2 is a front, or edge view of the same;



and Fig. 3 is a vertical side view. This wheel is designed to operate like a circular saw, and in undercutting coal it is forced forward until the box on the pinion 7 encounters the face. The wheel is rotated by means of the teeth sunk in its upper face, and the pinion 7, shaft 8 and pulley 9. The main frame 1, has shoes 20, which ride upon the single rail 19. The frame 2, has circular V edges 11, which are clamped by the gibs 10. One end of the frame has a toothed sector 13, which engages the pinion 14. By turning the handwheel 18, the pinion may be revolved, and the saw frame may be inclined to any angle desired. As the shaft 8, lays in the axis of the center pin 3, about which the movement is made, the gears will mesh properly and will not be affected by the change of position.

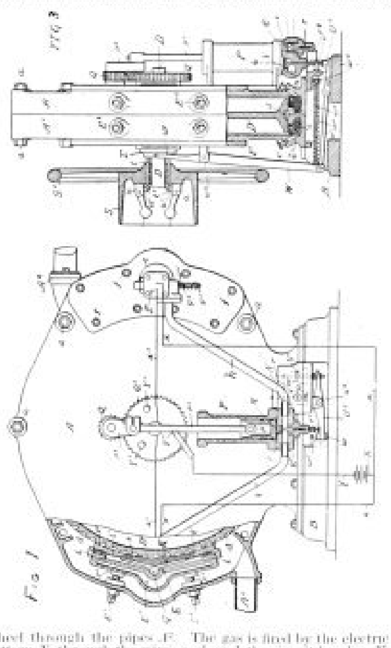


FEEDING COAL DUST.

No. 551,674. Ferdinand De Camp, Berlin, Germany. *Patented Dec. 10th, 1895.* This machine is designed to feed pulverized fuel into the furnaces of steam boilers, etc. The fuel is held in a bin *F*, and is delivered through a gate *g*, and chute *p*, into the hopper *E*. The sides of the hopper converge to a narrow slit, and discharges onto a tapering spiral conveyer *C*. The length of the opening may be varied by moving the block *m*, by means of the screw *z*, and lever *n*. As the fuel is discharged into the chamber *k*, it falls onto the perforated rim of the drum *D*, which is rotated by the gearing shown. All lumps are thus broken up and the fuel falls into the interior of *D*, in a shower of dust. The air which supplies the fan *A*, passes through the drum and carries the fuel with it. The fuel is thus divided properly, and is mixed with enough air to ensure good combustion; and is driven through the outlet *a*, into the furnace. The speed of the feeding spiral *C*, may be modified by shifting the belt upon the cone pulleys *bb'*.

GAS TURBINE.

No. 550,742. Wesley R. Campbell, Philadelphia, Penna. *Patented Dec. 3rd 1895.* Fig. 1 is a sectional side elevation; and Fig. 3 is an end view, also partly in section. This motor consists mainly of a wheel having a great number of small buckets formed in its rim, and two opposite gas chambers, in which gas is exploded at very short intervals. The exploding gas is directed by guide plates *K*, so that a considerable part of its force is spent upon the buckets *d*, in the rim of the wheel, thus causing it to revolve with great rapidity. The gas is mixed with air and is forced by the pump *P*, through the pipes *N*, into chamber *E*, one upon each side of the wheel. Here it is exploded, and passing through the channel *G*, is received by the guide plates *K*, and directed upon the wheel. Six explosions are made to each revolution of the wheel, three in each gas chamber, thus they follow each other so closely that the impulses given to the wheel are practically continuous. The governor *S*, controls the valves of the pump *P*, by means of the lever *W*, and wedge *w*, which limits their movement. The spent gases escape from the

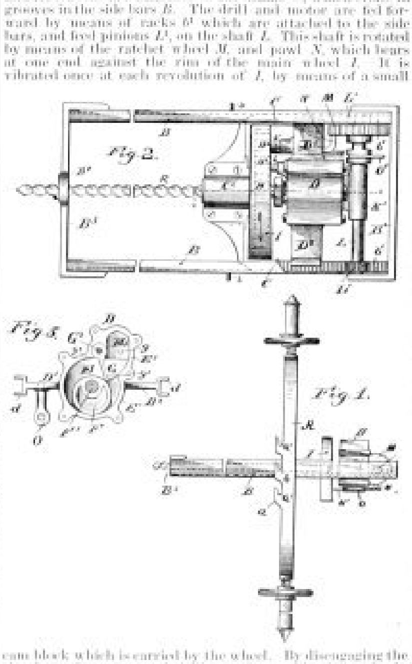


wheel through the pipes *F*. The gas is fired by the electric battery *X*, through the wires *x*, x^1, and the circuit breaker *Y*. The rim of the wheel is cleaned and lubricated by an oil pad *Z*, as shown in Fig. 3.

COAL DRILL.

No. 550,892. Benjamin A. Legg, Columbus, Ohio. *Patented Dec. 3rd, 1895.* Fig. 1 is a side elevation of the complete machine; Fig. 2 is a top view of the motor and drilling mechanism on a larger scale; and Fig. 5 is a cross section of the motor.

The motor is a rotary engine, which may be driven by compressed air or steam. It has two working chambers, each of which contains a rotating piston *F*, and a vibrating sector *G*. As *F* turns round, *G* moves in and out of the chamber E^2. The main spindle F^1 carries a pinion *H* on its front end, which drives the internal gear *I*, by means of an idler pinion H^1. The spindle of the wheel *I* turns in the bearing C^2, and the auger *B*, is attached to it by a suitable socket. The motor and feed works are attached to the frame *C*, which slides in grooves in the side bars *B*. The drill and motor are fed forward by means of racks b^1 which are attached to the side bars, and feed pinions L^1, on the shaft *L*. This shaft is rotated by means of the ratchet wheel *M*, and pawl *N*, which bears at one end against the rim of the main wheel *I*. It is vibrated once at each revolution of *I*, by means of a small



cam block which is carried by the wheel. By disengaging the clutch *O*, the motor and drill may be readily drawn back. The main frame *B* is supported on trunnions *b*, in notches on the post *A*, which is double.

The Colliery Engineer

AND

METAL MINER.

VOL. XVI.—NO. 8. SCRANTON, PA., MARCH, 1896. With Which is Combined THE MINING HERALD.

ANTHRACITE MINING

AT THE SOUTH WILKES-BARRE COLLIERY.

Geological Features, Methods of Mining, Ventilating and Drainage, Etc., at an Anthracite Colliery of Large Capacity.

Written for THE COLLIERY ENGINEER AND METAL MINER by W. W. Jones, Mining Engineer.

This colliery is located in the southern portion of the city of Wilkes-Barre, Pa., and near the center of the western half of the Northern or Wyoming-Lackawanna anthracite coal field.

It is one of ten collieries owned and operated by the Lehigh and Wilkes-Barre Coal Co., in the Wyoming region, among which it ranks second in point of production—(The Nottingham colliery at Plymouth, Pa., being the largest producing colliery of this company)—and gives employment to 1,000 men and boys.

The breaker prepares a superior grade of coal, and being situated as it is in the midst of a thriving city of about 50,000 population, it naturally enjoys an extensive retail trade in addition to its regular line shipments.

The surface openings consist of two hoisting shafts, Nos. 3 and 5 respectively, and one air-shaft.

No. 5 shaft, which is located at the corner of Parrish and High streets, was sunk in 1888 to the Baltimore vein a depth of 1,040 feet. It is 12′x52′ in size and is divided into 5 compartments. (See Fig. 3). A downcast airway 12′x12′, 2 hoist-ways each 7½′x12′, a man-way or pump-way 7½′x12′, and an upcast airway 14′ 10″x12′. From the surface down to solid rock, a distance of 30 feet, it is double timbered. On the outside, next to the wash, sets of 12″x12″ timber are placed 3 feet between centers and sheeted on the outside with 2-inch plank. On the inside next to the shaft, sets of 10″x10″ timber are placed "skin to skin" from the surface line to solid rock and 5 feet between centers from there down to the bottom of the shaft. The cross buntons (A, Fig. 3) between compartments are of 8″x10″ timber. A clear space of 12″ is left between the inner and outer sets of timbers which is filled with concrete from the solid rock to the surface line.

No. 3 shaft is located about 400 feet northeast of No. 5 shaft and was first sunk to the Hillman vein a depth of 700 feet and afterward extended to the Baltimore vein 267 feet deeper, or to a total depth of 967 feet. There is a landing in this shaft at the Hillman vein, but none at the Baltimore vein, that portion of the shaft extending below the Hillman vein being used only as an air-way or second opening for the Baltimore vein workings from No. 5 shaft. From solid rock to the surface line the No. 3 shaft is walled with a 5-foot wall of substantial masonry. Aside from this it is timbered similar to No. 5 shaft.

Each shaft is provided with electric signaling bells and the mine foreman's office on the surface is connected with the fire-boss's station at the foot of each shaft by telephones.

The topography of the coal beds in this region is marked by numerous anticlinals and basins (See Fig. 2) lying nearly parallel and extending in a southwesterly direction, the tops of the anticlinals and the bottoms of the basins descending more or less toward the west.

The most prominent flexures defined by the workings of this colliery are the South Wilkes-Barre basin with the Stanton air-shaft anticlinal (See Fig. 12, Map), the South Wilkes-Barre anticlinal immediately to the south of this basin, and the Buttonwood anticlinal to the north of it.

Fig. 12 also shows the shafts, gangways and airways, slopes, planes and tunnels, but not the breasts. The gangways in the Baltimore vein are shown in solid lines and those of the Hillman vein in dotted lines.

The average width of the South Wilkes-Barre basin in that portion of it extending east of No. 5 shaft is about 1,400 feet while in its western portion it has a width of about 3,000 feet.

This basin extends westward several miles, and into this and also into the basin lying north of the Buttonwood anticlinal the workings of this colliery will extend.

The depth of this basin at a point immediately to the north of No. 5 shaft is 930 feet below sea level or 1,470 feet below the surface. In the lowest or Red Ash vein and at a point 5,000 feet west of No. 5 shaft and opposite the western extremity of the present workings the bottom of this basin is 1,100 feet below sea level, or 1,640 feet below the surface, in the same vein.

Mining has thus far been confined almost entirely to two veins—the Hillman and Baltimore, though gangways, but no breasts have been opened in three other veins—the Stanton, Five-foot and Kidney. (See Fig. 2.)

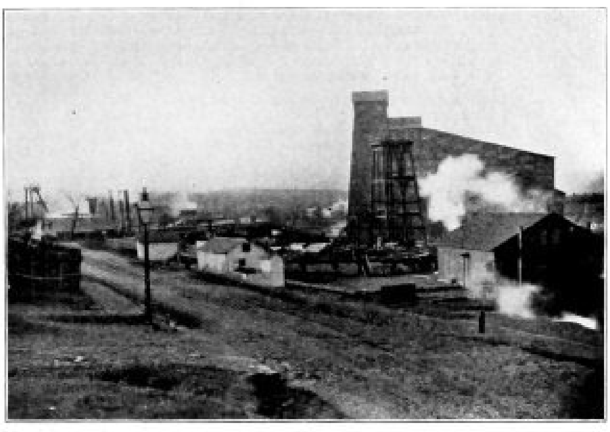


FIG. 1. GENERAL VIEW OF OUTSIDE IMPROVEMENTS, SOUTH WILKES-BARRE COLLIERY, LOOKING WEST.

The positions of these veins in relation to each other, as well as all the veins in the coal measures, are shown in Fig. 2 which is a section through the workings of this colliery on the line shown in Fig. 12.

The workable veins in this vicinity may be summed up as follows, commencing with the lowest and naming them in the order of their occurrence upward: 1, Bottom Red Ash, 12ft.; 2, Top Red Ash, 6 ft.; 3, Ross, 6 ft.; 4, Skidmore, 6 ft.; 5, Baltimore, 16 ft.; 6, Five-foot, 5ft.; 7, Stanton, 5 ft.; 8, Hillman, 8 ft.; 9, Kidney, 6 ft.; 10, Abbott, 6 ft.; making a total of 76 ft. of coal. At a point in the middle of the South Wilkes-Barre basin, 3,500 ft. west of No. 5 shaft, a diamond drill hole showed, in addition to the above, several smaller veins overlying these and aggregating about 25 ft. which will most likely be mined sometime in the future.

The No. 3 shaft cut the veins nearly on the crest of the South Wilkes-Barre anticlinal, while the No. 5 shaft cut them on the north dip of the shallow basin lying between the two shafts. From both shafts gangways are driven east and west; those from No. 3 shaft being in the Hillman vein and those from No. 5 shaft in the Baltimore vein; from which it is to be understood that through No. 5 shaft, the coal is hoisted from the Baltimore vein and through No. 3 shaft, from the Hillman vein.

The east gangways from both shafts follow along the north dip of the South Wilkes-Barre anticlinal and have a total extent eastward of 4,400 ft. From these gangways breasts are driven on a south rise of from 20° to 25° to the crest of the anticlinal, or till they reach the barrier pillar separating the workings of this colliery from those of the Stanton colliery, and having a length of from 300 to 500 feet.

From the east shaft level gangway, Hillman vein, a slope 500 feet long was driven in the vein, on a north dip of 20°, to the bottom of the South Wilkes-Barre basin. From the foot of this slope three gangways were driven, two going west, one on each side of the basin, and one going east up along the bottom of the basin. A gangway was also driven east from the slope about half way down.

This slope was afterward continued a distance of 300 feet across the measures on a north dip of 20°, cutting the Stanton, Five-foot and Baltimore veins on the south dip, in each of which gangways were driven.

From the east shaft level Hillman vein gangway, above referred to, a tunnel 700 feet long was driven north across the South Wilkes-Barre basin to the Hillman vein on the south dip. This cut the Kidney vein also on both dips, near the middle of the basin. A gangway was driven east in the Kidney vein and one west in the Hillman vein.

This tunnel is now being extended, till it shall cut the Hillman vein again on the north dip of the Buttonwood anticlinal. It having already cut the Stanton and Five-foot veins on the south dip and the Five-foot vein on the

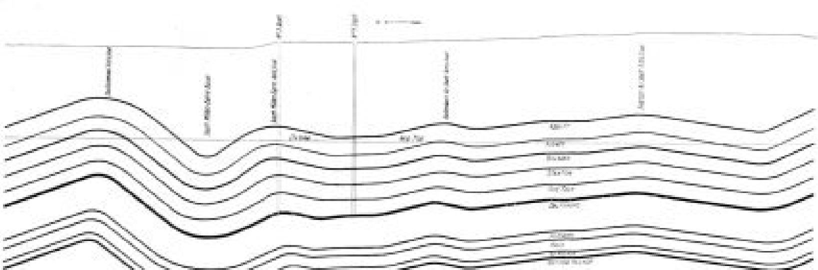

FIG. 2. CROSS SECTION THROUGH SOUTH WILKES-BARRE COLLIERY, LOOKING EAST. SCALE 1 INCH=800 FEET.

north dip also, it, when finished, will have opened up a vast extent of coal on the north side of the Buttonwood anticlinal.

From the No. 5 shaft level east gangway, a slope is being driven in the Baltimore vein going westward along the crest of the South Wilkes-Barre anticlinal on a dip of 12°. This will be continued to the bottom of the main South Wilkes-Barre basin.

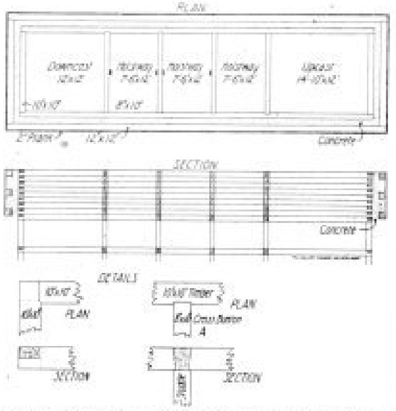

FIG. 3. PLAN AND SECTION OF NO. 5 SHAFT SHOWING METHOD OF TIMBERING.

The No. 3 shaft west gangway after going east about 300 feet struck an upthrow; after some time spent in proving the nature and extent of the disturbance, a tunnel 300 feet long was driven south through the anticlinal, cutting the vein again in its usual condition. The gangway then continued south 300 feet till it struck the north dip of the Hollenback air-shaft anticlinal and continued thence westward along the north dip 700 feet

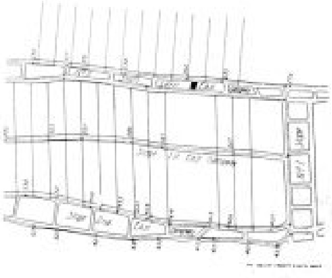

FIG. 4. METHOD OF LAYING OUT BREASTS.

to the crest of the anticlinal, and thence eastward again 700 feet to a basin, and thence directly westward 3,600 feet along the north dip of the Stanton air-shaft anticlinal, and then doubles back eastward again along the south dip 2,000 feet to the bottom of a basin.

The west gangway from No. 3 shaft went regularly westward along the north dip till it rounded the crest of the Stanton air-shaft anticlinal 4,800 feet west of the shaft, and then doubled up on itself in passing to the north dip of the next anticlinal to the south.

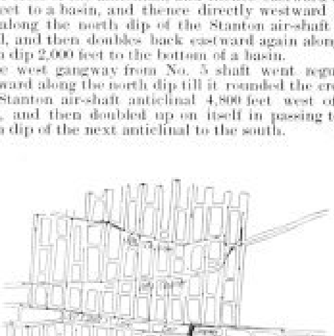

FIG. 5. PLAN OF WORKING BREASTS.

From the west Hillman vein gangway, breasts are driven either to the top of the anticlinal or till they reach the barrier pillar separating these workings from those of the Stanton colliery. The breasts are from 300 to 500 feet long on a dip of from 6° to 15°.

From the west Baltimore vein gangway, the workings extend by three lifts—the shaft level, the No. 1 plane level, and the No. 2 plane level—till they either reach the tops of the anticlinals or the barrier pillar above referred to. The width of this barrier pillar is 50 feet in the Baltimore and 40 feet in the Hillman vein.

From the shaft level west gangway, at a point 900 feet west of No. 5 shaft, No. 1 plane, 650 feet long, was driven in coal on a south rise of 9° and gangways driven east and west. From this No. 1 plane west gangway, No. 2 plane, 500 feet long, was driven in coal on a south rise of 6°, reaching the crest of the anticlinal. From this plane two gangways were driven, both going eastward, one on each side of the anticlinal.

Three thousand, five hundred feet west of No. 5 shaft, No. 1 tunnel, 700 feet long, was driven north from the Baltimore vein, cutting the Five-foot and Stanton veins on the north dip. In these veins gangways were driven. One thousand feet west of this No. 1 tunnel, a second or No. 2 tunnel, 350 feet long, was driven north from the Stanton vein to the Hillman vein, cutting it also on the north dip and near the middle of the South Wilkes-Barre basin.

Two hundred feet west of the first or No. 1 tunnel a rock plane 200 feet long was driven on a north rise of 20° from the Stanton to the Hillman vein. About 1,600 feet northwest from the point where No. 2 tunnel cuts the Hillman vein the No. 1 air-shaft is located. This shaft is 12'x37' in size and was sunk to the Hillman vein, cutting it on the south dip at a depth of 674 feet. From this a trial slope was driven in the vein on a south dip of 30° to the level of the tunnels just referred to. An outlet is now being driven in the Hillman vein from the No. 2 tunnel west gangway through the basin to the bottom of the trial slope from the air-shaft.

These tunnels are all 12 feet wide and 7 feet high above the rail.

"Up to the time of the completion of No. 5 shaft in 1888 the workings were confined to the Hillman vein from No. 3 shaft, and mainly to the west gangway from this shaft. At this time the workings comprised about 2,000 feet of gangway driven in the solid and having airway, and 300 feet of tunnel in rock.

When No. 5 shaft was completed the work of opening up the Baltimore vein was immediately begun, and another gangway also was started in the Hillman vein from No. 3 shaft. From that time on to the present the workings have expanded rapidly, and especially since the completion of the breaker, prior to which the coal mined here was taken to the Stanton breaker, where it was prepared for market.

In order to show the rapid growth of the colliery since the completion of No. 5 shaft, the present extent of the entire workings is shown, as follows:

Total length of gangways driven in solid and having airways	11 miles
Total length of planes and slopes in coal	2,300 feet
Total length of tunnels, outlets, and slopes in rock	4,000 "
Total number of breasts including those working and those stopped	401 "

The method of working here is the usual breast and pillar method. Gangways, usually 12 feet wide by 7 feet high, are driven on a grade of 6" per 100 feet, each gangway driven in the solid having an airway of the same size driven parallel with and separated from it by a pillar of from 10 to 20 yards, through which headings are driven every 20 to 30 yards for the purpose of ventilation.

Breasts are opened directly from the gangways and driven a uniform width of 24 feet, commencing with a width of 14 feet at the gangway and widening to the full breast width at 20 feet from the gangway. These are also connected by a heading every 20 to 30 yards for ventilation.

The breasts are worked usually in panels of ten breasts each, leaving a pillar between each two successive panels the width of three breasts, and the pillar in one vein is left immediately over or under that in another vein. All the breasts are driven in accordance with a previously prepared plan. See Figs. 4 and 5. This plan has the center lines of the breasts laid off on the gangways at uniform distances apart and parallel throughout each panel or throughout as many panels in succession as the dip of the vein will allow, changing the course of the breasts only when the lay of the vein compels it. On each center line is marked its course and also its distance from a station on the gangway—this distance to be measured in the gangway from the station.

In the Hillman vein the center lines are uniformly 50 feet apart, and in the Baltimore vein 65 feet apart, except where the vein is divided and is worked in separate splits, where the centers are 60 feet apart, and those in the top split are immediately over those in the bottom split. The point at which the Baltimore vein divides is 2,000 feet west of No. 5 shaft. From this point westward the vein is worked in two splits.

The gangways are made the main haulage roads; the coal from the airways being brought to them through cut-offs driven at suitable distances apart. After each cut-off is driven the portion of the airway outside of it is thereafter used only as an air course.

The motive power employed in moving the cars along the gangways is mules, but in the near future when the workings at a distance from the shafts will be sufficiently developed to require it, some system of rapid transit will be put in use.

There are three general methods of working breasts in use at this colliery. These are:

1. The road breast, where the vein dips less than 10°. (See Fig. 8).

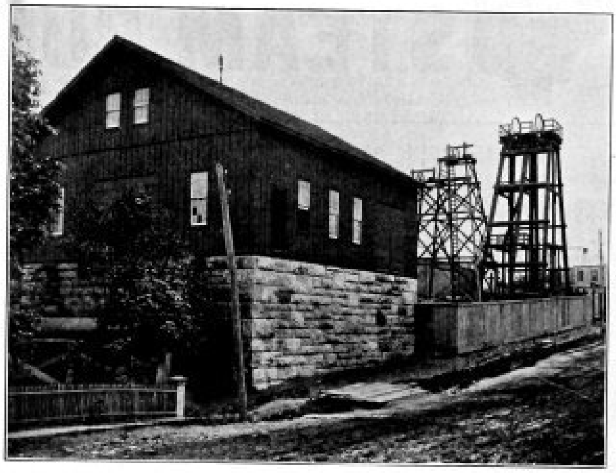

FIG. 6. NO. 5 SHAFT ENGINE HOUSE AND HEAD FRAME.

2. The shute breast, where the vein dips from 12° or 15° to 35° or 40°. (See Figs. 9, 10 and 11).
3. The battery breast, where the vein dips from 40° to 90° or vertically. (See Fig. 13).

The road breast is used to some extent in the western workings on the north dip. In this the car is taken directly to the working face on a road laid from the main haulage road on the gangway into the breast. Where this method is used here the breasts are driven nearly at right angles to the gangway, and the roads are laid in the middle of the breasts.

The shute breast is the one in most general use here. This admits of a good many modifications to suit the varying pitches and peculiar conditions of the vein. Figs. 9, 10, 11 and 13 show the principal modifications.

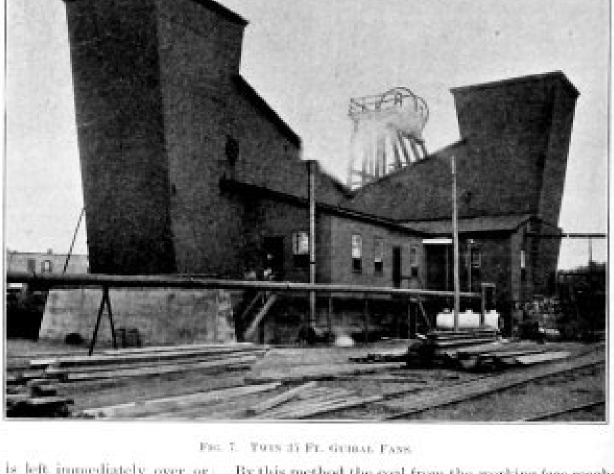

FIG. 7. TWIN 35 FT. GUIBAL FANS.

By this method the coal from the working face reaches the car by sliding down a sheet-iron shute to a platform or apron at the gangway, from which it is shoveled into the car; or, if the dip and thickness of the vein will admit, the shute is built out over the gangway far enough to allow the coal to run directly into the car.

As soon as the breast is opened off the gangway the platform is built as near the height of the car as the conditions will allow in order to lessen as much as possible the labor of shoveling the coal from it into the car.

From this platform the sheet-iron chute is continued up the breast as the working advances, and is kept within 10 or 15 feet of the face.

Coal runs readily on sheet-iron laid on a dip of 18°. The shute is therefore kept on this grade wherever the

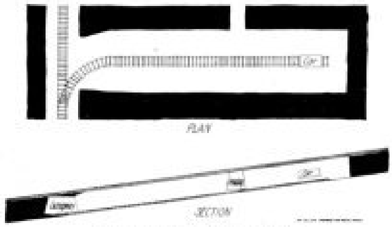

FIG. 8. SEAM 8' 0" THICK, DIP 8°.

conditions will admit. If the vein dips 18° or more—up to 30°—the shute is laid on the bottom of the breast, and if the vein dips as high as 35° to 40° the coal will run on the bottom without the sheet-iron. But, if the vein dips less than 18°, the shute is kept at the proper grade by gradually raising it from the bottom as it advances up the pitch, by building it up between two rows of props set at the proper distances apart. (See Fig. 11).

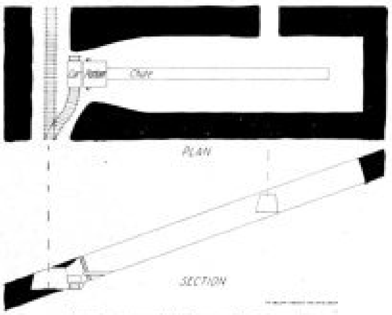

FIG. 9. SEAM 8' 0" THICK, DIP 18° TO 25°.

In a good many breasts the shute thus gets too high to shovel the coal into it at the face, in which case it is discontinued and a scaffolding or wheelbarrow run is extended from the shute into the face. Over this the coal is thereafter wheeled from the working face and dumped into the shute. Wheeling, however, is resorted to only for short distances.

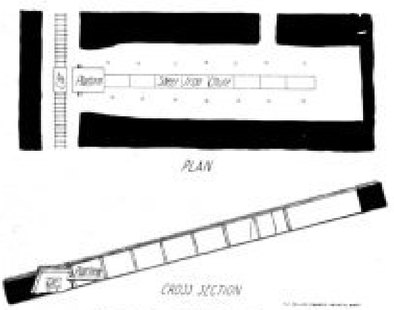

FIG. 10. SEAM 7' 0" THICK, DIP 16°.

Where several shute breasts in succession reach an extended light dip they are stopped at that point till crossed by a slant or counter-gangway, from which they are again continued as either road or shute breast, according to the dip. (See Fig. 5).

Building up the shute in order to get sufficient grade to run the coal down by gravity, as just described, can

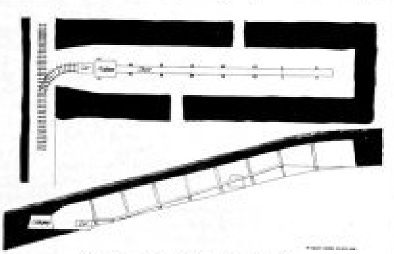

FIG. 11. SEAM 16' 0" THICK, DIP 15°.

only be done where the vein is thick enough to afford sufficient height, which is the case only in the Baltimore vein where it is not divided, it having a thickness there of 16 feet. Where the Baltimore is worked in two splits

FIG. 12. MAP SHOWING GANGWAYS, TUNNELS, SLOPES, ETC. SCALE 1 IN. = 800 FT.

—the top split being 7 feet and the bottom 8 feet thick, and also in the Hillman vein, which is 7 feet thick as first worked up—the bony bench of about 3 feet is always left up to secure a good roof. The shute must be laid always on the bottom of the breast. Then, if the vein dips 18° or more, the coal, of course, slides down the shute itself, but if the vein dips less than 18° it must, of necessity, be pushed down the shute by hand, the amount of labor thus expended depending on the lightness of the dip.

Nearly all shute breasts in the Hillman, and also in the two splits of the Baltimore vein, have a branch or siding laid in front of each, on which the car is placed away from the haulage road while being loaded. (See Fig. 9).

Where the Baltimore vein is not divided, the gangways are usually driven in the upper benches of the vein and the breasts are worked up in the bottom benches, leaving the upper or "three foot" bench to be taken down after the breast is worked to its limit, by "drawing back," *i. e.*, by commencing at the face of the breast and working toward the gangway.

This top bench is left up to secure a good roof under which to work the breast up, as the slate overlying the vein makes a bad roof.

In the Hillman vein the top or bony bench is also taken out after the breast is finished, provided there is enough good coal in it to warrant the extra work.

By driving the gangways in the upper benches of the Baltimore vein, the road breast is thus afforded a very easy grade on which to lay the branch into it, and the shute breasts consequently have a road laid from 25 to 50 feet into them before the bottom of the vein, where the platform is built, is reached.

In a few breasts on the No. 3 shaft level east gangway, Hillman vein, the dip of the vein suddenly changed from 20° or 25° to 45° or more after the breasts had advanced by the usual shute method about 125 feet from the gangway. (See Fig. 13.) From the point where the heavy dip commences they were "worked full" or by the "battery" method, as follows: A row of heavy props was set nearly perpendicular to the dip of the vein and extending across the middle of the breast. These were lagged from bottom to roof and formed the beginning of the battery.

A row of props was then extended up the breast from each end of this battery, leaving a space of 3 or 4 feet clear of the rib on each side of the breast for manways and also as airways.

These rows of props were lagged or planked on the side next to the battery and were kept well up to the face.

The coal as it is mined is allowed to remain in this battery, only the surplus coal not needed to keep the battery filled being allowed to go down the manways to be loaded into the cars at the gangway.

The manways have lagging placed across them on the bottom every 4 feet, to answer for steps by which to climb up or down.

After the breast has been thus worked up to its limit, the battery is opened at the bottom and the coal loaded out.

The arrangement of tracks on No. 1 plane is shown in Fig. 14, which is the form of gravity plane in general use in the collieries of this company. A wooden lagged drum provided with a brake and having two ropes attached is located at *I* a sufficient distance back from the knuckle or apex, to allow the branches to be laid with easy curves.

One rope, after being coiled upon the drum, has the loose end attached to a loaded car at the apex; and the other rope which is extended down the plane has its loose end attached to an empty car at the foot. The loaded car is then allowed to move down the plane, thus pulling the empty car up, the speed at which they move on the plane being regulated by the brake on the drum.

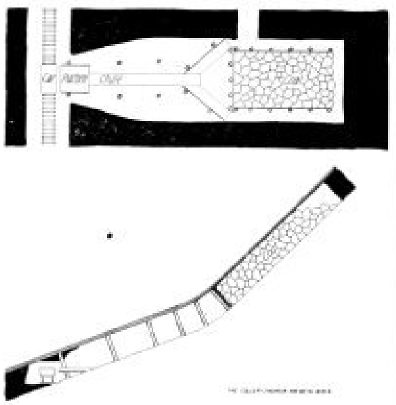

FIG. 13. SHUTE AND BATTERY BREAST.

At this plane the loaded branches at the head have a down grade from the frogs at *a a'* to the apex; commencing with a grade of a little less than one degree and gradually increasing to a degree or perhaps a little more as they approach the point *b*. The empty branches at the head have an up grade from the latches at *D* to the frogs at *a a'*, amounting to about the usual gangway grade of 6" per 100 feet.

The loaded branch at the foot has a down grade of about one degree from the foot of the plane to the frog at *C*, and the empty branch commences at the frog *C* with a slight down grade which, as it gets near the bottom of the dish, increases to one degree.

The latches at *a*, *a'*, *D*, *D'* and *C* are moved by hand to enable cars to be shifted from one branch to another as is frequently necessary. The latches *E* are spring latches set to run the car coming down the plane always on the loaded branch. The latches at *F* are operated by the footman at *H* by a lever connected to the latches *F* by an arrangement of rods. The latches at *G* and *b* are also operated by levers by the headman. The grade of this plane is 9° and that of No. 2 plane is 6°. Two and three-car trips are handled on each. The reason why the branches at the foot of this No. 1 plane extend in the line of the plane is because the vein lays very flat at that point, and by making the foot in the bottom and the head in the top of the vein, sufficient room was gained to arrange the branches as they are shown in Fig. 14.

No. 1 slope is operated by an engine located on the surface about 50 feet south of No. 3 shaft. The rope, which is 1¼" diameter, passes down this shaft and in along the gangway to the slope. At the top and bottom of the shaft it passes round 5 ft. sheaves set vertically and along the gangway it is carried overhead on 6" pulleys suspended from the roof. Between the shaft and the slope, a distance of 500 feet, it makes three turns, at each of which a 3 ft. sheave is placed horizontally, and at the point where it leaves the gangway to pass down the slope a 5 ft. sheave is placed on a sufficient slant to accommodate the pitch of the rope when it is stretched over the apex.

The head of this slope is arranged to land the cars directly on the loaded branch by hoisting them over the apex, which is the general practice under this company.

As has been noticed, all gangways and airways, as well as breasts, are connected by headings for the purpose of ventilation. As each new heading* is opened the one just passed is closed, so that all headings but those next the faces are closed. All headings between gangways and airways and all other headings which are closed for the purpose of separating the different splits of air are closed with a wall which is made of stone laid in mortar and from two to three feet thick.

All temporary stoppings between places in the same split, as well as all brattices of any great extent, are built of boards.

The usual arrangement of doors and brattices in ventilating a portion of workings, consisting of a panel of breasts and a gangway and airway, is shown in Fig. 15. In this case the gangway is the intake and the airway the return.

In order to keep the air current against the faces of the gangway and airway as they advance from one heading to where the next one will be opened, a door is placed across the gangway just outside the last heading and connected to the lower rib by brattice. (See *A*, Fig. 15.) From the opposite ends of the door a brattice is extended along and about three feet from the upper rib and kept within a few feet of the face.

In the airway a brattice is extended from a point in the upper rib just outside the last heading in the airway to within a few feet of the face, leaving a space of about three feet between the brattice and upper rib.

The air in going from the gangway to the airway is obliged to travel in around the ends of these brattices and is thus carried directly against the faces.

To ventilate a panel of breasts which are connected by headings a door is placed across the mouth of each breast except the first and last in the panel, and a door is also placed across the gangway just inside of the first breast and likewise one across the gangway just outside of the last one.

The air will then pass from the gangway up the first one, and through the last headings from one breast to the next and down the last one, and so on in the gangway.

It is generally found necessary in ventilating a panel of breasts to place a door across the gangway at every fourth breast in addition to those at the first and last breasts in the panel. As the faces of breasts extend beyond the headings far enough to require it, a door and brattice is placed in the first breast of the panel, (See *B*, Fig. 15) in the same manner as in the face of the gangway, while in the rest of them brattices only are used and arranged like the one in the face of the airway. This is assuming that the breasts are road breasts that are working. If they are abandoned the doors are substituted by brattices. If they are shute breasts that are working, no doors are to be placed across them, but an opening is left in each brattice crossing a breast, sufficient to accommodate the shute; over this opening and hanging down into the shute is placed a curtain of brattice cloth, and if these breasts are abandoned the brattices are, of course, made solid.

In ventilating a single breast or one with no headings, a door is placed across the gangway and a brattice extended from it up along the side of the breast. (See *C C* Fig. 15).

This colliery is ventilated by a 35 ft. Guibal fan, which making 45 revolutions per minute, exhausts 275,000 cu. ft. of air, with a water gauge of 1.9 inches. An average of several tests of the amount of explosive gas in the main return (which were made with the Shaw Gas Tester) showed it to be 2.5 per cent. This amounts to a total of 6875 cu. ft. of gas per minute, or the enormous quantity of 9,900,000 cu. ft. in 24 hours. This readily shows this to be a very gassy mine, and probably the most gaseous in the world. Owing to the great amount of gas generated in this mine the stoppage of the fan for but a very short time would result in making the air of the mine explosive and absolutely unsafe. Therefore, to provide for maintaining a constant and uninterrupted ventilating current, the fan is built in duplicate; each fan being separate and independent of the other, but similarly connected with the upcast, and capable of immediate use in the case of the other fan being stopped either for ordinary repairs or as the result of accident. (See Fig. 7).

This gas is given off from the coal in the working faces of the gangways and airways, and also in the faces of some breasts, as well as from feeders which are found in various parts of the mine, but mainly along the bottoms and lower ribs of airways. The places which give off most gas, however, are the working faces of gangways and airways, and of these the ones driven east along the heavier dips gave off the most. Generally, as the breasts are opened up along the gangways and the workings expand, the gas drains off sufficiently to permit the use of naked lights in the breasts, and also along the main gangways at a good distance back from the face.

Leading into every gangway and into some breasts is a line of 2½" water pipe, and in some gangways there are two lines, to be used in extinguishing fires that sometimes occur in spite of the extreme precautions taken to prevent them—all blasting in gassy places being done with dynamite fired by an electric battery, and the most rigid rules enforced in regard to the handling and use of explosives and in the use of naked lights. Yet fires do sometimes occur which require not only the united efforts of two streams of water for several hours, but also the closing of regulators on some splits in order to furnish additional air to the men fighting the fire.

* Small cross-cuts through pillars of coal.

It has been noticed that one compartment of No. 5 shaft is an upcast; this constitutes the upcast for the entire colliery. The balance of No. 5 shaft and all of No. 3 shaft constitutes the downcast or intake for the entire colliery.

The air entering the mine through No. 5 shaft ventilates the Baltimore vein or No. 5 shaft workings and is divided into six splits. (See Fig. 16.)

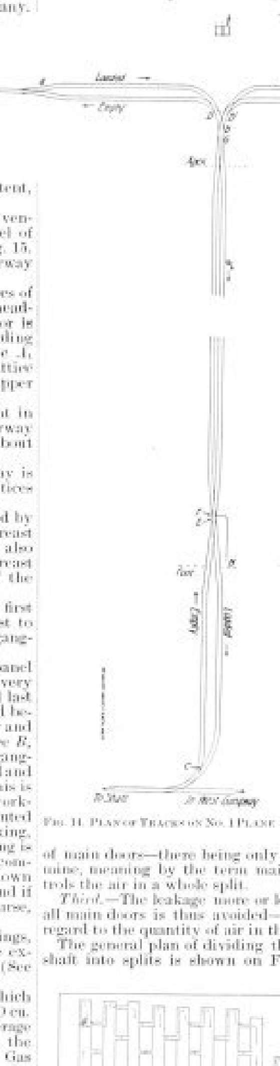

FIG. 14. PLAN OF TRACKS ON NO. 1 PLANE.

The air entering the mine through No. 3 shaft ventilates the Hillman vein or No. 3 shaft workings and is divided into four splits. So that in all there are ten splits.

In eight of these splits the air travels in through the breasts and gangways and returns through the airways, while in two of them it travels in through the airways and returns through the gangways and breasts.

The main advantages in making the breasts and gangways the intake and the airways the returns are:—

First.—The gas which is being given off at the faces of the gangways and airways and from the blowers along the airways is thus carried away from and not toward the naked lights, as no naked lights are allowed in any return showing a large percentage of explosive gas.

Second.—The air travels through the workings at a more uniform velocity on account of the absence of main doors—there being only four main doors in the mine, meaning by the term main door, one which controls the air in a whole split.

Third.—The leakage more or less which is incident to all main doors is thus avoided—giving better results in regard to the quantity of air in the several splits.

The general plan of dividing the intake air from each shaft into splits is shown on Fig. 16. The solid lines represent the intakes and the dotted lines the returns. The figures at the points of divergence of the solid lines are the distances in feet of each division of the intake air from the downcast. On each line representing a single split is its name, which indicates to some extent the territory which it ventilates, while the numbers at the ends of the solid lines are simply the number given it in the table on page 175 which shows the name of the split, or locality ventilated by it; number of breasts ventilated; number of men working in the split; total number cubic feet of air in the return, and percentage of gas in the return.

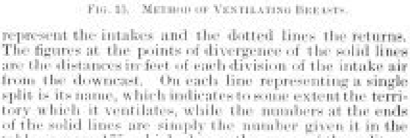

FIG. 15. METHOD OF VENTILATING BREASTS.

The positions of the overcasts or air-bridges by which the different splits cross each other are marked thus ‡‡ on Fig. 12.

(In the following description of the splits of air, references are made to Figs. 12 and 16):

The air entering the mine through No. 3 shaft is divided first at *E*, 100 feet from the downcast, one portion going in the east gangway and the other in the west gangway. This latter remains as one split and ventilates all the workings west of the shaft, going in through the breasts and gangway and returning through airway. The total length of this return airway is 9,800 feet with a sectional area of 84 square feet.

The air going in the east gangway is divided at No. 1 slope, *F*, 500 feet from the downcast, one portion going down the slope, the other going on in the east gangway as far as No. 3 tunnel, thence through No. 3 tunnel, where it ventilates all of No. 3 tunnel workings, after which it goes down to the slope west south dip gangway, ventilates this gangway and airway—going in the gangway and out the airway—and joins the return from the slope at *L*; passes thence up to the shaft level east airway through which it reaches the main return at *N*.

The air going down the slope is divided at the slope west north dip gangway *G*, one split going in this gangway and returning through the airway to join the return at *L*; the other split continues down the rock

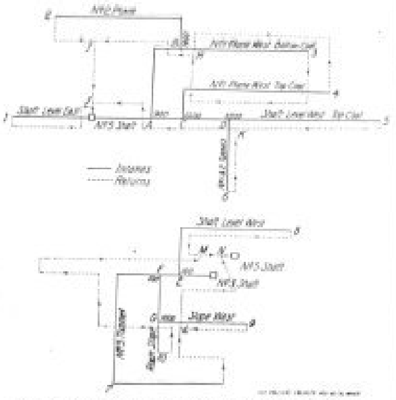

FIG. 16. PLAN OF DIVIDING INTAKE AIR FROM EACH SHAFT.

slope to the Baltimore vein gangway, which it ventilates, after which it passes through a rock outlet to the Hillman vein again and ventilates the workings east of the slope, after which it passes in through the shaft level east airway to the face and returns through the gangway and breasts, ventilating all the workings on the shaft level east gangway and joins the main return at *M*.

	10	Rock Slope and shaft level east	7	51	58	55	12	67	34,000	2.8
	*	Total			401			578	275,000	

Percentage of gas in main return of the whole mine at the fan, 2.5 per cent.
Total quantity of gas from mine, 6,875 cu. ft. per minute.

The air entering the mine through No. 5 shaft is divided first at the foot of the shaft, one portion going in the west gangway, the other in the east. This remains as one split and ventilates all the workings on the shaft level east gangway and a portion of the No. 1 plane east workings, going in through the gangway and breasts and returning through the airway. The length of this return airway is 5,300 feet with a sectional area of about 80 square feet.

The air going in the west gangway is divided at the foot of No. 1 plane, *A*, one portion going up the plane, the other in the gangway. This is subdivided twice, first at *C*, where a split enters the shaft level west top split workings, a part of which it ventilates and then passes up to No. 1 plane west top split workings, all of which it ventilates, after which it joins the return from the planes at *H*.

At *D* a split passes in through No. 1 tunnel, ventilates the workings of Nos. 1 and 2 tunnels and returns by rock outlets to the shaft level east top split airway and thus joins the main return from the west side at *K*. The air going in the west gangway beyond No. 1 tunnel (or the point *D*) remains as one split and ventilates the balance of the shaft level west top split workings and returns through the airway and joins the other return at *J* near the upcast. The length of this return airway is 7,400 feet with a sectional area of 72 square feet.

The air going up No. 1 plane (from the point *A*) is divided at No. 2 plane *B*, one split going up No. 2 plane and ventilating all of No. 2 plane workings, and then a part of No. 1 plane workings, after which it joins the returns from the planes at *I*; the other split ventilates first all the workings on No. 1 plane west bottom split gangway, then down to the shaft level west bottom split workings, all of which it ventilates, except the first panel of ten breasts (counting from shaft) which are ventilated by a portion of the air passing in from *A* towards *C*, and then passes through a hole to a top split breast, through which it passes up to the plane west airway and joins the return at *H*.

The water of this mine is collected finally in a sump (See *X*, Fig. 12), which was driven in coal in the shallow basin just to the north of the No. 5 shaft; from this it is pumped directly to the surface. From the workings the water naturally finds its way to the airways next the solid. Along these, in ditches made along the lower side, it runs toward the shaft and into the sump.

The water from the upper or Hillman vein workings is conveyed to the Baltimore vein workings through a pipe extending down No. 5 shaft from the Hillman to the Baltimore vein, and that from the slope workings is collected in a sump driven in rock at the foot of the rock slope, from which it is hoisted to the shaft level in a water car.

The pumping plant consists of one Jeanesville compound duplex plunger pump, manufactured by Jeanesville Iron Works, which has the greatest vertical lift of any pump in the anthracite region. The steam cylinders are 22″ and 36″x38″ and the plungers 9″ diameter with a 36″ stroke. The steam pipe is 6″ diameter, the tail pipe 10″ diameter and 80 feet long, with a vertical lift of 12 feet; the exhaust is 10″ diameter; the column pipe 10″ diameter with a vertical height of 1,040 feet. The column pipe has a water tight wood lining ⅞″ thick throughout its entire length, which reduces the internal diameter of the pipe to 8½″. The object of this lining is to protect the metal of the pipe from the corroding action of the water.

In order to accommodate the strength of the pipe to the varying pressures due to different depths, the metal is of different thicknesses, commencing with a thickness of 1½″ at the bottom of the shaft, and diminishing in thickness several times as it extends up the shaft.

The capacity of the pump at its normal speed of 40 strokes per minute is 24,000 gallons per hour.

This pump readily handles all the water of the mine at present by running two 10 hour shifts each week.

The pump is located near the foot of No. 5 shaft in a brick arched pump room (See *Y*, Fig. 12), 37 feet long, 14 feet wide and 9½ feet high in the center of arch. It is placed on stone piers, and the floor of the room is cemented.

The room was first excavated out of the coal in the pillar between the west side empty branch and the sump, and afterward walled and arched with a 17″ brick wall laid with cement mortar.

From the main pump room a heading extends back to the sump. This heading is also arched for a distance of 10 feet, and through this the tail pipe extends into the sump.

SURFACE PLANT.

The general arrangement of the surface plant is shown in Fig. 17. The No. 5 shaft engines are a pair of 28″x60″ direct acting hoisting engines, with cast iron grooved double-coned drum 8½ ft. end diameter., 14 ft. middle diameter and 19 ft. long. No. 3 shaft engines are 32″x60″ cylinders, and otherwise similar to No. 5 engines. Both are provided with Zehnder's patent steam brake, in addition to the ordinary hand brake. The ropes used on the drums are 1½″ Hazard wire rope, No. 5 shaft requiring 2,800 ft. and No. 3 shaft 2,500 ft. The normal hoisting capacity of each engine with a steam pressure of 75 lbs. is 70 cars per hour from No. 5 shaft and 80 cars per hour from No. 3 shaft.

The foundations of these hoisting engines are masses of stone work, each covering the entire area of the engine house, and are built up some 20 feet above the original level of the surface. They contain over 1,000 cubic yards of masonry each. A view of No. 5 engine foundation is shown in Fig. 6. The details of the standard cages in use are shown in Fig. 19.

Each fan is run by a 20″x48″ direct acting engine. The fans are provided with a Williams pressure recorder. The fan foundations contain about 525 cubic yards of masonry work each; the one is of concrete and the other of stone. The hoisting and ventilating machinery was built by the Vulcan Iron Works of Wilkes-Barre.

There are two separate steam plants. The Stirling boilers, located about 100 feet north of No. 5 engines, constitute one independent plant. The balance are located along High street about midway between the two shafts, and constitute the second plant. The whole steam plant consists of

	Total H.-P.
Eight cylinder boilers, 34″x30′, about 15 H.-P. each	120
Two Pollock boilers	100
Four National water-tube boilers, 125 H.-P. each	500
Two Stirling water-tube boilers, 125 H.-P. each	240
Total	960

(At No. 1 air-shaft are two Stirling water-tube boilers of 111 horse-power each which are not included in the above.)

Leading to No. 3 engines is a line of 8″ steam pipe from the National boilers, and to the No. 5 engines and also to the fans, are three independent lines from the different boilers. One of the lines leading to the fans is placed underground. These different lines are so connected at the fans and at the No. 5 engines that steam can be supplied to the fans and also to the No. 5 engines from either line desired by opening and closing the proper valves, which would be the work of but a few moments, so that should an accident happen breaking any line or all the lines but the one underground, the fans and also the No. 5 engine could still be supplied through this line.

In addition to these extra steam lines as precautionary measures, three lines of water pipe, two 4″ and one 8″ in diameter, are laid from a common valve to the head of No. 5 shaft, and two lines of 4″ pipe, also from a common valve, to the head of No. 3 shaft. Thus five streams of water could at a moment's notice be turned into the downcast by opening two valves, which are conveniently located, one near the head of each shaft, so that if from any cause both fans were disabled, the above means could be resorted to at once to produce a ventilating current that would at least make it possible for those inside the mine to get out before an explosive mixture would occur.

The breaker, one of the largest and best equipped in in the anthracite region, is 116 feet by 180 feet in size, and 145 feet high. In the foundation walls are some 3,500 cubic yards of masonry. Something over a million and a half feet of lumber was used in its construction.

The machinery is run by an 18″ x 36″ Vulcan engine and the cages in the breaker hoisting shaft are operated by a pair of 18″ x 30″ geared engines, geared 4 to 1 to a cast iron grooved drum 8 feet diameter by 20 inches long, also built by the Vulcan Iron Works. The principal machinery consists of 6 pairs of rolls as follows:—

Rolls:—
- 1 pair crushers,
- 1 pair main rolls,
- 2 pair prepared rolls,
- 2 pair chestnut rolls.

Elevators—
- 1 screening elevator,
- 1 pea and chestnut coal elevator,
- 1 bony coal elevator,
- 3 bony coal conveyors,
- 2 screening conveyors.

13 screens as follows:—
- 2 main screens, 8′ x 30′,
- 3 chestnut coal screens,
- 2 mud chestnut coal screens,
- 2 pentagon coal screens,
- 2 mud screens,
- 2 broken coal screens.

There are in all 1,481 feet of belting from 12″ to 24″ wide, the main belt is 159 feet long and 24 inches wide.

The breaker is heated throughout by steam. All screens, rolls, elevators, etc., are securely boxed in. Leading from each screen, thus enclosed, is a wooden pipe or airway of from 2 ft. to 4 ft. sectional area. These enter a common airway 5 ft. by 6ft. in size, which extends to a 14 ft. fan at the bottom of the breaker and thence horizontally to a 20 ft stack located about 100 ft. east of the breaker through which the current produced by the fan is discharged into the open air. At a point just outside the breaker the exhaust steam from the breaker fan and engine is discharged into this airway. The dust then comes from the screens through this airway where it is saturated by the steam and settles on the bottom of the airway from which it is removed from time to time as is necessary.

The loaded mine cars are run by gravity from the head of each shaft to the foot of the breaker shaft, where

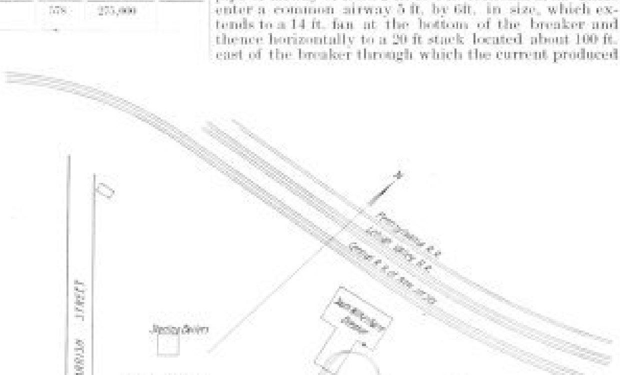

FIG. 17. PLAN OF SURFACE ARRANGEMENTS.

each loaded car is run on one of the two hoisting cages and hoisted to the top of the breaker, then run by gravity to the dump-shute. After a car has been dumped it is carried by means of a transfer rope and a transfer track around the breaker shaft and allowed to stand immediately back of the shaft on the same side that it was on when loaded. There is a sufficient fall between the transfer track and the breaker shaft to enable the empty car to "bump" the loaded car off the cage, and take the place of the next loaded car that comes up on the same side of the shaft. After the empty car leaves the cage at the foot of the breaker shaft, it runs, by gravity, to the foot of an empty car hoist, where it is hoisted to a sufficient elevation to carry it back to either shaft to be again lowered into the mines.

The mine car (See Fig. 18) is 8' 3¼" long, 4' 9½" wide at top, and 4' 2" wide at bottom, by 2' 1½" high for an iron bottom car, and 2' 0¾" for a wood bottom car. The iron bottom car contains 79 cu. ft., and the wood bottom car 75 cu. ft. when filled to the level of the top of the car, but as loaded in practice there are about 15 cu. ft. of topping, which makes the total load 94 and 90 cu. ft. respectively.

The average load, taken from a number of cars as they come from the shaft, is 6,337 lbs. The average yield of merchantable coal per car is 4,922 lbs. The refuse loaded in car, and dirt made in preparation is 1,415 lbs. or 22.3 per cent. of the total.

The percentage of the different sizes of coal as at present shipped from the colliery are:—

Lump	0.02
Broken	11.16
Egg	23.57
Stove	19.31
Chestnut	18.71
Pea	11.04
Buckwheat	14.29

The total shipments for each year and also the number of days worked since the completion of the breaker, are as follows:

	Tons.	Days worked.
1892	133,072	47
1893	258,368	186
1894	267,219	137
1895	312,188	162

The main steps in the preparation of the coal after it leaves the car at the dump shute are as follows: It first passes onto bars spaced 5" apart, all passing over these bars going to the lump coal shute; the balance passes onto bars spaced 2½", where a part goes through, the balance going to a platform where it is picked, and goes thence to the crushers, thence to the main rolls, and thence to the No. 1 or broken screens, from which come "egg" and "broken," which, after being picked, pass direct to the pockets. The balance from No. 1 screens goes thence to the main screens, from which "stove," "chestnut" and "egg" come, and after being picked go direct to the pockets. The balance from main screen goes by way of elevators to the chestnut screens, from which come "chestnut," "pea" and Nos. 1 and 2 "buckwheat" and pass direct to the pockets.

That going through the 2½" bars passes to the mud screens, from which come "egg" and "stove," which, after being picked, go direct to the pockets. Of the balance from the mud screens, that which is larger than egg goes to the prepared rolls, thence to the main screens, from which point its course is as has already been described. That which is smaller than stove goes to the mud chestnut screens, from which comes "chestnut" and "pea," which go direct to the pockets. All sizes smaller than "pea" go thence to a pentagon screen, from which come, ready for the pockets, Nos. 1 and 2 buckwheat. The balance passes directly over a shaker, from which some additional No. 2 "buckwheat" is obtained; the balance goes to the bank as dirt. That which goes through the 5" bars goes over a platform, where it is picked and goes thence to the main rolls and thence to the No. 1 or broken screen. From this point its course has already been described.

The culm piles are located about a mile west of the breaker, the culm being conveyed to them in cars by an eighty horse-power locomotive.

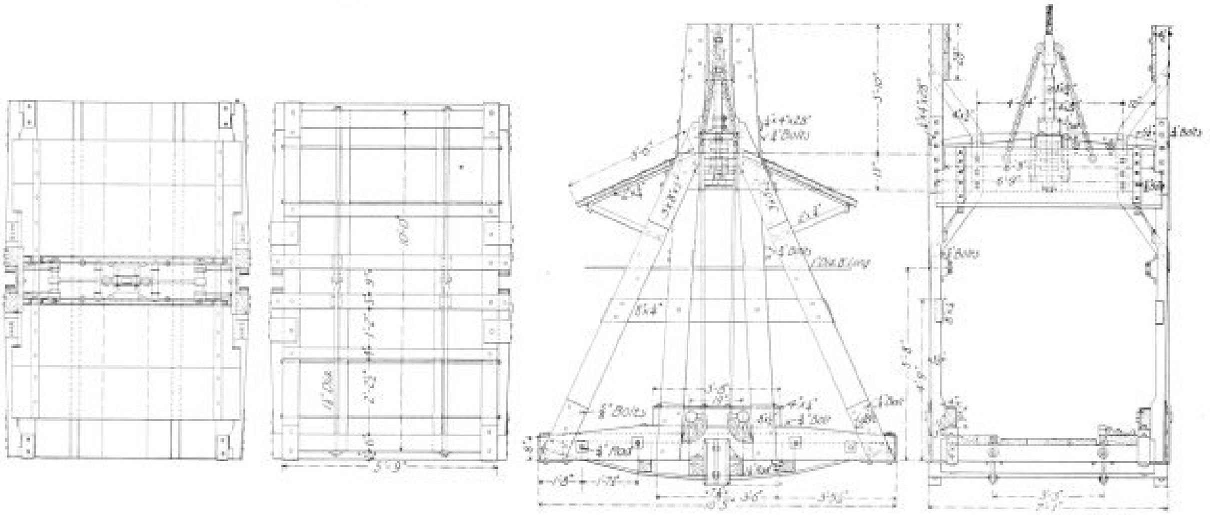

FIG. 19. LEHIGH AND WILKES-BARRE COAL CO.'S STANDARD SHAFT CAGE.

Telephones in the Mines.

Within the past year an interesting departure has been made in the method of communicating between the inside workings of coal mines and the out-side world.

For a number of years experiments were being made with telephones especially constructed to meet the requirements, and while some were in a measure successful, none were of a practical character. The expiration of the Blake patent gave additional impetus to the experimentation, and particular attention was given to improving and protecting the adjustment.

While the experiments have only been partially successful, the results obtained have contributed largely toward solving the problem of underground telephony. The Lehigh Valley Coal Co., has installed a number of telephones in their mines and the results are both satisfactory and gratifying.

The principal difficulty encountered arose from the corrosive action of the atmosphere of the mines upon the delicate mechanism of the instrument. The diaphrams rusted quickly and became useless. Again the dampness caused alternate warping and swelling to the boxes, throwing everything "*out of line*."

Col. D. P. Brown, Division Superintendent of the Lehigh Company, has arrived at a method which enables him to prevent the damp atmosphere from reaching the instrument. His plan is to locate the telephone in as dry a place as possible, generally in the pump house, or at a point near the intake. He uses No. 12 phosphor bronze wire strung upon porcelain insulators screwed to the timbers in the rib. He splits the air causing a current of fresh dry air to circulate about the closets enclosing the telephones. While it is impossible to prevent entirely the moist atmosphere from reaching the instruments, yet by this method and with superior transmitters success has been at last attained.

The great value of the telephone in mining operations was demonstrated at the fire which recently occurred at the Packer No. 4 colliery in the workings on the 5th lift. The fire broke out at night and in a few moments after its discovery, a connection was made to a grounded circuit outside and communication established between the superintendent's office at Lost Creek, 1½ miles distant, and a point within 200 feet of the fire. The length of the underground line was over 1,800 feet. So efficient was this service that orders were issued to place telephones in all of the company's mines. The Primrose colliery, near Mahanoy City, is now being equipped with a telephone system which when completed will enable communication to be carried on, not only with the colliery office on the surface, but also with the office of Superintendent John A. Grant at Lost Creek, and the office of General Superintendent Lathrop at Wilkes-Barre.

Underground telephone systems have been installed at the Brookside colliery of the Philadelphia and Reading Coal & Iron Co.; the Williamstown colliery of the Summit Branch Coal Co.; the William Penn colliery; the collieries of the Susquehanna Coal Co., at Nanticoke, and the Lytle colliery near Minersville. At all these operations the system is in successful operation. As success has been attained and at an extremely reasonable cost, the general introduction of this method of communication at all the collieries may be looked for in a short time.

Tennessee's Coal Production in 1895.

Mr. F. P. Clute, Commissioner of Labor, Statistics and Mines of Tennessee, sends us the following table of the coal production of that State in 1895:

	Short Tons.
Anderson county	345,291
Claiborne "	147,122
Campbell "	323,289
Grundy "	446,786
Hamilton "	166,889
Marion "	302,298
Morgan "	58,862
Putnam "	7,720
Roane "	120,423
Rhea "	140,852
Scott "	112,178
White "	125,334
Total	2,304,720

To which must be added 15,000 tons as the estimated production of small mines whose output has not been reported, making a grand total of 2,319,720 short tons.

The earth's magnetism, although practically useless as a great power for driving mills, has one of its uses in operating a mariner's compass, which, next to Columbus, was the means of discovering America. This illustrates that although several of the natural forces are of little service for driving machinery, yet in other ways they may become of utmost importance.—*Electric Power.*

PROSPECTING FOR GOLD.

GOLD PLACERS; HOW THEY ARE WORKED.

Theories of the Origin of Gold Sands and the History and Distribution of Gold Placer Deposits Throughout the World.

Written for THE COLLIERY ENGINEER AND METAL MINER by Prof. Arthur Lakes.

(Continued from February.)

Gold was known to exist in Brazil in the beds of streams, and Indians in early days made their fish-hooks of it. The gold placers were first discovered in 1577. The gold was first found in Rio das Mortes, or River of Death, so named from the bloody encounters between the gold hunters, who it is said "met and set upon each other like famished tigers, impelled by the accursed hunger for gold." Along this river are abundant evidences of their extensive search for gold. The banks are everywhere furrowed and the vegetable mould has been entirely removed. Nothing remains but the

SOUTH AMERICA.
Dots Show Location of Gold Deposits (After Locke).

red dirt cut into squares by channels divided by narrow ridges. These channels were used for washing gravel and were cut on an inclined plane. The water was introduced at the head of them, the dirt was then thrown in, and the lighter particles of clay were washed away while the gold remained behind. (The appearance of these furrowed banks reminds one of the furrowed appearance on a larger scale of the Alma placer banks as pictured in a former issue of THE COLLIERY ENGINEER AND METAL MINER.)

The first placers were called "cata." The surface dirt which contained gold was mined until the "cascallo" or cement gravel was reached. This was broken up by pickaxes, brought to the river and washed. The first improvement was (as in early days in California) to conduct the water to the ground and wash the gravel on the spot. These works were called "lavras," and hundreds of them were to be seen on the banks of the river. In some districts water wheels were used to assist in the drainage of the excavations, but were found to be so unmanageable that they were thrown aside and negroes were employed to pack off the gravel and rubbish on their heads in small casks. From 1691 to 1875 the gold production of Brazil amounted to 2,281,510 pounds Troy.

Chili has golden sands and deposits which do not appear to have been formed by the decomposition of regular veins. They are found in decomposed granite and red clay near Valparaiso. Similar deposits occur along the flanks of the Andes. Recent attempts by Americans to hydraulic the deposits have not been successful—yield of gold very small and water scarce.

In Peru gold was gathered by the Incas. Under Spanish rule $33,000,000 was extracted from the mines and washings of Caravaya. The work was put an end to by a massacre by the Indians.

In Venezuela large placers have recently been discovered. United States of Colombia contained the famous El Dorado visited by Sir Walter Raleigh in 1517 and by the buccaneers in the seventeenth century. It was situated in the province of Castilla del Oro. The Cana mines of this district, worked by slaves, yielded largely in the seventeenth century. The mines of Choco west of the Andes are among the most productive in the west of South America. They contain platinum as well as gold.

Cortez's exploring parties in Mexico obtained gold from the beds of rivers several hundred miles from the capital. Gold cast into bars or in dust was a regular export. The gold from Mexico now is mostly from quartz leads. The gambusinos or native prospectors, however, wash with the batea in local placers. Rivers supposed to carry bonanzas in their beds have been turned from their courses, but without success. Prospectors obtain some gold from crevices in bed rock which they reach with shafts.

Australia's most important gold fields are in the colonies of Victoria and New South Wales. Queensland and South Australia also contain gold alluvions.

The gold product of Victoria in 1880 was 529,129 ounces, 299,926 of which came from placers. Although the old placers have been worked extensively and exhausted in many cases, new areas have been opened and worked by improved means. From its discovery in 1851 to 1880 gold amounted to £198,196,206, mining operations extending over 1235 square miles.

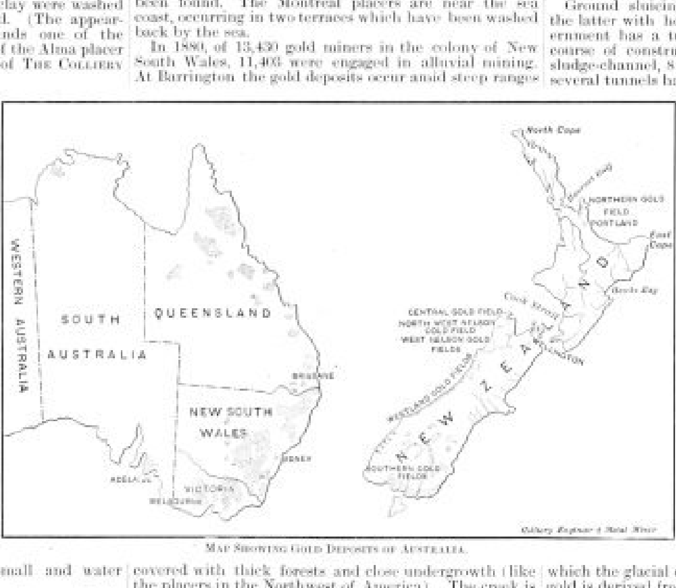
Ararat district contains large deposits from the Upper Pliocene of marine origin, but no gold is found in these. The gold occurs in the Lower Pliocene of fresh water origin. We may mark here that not a single quartz vein occurs in this district from which the gold could have been derived. The depth of deposits is 90 to 100 feet, resting upon granite and mined for a length of two miles and a width of 1,200 feet. The lead, owing to the presence of saline water, is supposed to be a depression in an old sea bottom.

In the Ballarat fields are four clearly defined epochs of gold drift, known as oldest, older, recent and most recent. The "oldest" is a deposit made before the time at which the channels were eroded to their present depths. The "older" is the deposit intervening between the lava flows. The "recent" are those following immediately the uppermost lava flows. The "most recent" are those in recently eroded gullies. (These lava-covered placers are very like the lava covered deep beds of California.) There are three great lead systems—the Southern, Western and Eastern. The Southern has been explored extensively, the Western is looked on as the future hope of Ballarat, and the Eastern is but little known.

In Beechworth district the placer material is derived from Silurian strata, not from granite (in this respect reminding us of the Homestake gold mines in the Black Hills which are worked in Cambro Silurian or Pottsdam conglomerate). Mining is by ground sluicing on a grand scale. The thickness of gravel is 30 to 50 feet, mostly in creeks and on the banks. Sandhurst district was worked since 1853 on a cement deposit of Pliocene. The gravel is shallow—the deepest shafts 35 to 55 feet. The gold-bearing districts of New South Wales are the richest and largest in Australia. The fields extend the length of the colony, with breadth of 200 miles. Immense tracts in the interior are still unprospected. Up to 1871 placers alone were worked, gold quartz mining being, as usual in those early days, neglected. Sixteen thousand men were then at work. From 1851 to 1871 the product was £26,457,160. The gold regions are but two days' journey from the capital.

In several of the districts water is scarce, yet in places, as at Tenora, a large amount of very coarse gold has been found. The Montreal placers are near the sea coast, occurring in two terraces which have been washed back by the sea.

In 1880, of 13,430 gold miners in the colony of New South Wales, 11,403 were engaged in alluvial mining. At Barrington the gold deposits occur amid steep ranges covered with thick forests and close undergrowth (like the placers in the Northwest of America). The creek is worked for gold, but the water supply is uncertain and in summer the creek ceases to flow. The Kiandra field is on the table land of Maneero, 5,000 feet above sea level, close to the highest mountain of the colony. Near Mt. Tabletop the alluvions have been covered with basalt and so far but little exploited. The sluicing operations toward Mt. Tabletop have been compared to the gravel deposits of Placerville, California.



Map Showing Gold Deposits of Australia.

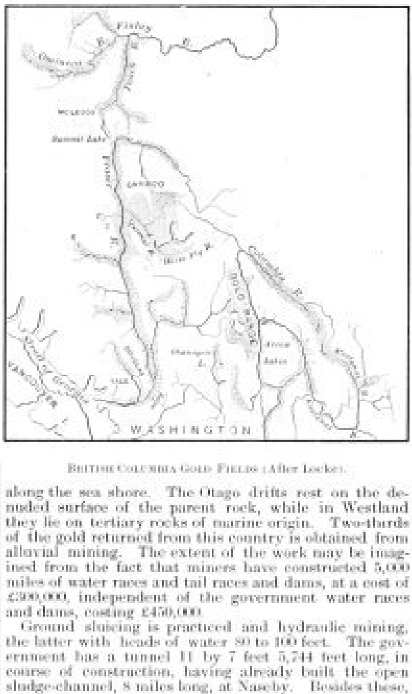
In the Tallawang field the gold occurs in one of the most ancient alluvial deposits in the world, belonging to the Tertiary, and in conglomerates of the coal measures gold has been found. (This suggests that in Colorado and elsewhere we pay some attention to the old consolidated conglomerates of different past periods as well as to the modern alluvial deposits of more recent date.)

At Clough's Gully the conglomerate is worked, yielding from 1 to 15 pennyweights per ton, and nuggets of 5 ounces are occasionally found. (In this connection we may observe that gold in small amounts has been found in the tertiary sandstones and conglomerates near Colorado Springs.)

The colony of Queensland has 3,100 square miles of gold-bearing gravel worked in 1876. The fields occur on both sides of the dividing range, separating the eastern and western waters, and on the spurs of the range forming the watershed to the Gulf of Carpentaria. (Placers in similar relations to the Front range occur in Colorado.)

In South Australia gold is found in every part of the colony in deposits of limited size. In Spike's Gully a drift 20 to 100 feet deep consists of quartz pebbles, boulders and rusty conglomerate, and the gold is waterworn.

Gold was discovered in New Zealand in 1842. The alluvial deposits are chiefly in the south island, where operations are carried on over an area of 20,000 square miles. The detritus is in beds of rivers, on large deposits of gravel 300 to 500 feet deep, and on the sands



British Columbia Gold Fields (After Locke).

along the sea shore. The Otago drifts rest on the denuded surface of the parent rock, while in Westland they lie on tertiary rocks of marine origin. Two-thirds of the gold returned from this country is obtained from alluvial mining. The extent of the work may be imagined from the fact that miners have constructed 5,000 miles of water races and tail races and dams, at a cost of £300,000, independent of the government water races and dams, costing £450,000.

Ground sluicing is practiced and hydraulic mining, the latter with heads of water 80 to 100 feet. The government has a tunnel 11 by 7 feet 5,744 feet long, in course of construction, having already built the open sludge-channel, 8 miles long, at Naseby. Besides these, several tunnels have been built by private individuals.

In the river Clutha dredging machines are used, and north of Charleston the sea beach sands containing gold are worked by Shetlanders. At Tinkus 40 sluice heads with 130 feet head, conducted through 4,500 feet of iron piping, are used to hydraulic the gravel. The depth of deposit is 30 feet. In Tapir district gold is found in considerable quantities *in decomposed soil on the slopes of the hills*. It is usually flaky and not at all waterworn. (This is very like the occurrence of gold in so-called placers on Mineral Hill, near Cripple Creek, Colorado, where the gold occurs in soil and in a gravel of small, angular pebbles to a depth of 10 feet on the hillside. The deposits bear little evidence of transportation by water and the gold is flaky and not waterworn. It was evidently derived from decomposition of float, etc., very close to the deposits.)

In the conglomerate formation the gold is caught in the brown sandstone bottom over which the conglomerate lies. In the glacial drifts extensive claims have been worked and large quantities of gold obtained (as in Colorado). These deposits derive their gold from the slates of which the glacial drifts are composed. (In Colorado the gold is derived from all kinds of crystalline rocks, principally granites, schists and porphyries).

The "black sand beaches" on the sea coast are composed of crystals of magnetic iron ore (as in California), which are found disseminated through the chloritic schist. In places the ground is "spotted" and the gold unevenly distributed.

In Canada, North America, the gold is derived from

(Continued on page 182.)

THE COLLIERY ENGINEER

AND

METAL MINER.

WITH WHICH IS COMBINED THE MINING HERALD.

Established 1881. Incorporated 1890.

PUBLISHED MONTHLY AT SCRANTON, PA.

TERMS.

Subscription, (Postage in the U. S., Canada, or Mexico, prepaid.) **$2.00 a Year.**

To Foreign Countries in the Universal Postal Union, $2.50.

THE COLLIERY ENGINEER AND METAL MINER and HOME STUDY, $2.00 per year.

Remit by P. O. Order, Express Money Order, Bank Check or Draft or Registered Letter.

P. O. Orders.—You can buy a Money Order at your Post-Office payable at the Scranton Post-Office.

Express Money Orders can be obtained at any office of the American Express Company, the United States Express Company, and the Wells, Fargo & Co.'s Express Company.

Registered Letters.—If a Money Order Post Office, or an Express Office is not within your reach, your Postmaster will register the letter you wish to send us on payment of eight cents.

We Cannot Be Responsible for money sent in letters in any other way than by one of the four ways mentioned above.

EXPIRATION OF SUBSCRIPTION.

The date after your name on the wrapper of THE COLLIERY ENGINEER AND METAL MINER shows to what time your subscription has been paid.

RENEWALS, ETC.

If you do not want THE COLLIERY ENGINEER AND METAL MINER continued for another year after your subscription has run out, notify us by postal card to discontinue it. The courts have decided that subscribers to newspapers who do not order their paper discontinued at the expiration of the time for which it has been paid, are held liable for the payment of their subscriptions up to the date when they order the paper discontinued.

NOTICE OF DISCONTINUANCE.

THE COLLIERY ENGINEER AND METAL MINER is sent to subscribers until an explicit order for its discontinuance is received by us, and all payment of arrearages is made, as required by law. *Papers returned are no notice of discontinuance, as we cannot tell where they are from.*

CHANGES OF ADDRESS.

A subscriber wishing to have his address changed should be careful to give his *former* as well as his present address; otherwise we cannot find his name on our mailing list.

All communications should be addressed,

THE COLLIERY ENGINEER COMPANY,
Coal Exchange,
Cable Address—"Retsof, Scranton." Scranton, Pa.

For Table of Contents see page viii.

THE MINERAL RESOURCES OF VARIOUS NATIONS.

WE have before us the "First Annual General Report upon the Mineral Industry of the United Kingdom of Great Britain and Ireland."

Being the first Annual Report, it is commendable as such, for its collection of facts that are intended to furnish a basis for a "Comparison of the Mining Industry of Great Britain with other Foreign Countries."

The mineral resources of other nations shown in tables in this report teach lessons of great value. For example, we learn that a high civilization and good government are necessary for the development of the mineral resources of any country, and therefore we find the Chinese in possession of the richest mineral treasures of any people on the earth, and yet they do not develop them.

On page 59 of the report we read:

"The mineral wealth of China is enormous. In addition to important coal fields, it possesses numerous workings for metallic ores. The province of Yunnan in the south of the empire seems to be specially favored with regard to metalliferous wealth, for mines of gold, silver, copper, iron, lead and tin are worked there; whilst jade and precious stones are found in the beds of rivers. Brine springs yield salt, and natural gas discovered in boring for salt is used in evaporating the brine.

"The peninsula of Corea has likewise been richly endowed with minerals by nature, and gold is worked in various parts of the country, and though the methods of extraction adopted are primitive, the output is by no means inconsiderable; anthracite and the ores of lead and iron could be wrought by an energetic population, to say nothing of the other minerals."

The decline in the copper mining of the British Isles is the result of the ores of poor quality having to compete with those of a richer yield, and therefore British capital is transferred to foreign mines, so that here we have conditions in industry and trade the opposite of those found in China. From the Report we learn that the output of metallic copper from the British mines in 1860 was 236,000 tons, and in 1894 it had fallen to 5,994 tons; or in 34 years the output had fallen to $\frac{1}{40}$th of its former value.

The phosphate industry of the British Isles is dying a lingering death. The phosphates of Florida are of better quality, and for the price, the British farmer is finding them a better paying investment. Here, then, is a nation, ready to compete with the world in the development of her resources, beaten at home, while the Chinese, having the best resources in the world, are lacking in the enterprise to open them out.

Speaking of Arabia, the report says:

"The Arab is not a miner by nature, and there is little or no working for minerals on the great Arabian peninsula. In days gone by, according to Burton, gold mines were worked in the land of Midian."

Contrast this case again with that of England: Here their principal supply is the Cleveland ore, that is an earthy carbonate, and only yielding 30 per cent. of metallic iron, and in addition to which they have the brown hematite confined to a restricted area in Yorkshire and Lancashire yielding from 50 to 60 per cent. of metallic iron; and the black band ironstone of Scotland that gives a moderate yield both of ore and metal, and yet by enterprise this people according to the report have to import large supplies of iron ore from abroad, for, says the report:

"Algeria is rich in iron, and two-thirds of the value of its total mineral output are due to the ores of this metal. The principal mines are those of the Moktael-hadid Company, which works magnetic iron ore in the department of Constantine, and manganiferous red hematite in the department of Oran. The whole of this ore is exported, England taking a far larger share than any other country."

No nation in Europe has smaller mineral resources than Italy, and, notwithstanding the fertility of her soil and the great industry of her people, having no coal to smelt her iron ores, that are abundant, and develop manufactures, she does not take rank as a rich nation, for she is only an exporter of zinc, marble and sulphur.

Coal mines make nations richer than do gold mines, and the nations that most actively compete with each other are those that develop their coal resources most, as can be seen by the following output in tons, taken from the report under consideration, and given in *millions* of metric tons, for the year 1894.

The following is the coal production for 1894, in millions of metric tons, of the most powerful nations of the earth; the names are set according to the magnitudes of the outputs:

	Tons.		Tons.
Great Britain	190,000,000	France	28,000,000
United States	162,000,000	Austria-Hungary..	15,000,000
German Empire	98,000,000	Russia	9,000,000

The iron ore productions for 1894, in millions of metric tons, of the most powerful nations of the earth are as follows, the names are set according to the magnitudes of the outputs:

	Tons.		Tons.
United States	20,000,000	France	1,000,000
Great Britain	13,000,000	Austria-Hungary	1,000,000
German Empire	8,000,000	Italy	0.100,000
Russia	4,000,000		

Altogether, the facts furnished by the report indicate that the United States in the immediate future will be the greatest mining and manufacturing nation on earth, because she has the mineral resources and the energy and high degree of civilization necessary for their utilization.

ILLINOIS COAL INDUSTRY.

HON. GEORGE A. SCHILLING, Secretary of the State Bureau of Labor Statistics of Illinois, has completed the compilation of the report of the coal industry of that State for 1895. A study of the summary of Mr. Schilling's report, as given in the following table, will prove of interest. The comparisons of the statistics for the years 1894 and 1895 are very complete:

	1894	1895
Number counties mining coal	56	54
Number mines and openings	836	847
Number shipping mines	319	319
Number mines in local trade	517	528
Number tons coal mined, all grades	17,113,576	17,735,864
Number tons lump coal mined	13,865,284	14,045,962
Number tons other grade of coal	3,248,292	3,689,902
Number of tons nut coal included in other grades	479,595	897,912
Number acres worked out (estimated)	2,818.01	2,950.69
Number employes, all kinds	38,477	38,630
Number miners	31,595	31,515
Number other employes, including boys	6,882	7,115
Number boys over 14 under ground	701	811
Number employes under ground	32,046	34,648
Number employes above ground	6,431	3,982
Average number of days of active operation, shipping mines	181.1	182.2
Aggregate home product	$15,282,111	$14,239,157
Aggregate home value lump coal	$13,998,788	$13,090,836
Aggregate value other grades of coal	$1,283,331	$1,148,321
Average value lump coal at mines	$1.0086	$0.932
Average value other grades at mines	$0.395	$0.309
Average price for hand mining (the year)	$0.761	$0.573
Average price for hand mining (summer)	$0.6435	$0.516
Average price hand mining (winter)	$0.6847	$0.596
Number tons lump coal mined by hand	7,368,860	7,868,000
Number tons mined by hand, day wages	1,290,860	1,100,540
Number tons mined by hand, gross weight	2,727,331	2,934,998
Number mining machines in use	296	322
Number tons coal, all grades, machine mined	3,396,139	3,531,436
Number tons lump coal, machine mined	2,496,793	2,409,904
Number tons, other grades, machine mined	798,781	824,235
Number kegs powder used	758,383	824,998
Number men killed	72	75
Number wives made widows	41	42
Number children left fatherless	114	111
Number men injured, losing time	521	605
Number tons coal mined to each life lost	237,689	236,478
Number tons coal mined to each man injured	32,847	29,312
Number employes to each life lost	534	515
Number employes for each man injured	74	64
Number of mines opened and old ones reopened	156	115
Number mines closed or abandoned	108	78

STATE GEOLOGICAL SURVEYS.

UNFORTUNATELY the value of State geological surveys is realized by comparatively few citizens not interested in the development of the mineral resources in their respective States. As a result such surveys are accorded either very lukewarm support or very decided opposition by many citizens and members of legislative bodies. A number of the States of the Union have now in progress such surveys, and Pennsylvania (the richest mining State) has practically closed hers as *finished*. The value of a first-class, up-to-date, geological survey of a State to its material development cannot be estimated. Such a survey determines the presence or absence of minerals, and makes such facts public. If the minerals are present, the State is enriched by their development and utilization. If absent, the State is benefited by the saving of the capital and labor of its citizens who are informed of the futility of spending time and money prospecting for an absent mineral.

A geological survey may be either very general in its character or may be very detailed. The latter is the better, and the money expended in procuring it will be returned, in an indirect manner, many time over. It is a grave mistake for any State to follow the example of Pennsylvania in terminating its geological survey. While it is true that Pennsylvania's geological survey has pretty thoroughly covered the State, it has not completed the work. In fact the work will never be completed until the last ton of mineral available in the State has been mined. Thanks to conscientious work on the part of the officials of the survey and the assistance of the mine owners and the mining engineers of the State, the one hundred and twenty volumes of Geological Survey Reports of Pennsylvania are in excellent shape, *up to the date of issue* of each. But in some instances they are "back numbers." The actual opening up of the minerals with pick and drill, has in very many instances proven that abnormal features in the strata, which could not be determined on the surface, have changed the conditions so that the approximations of the survey were incorrect. This is in no wise an adverse criticism on the work of the survey. There are fully as many instances in which the approximations have been proven remarkably exact. To make Pennsylvania's survey of permanent value and use, the records made by pick and drill should be collected by the State, and a permanent geological survey force should be maintained to issue an annual report, which would note all newly discovered geological features and correct all mistakes made in previous reports. Such a force would not entail any great expense on the State. A State Geologist with a corps of three or four young men as assistants would be force enough to keep Pennsylvania's geological survey reports up to date. In Prof. Peter Leslie the State has a citizen eminently qualified for the work, and one to whom the Commonwealth owes a debt that it will be difficult to pay. He was at the head of the Second Geological Survey and is familiar with every detail of the work. Besides, his personal sacrifices of time and his own means, in the interest of the work, when State funds were not available, make it but an act of justice that the State of Pennsylvania should install him in such an office. Every State now having a geological survey in progress, will be greatly benefited if it makes the office of State Geologist a permanent one, and thus keeps up a system of annual reports after the main work of surveys now in operation is completed.

Naturally, the appointment of a State Geologist must not be given to a politician. The men qualified for such positions are not active in politics. Therefore, the office should be an appointive one.

Book Review.

Shop Kinks and Machine Shop Chat. A series of over Five Hundred Practical Paragraphs in familiar language, showing special ways of doing work better, more cheaply and more rapidly than usual. By Robert Grimshaw, M. E., etc. Octavo cloth. 293 pages. 222 illustrations. Published by Norman W. Henley & Co., New York. Price $2.50. This is Mr. Grimshaw's latest production, and it is fully up to the practical standard of his other works. It is written in the author's well known and unique style, which presents technical facts in such language as to amuse as well as instruct the reader. In fact Mr. Grimshaw might be aptly called the Mark Twain of technical writers. Technical subjects as a rule are treated in a manner that makes their study a task of more or less magnitude, depending on the interest of the student. Mr. Grimshaw's method of treating such subjects makes them attractive and pleasurable. The volume before us, with its five hundred hints, must contain a large number of great value to every shop manager, foreman, machinist and engine driver. It is not an exaggeration to say that the man connected with machinery who reads this book will strike at least one idea that will be worth many times its price to him. It would pay the manager of every machine shop in the country to get a copy of this work and also to present a copy to each of his foremen. It don't take much of a "kink" to save $2.50 on any ordinary job.

Proceedings of the Alabama Industrial and Scientific Society, Vol. V, 1895. Published by the Society, University Post Office, Alabama. This pamphlet contains in addition to the official addresses, reports, etc., the following papers: Utilization of By-Products from Coke Oven, by J. A. Montgomery; Mobile Point Alabama's Deep Water Harbor, by G. D. Fitzhugh; Alabama Barite or Heavy Spar, by Henry McCalley; The Pig Iron Market, Its Extent and How to Improve It, by James Bowron; Value of Raw Materials in Iron Making, by Prof. W. B. Phillips; Alabama's Resources for the Manufacture of Portland Cement, by Eugene A. Smith.

Seventh Biennial Report of the State Mine Inspectors of Iowa. For the two years ending June 30, 1895. In this State there are three Inspection Districts, under the supervision of, Mr. James A. Campbell, 1st District; Mr. J. W. Miller, 2nd District, and Mr. Morgan G. Thomas, 3rd District. The reports furnish few numerical statements and we are not therefore able to give the mortality and injury arising from different and prevailing causes in percentages, so as to contrast Iowa mining with that of other States. We learn, however, that the output of coal for the year ending the 30th of June, 1895, was a little over three millions of tons, and that the number of persons employed in the mines and on the surface for that output was 10,992.

We have by counting out of a great number of small tables found the following facts: Out of 320 collieries artificial ventilation is produced as follows:

Steam jet, 4; furnace, 218; fan, 98. Classifying the modes of working under two heads, we have: Room and pillar, 221; longwall, 99.

The Journal of the Iron and Steel Institute of Great Britain, 1895, Part II. This is the forty-eighth volume of the transactions of this great engineering society, and it is edited by Mr. Bennett H. Brough, secretary. It is an octavo volume of 658 pages, bound in cloth, and published for the Institute by E. & F. N. Spon, London and New York. Besides a large number of valuable papers by members of the Institute and discussions on the same, it contains in Section II, "Notes on the Progress of the Home and Foreign Iron and Steel Industries," which are abstracts from the latest and best literature on the subjects directly and indirectly connected with the iron and steel industry. These abstracts with references to their source have been made by Edwin J. Ball, Ph. D., and the secretary.

The Origin and Rationale of Colliery Explosions, *Founded upon an Examination of the Explosions at the Timsbury, Albion, Malago Vale and Llanerch Collieries, and upon the Principal Phenomena at over a score of other British Collieries.* By Donald M. D. Stuart, F. G. S., Mining and Civil Engineer, author of "Coal Dust an Explosive Agent." Quarto, Cloth. Published by John Wright & Co., Bristol, Eng.; Simpkin, Marshall, Hamilton, Kent & Co., London; Hirschfeld Bros., New York. Price, $3.00. The writer very ably maintains his theory of the cause of explosions in what he calls non-gaseous mines, and he attributes to coal dust more than to fire damp, the origin of nearly all the explosions in mines. One cannot read a page of this book without being impressed with the conviction that the writer is intensely in earnest, and therefore his book is worth reading; for, whether we can accept the dictum or not, that there is or can be a seam of coal that in course of working gives off *no gas*, and the dust of which when heated gives off *much gas*, or the other conclusion of the writer that the heating of the dust by flame separates pure hydrogen entirely disassociated with carbon, we still learn a great deal from the writer's collection and arrangement of facts. He shows clearly that at the explorations of the workings of the Timsbury and Camerton mines immediately after the explosions in the "*non-gaseous*" workings, it was evident that the explosive force was repeated at several points in succession, or in short that instead of a single explosion in both these and other cases that he refers to, the blasts were of a multiple character. This conclusion we can fully endorse by experience, and the fact of the multiple character of explosions has been known for more than half a century. Mr. Stuart finds that there were no less than 18 centres of explosions located in the Timsbury workings after the disaster there, and in every one of them the force had acted destructively in opposite directions; and further, the coked carbon was found to adhere to the roof and sides in the regions of the hottest flames. He concludes with good reason that the gas given off by the heated dust was in excess of the oxygen required for its combustion, and therefore along certain lines the gas traveled with the swift current until fresh supplies of oxygen quickened it at certain points into a fresh explosive mixture. These are the claims among others of no less importance that the author tries to establish, and whether his conclusions are right or not, the book is of great value, being ably written, and being also the best presentation of the claims of the coal dust theory we have seen.

Hand Books for Mining Students and Colliery Managers, Part II. *Boilers and Fittings—Heat and Steam—Steam and Other Engines.* Octavo. Cloth. 51 Pages. Price, 1s. (24 cents.) Published by *The Science and Art of Mining*, Wigan, England. This little volume treats on Steam Boilers, the Properties of Steam, and the Powers and Modes of Action of Different Steam Engines. The style of the book is that of a catechism. The answers to the questions are correct in principle and so simply rendered that like all other books of this character, it will prove an invaluable aid to progress, when in the hands of men who are striving to advance.

The Natural Philosophy of a Ventilating Regulator, By H. W. Halbaum. Octavo, paper covered, price, post paid, 1s. 1d. (27 cents). Published by Thos. Wall & Sons, Wigan, England. This is a small treatise that aims at showing that former writers were wrong in their mathematical expressions for calculating the velocities of air currents through the regulators in the air passages of mines. From the style and confidence of the writer we are led to conclude that Mr. Halbaum is a young man of small experience yet of considerable ability, and for that reason he appears to require a little regulating to correct his ideas of respect for such writers as Mr. Pamely. Why the latter gentleman should be singled out for attack we are at a loss to understand. In the first place it is true that some carelessness has been practiced by writers on mine ventilation, in making equations for regulator velocities, but Mr. Pamely appears to be only one of the number, and as he is a man of considerable weight, the writer of the pamphlet goes boldly for him. Under these circumstances the author cannot wonder if we remind him of two things that concern us.

First:—In our issue of November last we gave on page 92 of The Colliery Engineer and Metal Miner the correct expression for the velocities of air currents through regulators, and that is the month in which Mr. Halbaum printed the treatise under consideration.

Second:—We began in the last September issue of The Colliery Engineer and Metal Miner, a series of articles on the ventilating fan, in which it was shown that it was altogether an error to calculate the velocities of air currents entering ventilating fans, by taking the equivalent pressure that balances the mine resistance, to find the effective pressure for the *fan's* not the *mine's* equivalent orifice. Now here is a common mistake just as great as that of the usual formula for calculating regulator velocities, and yet on page 46 of Mr. Halbaum's treatise he says, "And, indeed, to refuse to grant its truth as an abstract statement would be to call in question the whole theory of the conservation of energy." Mr. Halbaum should have detected the misapplications of M. Murgue's theory of the equivalent orifice.

Lidgerwood Cableways for the Panama Canal.

Spencer Miller, M. E., engineer of the department of hoisting and conveying machinery of the Lidgerwood Manufacturing Company, New York City, who recently went abroad in the interests of that company, has just closed a contract with the Compagnie Nouvelle Du Canal De Panama at Paris, for seven Lidgerwood cableways, to be used on the Panama Canal. This company is one which has recently been formed to complete the great Panama canal, and the seven cableways will be used exclusively for earth excavating. They will be equipped with all the latest improvements, including the patent aerial dump, which is such an important feature of these machines, the apparatus throughout being similar in construction to the twenty Lidgerwood cableways used on the Chicago Main Drainage Canal, except that the Panama cableways will have fixed towers and anchorages. The spans will range from 250 to 300 feet. This order was not placed until after a most careful and extended investigation had been made of the various apparatus available for canal excavating purposes. Engineers were sent by the Compagnie Nouvelle Du Canal De Panama from Paris to examine the Lidgerwood cableways and other excavating machinery in use at Chicago on the canal there building. The result of their investigation was a most flattering report in favor of the Lidgerwood cableways, and the negotiations then begun have resulted in the large order secured by Mr. Miller. This is one of the largest single orders for cableways of any description ever received by any concern in this country from abroad, and points to a world-wide appreciation of the merits of the Lidgerwood cableway that fully justifies the claims advanced by the manufacturers that it is the most perfect, most economical and efficient apparatus of the kind ever devised.

The Tennessee Centennial and Industrial Exposition.

Tennessee proposes to celebrate the One Hundredth Anniversary of her admission to the Union by holding at Nashville an exposition, beginning Sept. 1, 1896, and continuing 100 days.

The Tennessee Centennial and International Exposition has been organized and will be carried out on a grand scale and in a manner worthy not only of the state of Tennessee, but of the whole country. While it is the purpose to emphasize the natural resources of Tennessee, yet we invite and desire competition from all quarters. It will be a rare opportunity for those who may wish to advertise to the public at large their ores, minerals, coals, clays, marbles, building stones and kindred material, as well as machinery and appliances for mining, quarrying and finishing the same.

No charge will be made for space in any of the buildings of the Tennessee Centennial and International Exposition, but exhibitors will be required to make a small deposit at the time their exhibits are accepted, as a pledge of good faith that the display will be ready for inspection September 1, 1896. If it is ready then, the deposit will be promptly returned. The above applies to those who make exhibits for profit; no others are required to make such deposits.

We trust that you will see fit to avail yourself of the opportunity presented and supply us with a generous exhibit.

Inquiries for additional information will be promptly and cheerfully answered, if addressed to Paul M. Jones, Secretary, Nashville, Tenn.

A Most Effective and Inexpensive Pump.

We desire to call the attention of our readers to the Vanduzen Steam Jet Pumps (see advertisement in another column). These pumps are of unique simple design, and so constructed that when placed in position for regular duty, they cannot retain water while not at work, and hence cannot freeze up in the coldest weather. Being made of brass, they will not crack or break because of extremes of temperature, and will stand greater strain and will not rust. They will always be found ready for work and need no watching nor constant looking after; when put in place it is only necessary to turn on steam and it starts to work, and turning off steam will stop it. It is used for many different purposes; in wells, pits, quarries, mines, river and lake sides, tube wells, in tanneries, mills, factories, on steamships, tugs, ferry boats, and so we might name numerous other uses for this excellent pump. As they operate in conformity to the law of nature with steam as the active agent, it is an absolutely reliable pump at all times. Thousands of them are in daily use, not only in the United States, but in at least twelve foreign countries, Australia, Hawaii, Japan, India, South Africa, Cuba, West Indies, and in Mexico, and Central and South American countries, and everywhere they give full and entire satisfaction. The price is so low, and the setting up is so simple that any one in need of a simple steam pump should certainly secure one or two as the case may require, at once. The cost ranges from $7 for the smaller size, up to $75 for the largest size, which will elevate from 10,000 to 15,000 gallons of water per hour to any height not exceeding 50 feet, vertically measured. Where the height exceeds 50 feet but not over 100 feet, two pumps are used, one above the other. We can recommend these pumps, and the manufacturers, the E. W. Vanduzen Co., Cincinnati, Ohio, will take pleasure in sending price and illustrated catalogue free.

Proposals Wanted from Engineers.

Sealed proposals will be received by the Council of Oakmont Borough, Pa., for the following work:

1st. For a complete profile and grade plan of all streets and alleys in the Borough.

2nd. To erect boundary monuments at the intersection of each and every street.

3rd. For a complete sewer plan of the entire Borough giving dimensions of sewers and showing location of streets, inlets and man-holes. Separate bids must be presented for each part of the work, but a bid for the entire work will be accepted in addition. Blue print of Borough plan will be furnished on application to Borough Engineer.

All bids must be in by April 1st, 1896. The Council reserves the right to reject any or all bids, and also reserves the right to divide the work, letting it out in parts to different contractors if they see fit. For further information apply to Borough Engineer. Mail to Clerk of Council, Oakmont, Pa.

February 17, 1896.

Electric Pumps.

"Electrically Operated Power Pumps" is the title of a handsome 44-page illustrated pamphlet recently issued by the Knowles Steam Pump Works, of New York, Boston, Chicago and London. The compiler of this pamphlet says in his preface that the pamphlet "is compiled, not from designs and data of types as yet largely on the drafting board, but from knowledge of apparatus already built and thoroughly proven in actual service." Pumps for almost all classes of service run by electric power are clearly illustrated and described. This pamphlet is sent free on request to every mine official.

This department is intended for the use of those who wish to express their views, or ask, or answer, questions on any subject relating to mining. Correspondents need not hesitate to write for supposed want of ability. If the ideas are expressed, we will cheerfully make any corrections in composition that may be required. Communications should not be too lengthy, and personal reflections should be carefully avoided.

All communications should be accompanied with the proper name and address of the writer—not necessarily for publication, but as a guarantee of good faith.

The Editor is not responsible for views expressed in this Department.

☞ Correspondence should be in as simple language, and as free of technical terms and formulæ as possible, consistent with clear solution.

Questions on subjects not directly connected with mining will not be published.

Broken Shaft.

Editor Colliery Engineer and Metal Miner:

SIR:—I will be obliged if one of your readers will answer the following questions for me:

At Kangley Mine No. 2 we are using an endless rope system of haulage with 2¼ miles of ⅝" crucible steel wire rope worked with an engine of the Litchfield pattern with 12" × 20" cylinders and a 7 foot cog-wheel to which is attached a 4 foot drum. Placed 3 feet behind this drum is another drum which is equipped with Walker's slide rings. This drum is not connected with the engine, but is worked by the rope passing from the forward drum back over the Walker drum with five laps, thence to the tension wheel, and on to the inside. The shaft, which is a six-inch one, has broken at two different times within four months. What would cause the breakage of such a large shaft, it being only 4 feet long? Could the variations in the grooves of the drum made made by the wear of the rope cause the fracture?

If the drums were not set true with each other would that cause the break? Yours, etc.,

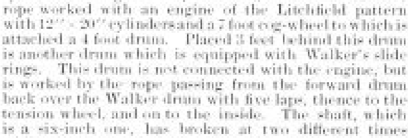
REESE NOLL, Kangley, Ill.

February 4th, 1896.

A Fan Question.

Editor Colliery Engineer and Metal Miner:

SIR:—Can you, through your paper, say whether a fan will give more or less air at a certain speed with one or two discharges of same area, and why?



A, B, C, all have same area.

Yours, etc.,

BAIRD SNYDER, JR., Asst. Supt.

Lansford, Pa., Jan. 29, 1896.

Ventilation.

Editor Colliery Engineer and Metal Miner:

SIR:—Will you please publish the following in answer to P. C., Dominion No. 1, C. B., Nova Scotia:

1\. Two shafts 6 feet by 6 feet, each 1,000 feet deep, pass 45,000 cubic feet of air per minute. How much must they be enlarged to reduce the power required one-half?

2\. In a certain mine there are 10,500 cubic feet of air per minute passing in an airway 5 feet by 6 feet and 2 miles long. Work was continued until the airway was 2½ miles in length, when a creep came on, which reduced the airway in area for 1 mile to 15 feet, or 5 by 3 feet, and for a further distance of one-half mile to an area of 10 feet, or 4 feet by 2½ feet. What quantity of air should then pass, the power remaining the same?

ANS. 1. The work done to pass a given quantity of air through an airway is expressed by the following equation:

$$\frac{k\,l\,o\,q^3}{a^3} = u. \quad (1).$$

Now, let x = length of one side of shafts after being enlarged.

Then $4\,x$ = perimeter.

And x^2 = area.

Whence $\frac{k\,l\,4\,x\,q^3}{x^6} = u$ for enlarged shafts. (2).

The value of u in (1) is twice that of u in (2).

Hence, $\frac{k\,l\,o\,q^3}{2\,a^3} = \frac{k\,l\,4\,x\,q^3}{x^6}$ (3).

Dividing (3) by $k\,l\,q^3$ it becomes

$$\frac{o}{2\,a^3} = \frac{4\,x}{x^6} = \frac{4}{x^5} \quad (4).$$

Clearing (4) of fractions, substituting known values and simplifying, it becomes $x^5 = 15{,}552$.

Therefore, $x = \sqrt[5]{15552} = 6.892$, and $x^2 = 47.4996+$.

ANS. 2. $k\,s\,v^3 = u$. Therefore, to pass 10500 cubic feet of air through an airway 5 ft. × 6 ft. and 2 miles long, it would require

$.00000001 \times [(2 \times 5) + (2 \times 6)] \times 2 \times 1760 \times 3 \times \left(\frac{10500}{5 \times 6}\right)^3 = 99697.2$ units of work.

The velocity through the altered airway will be inversely as the area, that is, if 1 be the velocity through 30 ft. area, 2 and 3 will be the velocities through 15 and 10 ft. area respectively.

The work necessary to pass the same quantity through the different sections will be proportional to $s\,v^3$.

Where the airway is

5' × 6' × 1 mile long	$s\,v^3$ = 22 × 1 × 1³	=	22.
5' × 3' × 1 "	$s\,v^3$ = 16 × 1 × 2³	=	128.
4' × 2½' × ½ "	$s\,v^3$ = 13 × ½ × 3³	=	202.5.
Total			352.5.

352.5 : 22 :: 99697.2 : 6216.62.

Therefore, 6216.62 units of work are spent in overcoming the friction of the air, through one mile of airway 5 × 6 in section.

$$\sqrt[3]{\frac{u}{k\,s}} \times a = q, \quad \sqrt[3]{\frac{6216.62}{.00000001 \times 1760 \times 3 \times 22}} \times 30 =$$

5247.48 cubic feet, the required quantity.

ADOLPHE COOK,

Feb. 20th, 1896. Houtzdale, Pa.

The Fifth or Higher Roots.

Editor Colliery Engineer and Metal Miner:

SIR:—The following rule for extracting the fifth or higher roots, without the aid of a table of logarithms, is of more universal application than any of those recently proposed in your "correspondence" column, and may be of interest to your readers. Let it be required to find the nth root of a, in which n and a are both positive numbers, whole or fractional.

Rule—Take b, some number, whole or fractional, whose nth root is known, substitute for a and b their values in the following equation:

$$k = 2\left[\frac{a-b}{a+b} + \frac{1}{3}\left(\frac{a-b}{a+b}\right)^3 + \frac{1}{5}\left(\frac{a-b}{a+b}\right)^5 + \&c.\right] (1).$$

Find the value of k from equation (1) and substitute for k and n their values in the following equation:

$$x = 1 + \frac{k}{n} + \frac{k^2}{1 \times 2 \times n^2} + \frac{k^3}{1 \times 2 \times 3 \times n^3} + \&c. \ (2).$$

Reduce and find the value of x. Multiply the value of x thus found by the nth root of b and the product is the nth root of a required.

(*Note*—The number b, should be assumed with the view of making the fraction $\frac{a-b}{a+b}$ as small as possible. Should the fraction $\frac{a-b}{a+b}$ be negative, change its sign and proceed as before, but place the second member of equation (2) equal to $\frac{1}{x}$ instead of x.)

Example—Find the fifth root of 9, (which is the problem given by Mr. Torey in your January number). Here $a = 9$, $n = 5$. Let $b = \left(\frac{3}{2}\right)^5 = \frac{243}{32}$.

Substituting these values of a and b in equation (1), we get $k = 2\left[\frac{5}{59} + \frac{1}{3}\left(\frac{5}{59}\right)^3 + \&c.\right] = .169807+$.

Substituting the values of k and n in equation (2) we get $x = 1 + \frac{.169807}{5} + \frac{(.169807)^2}{1 \times 2 \times 25} + \&c. = 1.034556+$.

Multiplying this value of x (1.034556+) by $\frac{3}{2}$ (the nth root of b), we find that $\sqrt[5]{9} = 1.551834+$, which is correct to 5 or 6 decimal places.

Yours, &c., S. A. COREY,

Feb. 3rd, 1896. Hiteman, Iowa.

The Fifth Root.

Editor Colliery Engineer and Metal Miner:

SIR:—I have read the explanation of the approximate rule for the extraction of the fifth and other roots by Mr. Thomas Hannah with interest and pleasure, but as practical mathematicians practise a more simple and more correct method when a table of logarithms is not to hand, I beg to give the rule for the assistance and encouragement of your most industrious correspondents. Suppose we require the fifth root of the number 14348907. By pointing off five places it becomes 143,48907, and by trial we see the root lies somewhere between the numbers 26 and 28, and we then proceed to reduce the number to the fourth power by dividing twice the given power by the sum of the trial roots, as

$$\frac{14348907 \times 2}{(26 + 28)} = 531441.$$

Then $\sqrt[4]{531441} = 27$, the true root. Or, to extract the biquadrate root, extract the square root of the square root. The sixth root can be found by the square root of the cube root, and the seventh root can be found by multiplying the given number by the sum of the trial roots, when the product will be double the eighth power of the root required, therefore divide by 2, and extract the square root of the square root, and the third root thus obtained is the required seventh root. The ninth root is found like the fifth by reducing, that is reduce to the eighth power.

Take care that in all cases that one of the roots is a little less, and the other a little greater than the required root. Yours truly, AJAX.

Otto-Hoffman Coke Ovens.

The plant of sixty Otto-Hoffman coke ovens erected at Johnstown, Pa., is now in operation. Mr. John Fulton furnishes us the following data regarding this plant:

The plant cost $301,500.23, including exhausting and condensing plant with ammonia factory, or $5,025 per oven. It is designed to add 60 ovens to this plant, at an estimated cost of $166,000. This addition shows the cost of each oven itself to be $2,766.66. The plant thus enlarged will exhibit a cost of $3,895.85 per oven, including by-product saving appliances. The exhausting and condensing plant, with ammonia factory, has cost $134,301.03, or $2,238.35 per oven for the 60 ovens now in blast, and for the 120 of proposed plant, $1,119.18 per oven.

PRIZE CONTEST.

Prizes Given for the Best Answers to Questions Relating to Mining.

For the best answer to each of the following questions, the value of $1.00 in any of the books in our book catalogue, or six months' subscription to THE COLLIERY ENGINEER AND METAL MINER.

For the second best answer to each question, the value of 50 cents in any of the books in our book catalogue or three months subscription to THE COLLIERY ENGINEER AND METAL MINER.

Both prizes for answers to the same question will not be awarded to any one person.

Conditions.

First—Competitors must be subscribers to THE COLLIERY ENGINEER AND METAL MINER.

Second—The name and address in full of the contestant must be signed to each answer, and each answer must be on a separate paper.

Third—Answers must be written in ink on one side of the paper only.

Fourth—"Competition contest" must be written on the envelope in which the answers are sent to us.

Fifth—One person may compete in all the questions.

Sixth—Our decision as to the merits of the answers shall be final.

Seventh—Answers must be mailed us not later than one month after publication.

Eighth—The publication of the answers and names of persons to whom the prizes are awarded shall be considered sufficient notification. Successful competitors are requested to notify us as soon as possible as to what disposal they wish to make of their prizes.

Competition Questions for March.

QUES. 211.—As we are striving to make our proposed new safety lamp the best in the world, it certainly should be of some service in testing for gas, and as we require some additional information to enable us to make it so, let us band ourselves together for mutual help and we are sure to succeed. Then let us know at once what makes the gas cap tail up in a blue stream above the ordinary flame of the safety lamp.

QUES. 212.—When an explosion of fire-damp occurs in a coal mine, immense volumes of gas and air rush up and out of the shafts, and at the same time the expanded air and gas rushes into and becomes compressed in the gobs, do you think then that a correct sample of the after-damp produced by the explosion is procurable, and if so, where would you expect to find it? And while so doing, will you explain the recoil, or back rush of air into the levels, rooms, etc., after the blast has expended itself?

QUES. 213.—I am a mine superintendent for the Black Band Coal and Iron Co., and the principal director has requested me to read a paper before a meeting of the mine foremen of the district on the principles of construction and the mode of action of the electric motor, such as is used for mine haulage. He says the description must be brief and applied entirely to the magnetic field, and must only mention the commutator by a reference to its use. Now, as electrical appliances have come to the front for mining, I must either write this paper or lose my position, and I do think you will therefore make an effort to help me. Then, please give me the principal points required for a good paper.

QUES. 214.—We are about to open out a fine seam of bituminous coal that is 5 feet thick; and to work it we are going to sink shafts that will be 820 feet deep. Before, however, fixing on what should be the sizes of the shaft sections, we wish to determine what have to be the dimensions of the cars. The specific gravity of the coal is 1.27, and we want an output of 1,000 tons per day; will you, then, give us a sketch in elevation of the car you would recommend, and be careful to give the dimensions and capacity of the box, the sizes of the details of the bottom frame, and the sizes of the wheels and axles.

QUES. 215.—In surveying around the bottom of a mountain, we made all the necessary levels and insets to determine the correct figure of a truly horizontal base that was just touched by the western side of an outcropping coal seam. From the plat we found the figure to be practically that of an ellipse, with its major axis coursing from south to north 6,012 feet, and the minor axis coursing from east to west for 2,842 feet. The mountain is 1,800 feet high. The coal seam is 4 feet thick, and is overlaid with a strong sandstone. We levelled our transit at a distance of 64 feet eastward of the eastern end of the minor axis, and with the center of the telescope at an elevation of 4 feet 1 inch above the calculated level of the base, the bottom of the coal seam here made an angle of elevation of 38° 26', and the distance measured in a straight line from the plumb point on the ground to the bottom of the coal seam was found to be 1,026 feet. Now, I wish to know three things that I am sure you will calculate for me.

First.—What is the pitch of the seam?

Second.—What is the area of the seam?

Third.—What percentage of this seam could be reasonably worked? Show with a sketch how you find the pitch.

QUES. 216.—One of the air-ways in a mine is 6 feet high and 9 feet wide, and formerly a large volume of air was passed through it with a ventilating pressure of 1.2 inches of water gauge. Afterwards a regulator was fixed in this air-way to reduce the quantity passing to one-third of the former volume, and recently a new ventilating fan has been started at this mine, and it is treble the power of the former one. Now I will be obliged if you will determine for me five things:

First.—What is the length of the air-way, taking the co-efficient of resistance at .00000001?

Second.—What was the original quantity passing through the air-way?

Third.—What is the difference of pressure on the two sides of the regulator now, and what was it before the new fan was started?

Fourth.—What is the height of the water guage now for the drift?

Fifth.—What is the quantity now passing through the regulator in cubic feet per minute?

Answers to Questions which Appeared in the January Issue and for which Prizes Have Been Awarded.

QUES. 199.—In the construction of our new safety lamp, do you think we should adopt the principle of the tubular poles that are the distinguishing feature of the Gray lamp. This lamp is preferred for gas testing because it can detect a thin stratum of gas just under the roof of the seam. A shunt is provided in some "makes" of this lamp, to cut off the supply of air down the poles, and admit the supply above the glass cylinder, as in the Marsaut lamp, when it is not required to test for gas near the roof. Now I should like you to answer me three questions to aid me in deciding the point at issue:

First.—Why is the supply of air from the poles cut off when the lamp is in ordinary use?

Second.—When the lamp is fed with air from the poles, if you give it a quick sudden drop the light goes out. How is this?

Third.—When the lamp is carried in air charged with gas, if you move it quickly and suddenly upward, it fills with flame. How is this?

ANS. *First*—The supply of air from the top of the poles is cut off for ordinary use for three reasons: 1st. To prevent the entry of gas that might fill the lamp with flame; 2nd, if by any means the lamp was rapidly lifted it might fill with flame; 3rd, if the lamp was rapidly lowered when fed by the poles it might be extinguished.

Second—The air moves down the poles with a velocity due to the pressure set up by the motive column, and when the downward velocity of the lamp exceeds the downward velocity of the air in the poles the supply of air to the flame is cut off and the light is extinguished.

Third—When the lamp is suddenly lifted upward the supply of gas and air to the flame is increased and the result is the lamp fills with flame.

JOHN VERNER,
Lucas, Iowa.

Second prize, JOHN JENKINS,
Dingess, West Va.

QUES. 200.—We are going to prospect for coal, and at first we will only search for indications by examining the exposed rocks, and therefore we must get up in good shape our paleontology, in so far as the fossils that characterize the Silurian, the Devonian, the Carboniferous and the Triassic formations are concerned. Will you then assist us by naming the examples that we ought to know, and give them under four heads:

First.—Negative examples, as of the fauna of the Silurian and Devonian series.

Second.—Positive examples, as of the fauna of the Carboniferous and Triassic formations.

Third.—Negative examples, as of the flora of the Silurian and Devonian formation.

Fourth.—Positive examples, as of the flora of the Triassic and Carboniferous formations.

ANS. *First.*—Negative examples supplied from the Devonian fauna, are trilobites such as the Dalmania and phacops, and the characteristic ganoid fishes such as the cephalaspis, and among shells the spirifer formacula, a Devonian brachiopod. The Silurian fauna that give above all other examples, the most abundant negative indications of coal, are the graptolites, or peculiar sea pens of the period.

Second.—The footprints of reptiles on the bedding planes of the sandstones are first met with in the rocks of the Carboniferous period; and on the bedding planes of the shales of the same period lamellibranchs, such as the Solenomya anodontoides are frequently found. In the Triassic rocks the true encrinites, and beautiful cephalopods are found, such as the Ceratites nodusus, and now we find reptilian life most abundant and especially the teeth of labyrinthodonts.

Third.—Very few examples of plants are met with in the Silurian rocks, and what are found are lowly examples of acrogens, but the Devonian flora is somewhat abundant and is closely allied to that of Carboniferous times, although its negative character may be seen in its lower development.

Fourth.—Positive examples of the Carboniferous flora are abundant, such as pecopteris neuropterus, sigillaria, stigmaria, calamites, etc. Positive examples in the Trias, the peculiar horse-tails and coniferous trees.

JOSEPH VIRGIN,
Second, JOHN FLETCHER, Holsopple, Pa.
428 Tonti St., La Salle, Ill

QUES. 201.—In M. Murgue's theory of the equivalent orifice, the following equation is given: $A = \frac{.4Q}{\sqrt{WG}}$, and I will be obliged if you will inform me how he gets .4 for a constant. I know he takes the *vena contracta* at .62 and that A is the square feet in the equivalent orifice, Q is the quantity of air in thousands of cubic feet per minute, and $W\,G$ is the water gauge.

ANS.—The "equivalent orifice" depends upon the law that the speed of flow is the velocity due to the height of column of the flowing air, which is represented by the gravity formula,

$$V = \sqrt{2\,g\,h}.$$

The quantity passing through an orifice in a thin plate is taken as 0.62 of the quantity due to the area of the whole orifice. Hence, for the *vena contracta* the formula becomes

$$V = 0.62\,A\sqrt{2\,g\,h}, \text{ or,}$$

$$A = \frac{V}{0.62\sqrt{2\,g\,h\,\frac{d}{d'}}}$$

In the last, equation, as h must be reduced to air column, there is introduced the factor $\frac{d}{d'}$ expressing the relative densities of water and air.

Simplifying this equation for water gauge as usually taken in inches, remembering $2\,g = 64$, we have

$$A = \frac{V}{1.43\sqrt{h\,\frac{d}{d'}}}$$

The normal relative densities of water and air being 1,000 and 1.2; this becomes $A = \frac{V}{41.28\sqrt{h}} = \frac{0.024\,V}{\sqrt{h}}$.

In the above, V = volume in cubic feet per second. The volume in thousands of cubic feet per minute is used by Murgue. Representing this by Q, the equation becomes

$$A = \frac{24\,Q}{60\sqrt{h}} = \frac{0.4\,Q}{\sqrt{h}} \text{ or } \frac{0.4\,Q}{\sqrt{W\,G}}.$$

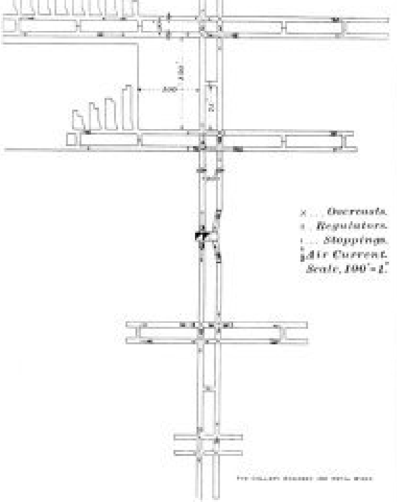
J. J. ORMSBEE, Henry Ellen, Ala.

Second Prize, JOSEPH JAMES,
Sioux Falls, South Dakota.

QUES. 202.—We have a seam of coal with a soft wet floor, and the immediate roof is a slate 2 feet thick and it falls. The seam is 4 feet thick, is at a depth of 612 feet, and consists of a soft coking coal lying nearly level.

We have tried longwall working and it has proved a great failure, as the packs sink into the floor. We have 700 acres available and the field is nearly square. The coal is valuable for coke making and we cannot give it up, then will you send us a neat plot of how you would work it. You might locate your shafts in the middle of the field; and give us the sizes of your roads, and pillars, if any.

ANS. I would work this seam on the room and pillar double-entry system and would if possible drive each entry to its limit before starting any rooms on it and would begin to draw the room pillars and entry stumps



together as soon as the rooms were up, starting rooms at the end of the entry first; in this way we would maintain good haulways, drainage and ventilation, with the least waste of coal from crushing and the least danger of gob fires, etc. The dimensions, the sizes of the roads, pillars, etc., and courses of the air are given in the sketch.

CHAS. ED. BOWRON,
Tracy City, Tenn.

Second prize, H. K. MOBERLY,
West Newton, Pa.

QUES. 203.—The same coal seam is pitching heavy in one region and in another it is lying quite level. The thickness and quality of the coals are, however, equal in the two cases, and we wish to invest in one of them, which do you prefer and why?

ANS. The areas and the qualities of the coals not being given. I will assume that the areas are equal, and that the qualities are first-class bituminous, and under such conditions I would, if the level coal is dry, prefer it to that lying in the pitching region for the following reasons:

First—There is less probability of the coal cropping out in the level field than there is in the pitching one.

Second—The level region furnishes a choice of location for the shafts, and better facilities for drainage, hoisting and ventilation.

Third—The level coal can be worked by any system that will favor a reduced cost and less crushed and injured coal.

Fourth—No pillar coal need be lost, or at any rate a higher percentage of the level seam can be secured than that of the pitching one.

Fifth—The first cost and maintenance of cars, ropes and roads is much less for a level seam than for a pitching one.

JAMES TASKER, Old Forge, Pa.

Second Prize, P. H. CARROLL, Vivian, W. Va.

QUES. 204. We have three mines all working the same vein, and we will call them A, B and C. The cover, the floor and the depth and thickness of the coal are in all the cases about equal and the system of working this 4 foot vein is the same at each mine, and that is longwall advancing. Now the superintendent at A, works on the principle of having plenty of "pit room" or a working face far in excess of that required for immediate use. The superintendent at B keeps no more working face open than is required for immediate use, but believes in having all ready for unexpected events. The superintendent at C does not believe in plans for future working, because, says he, some one may come after him and reap the harvest of his labor. This being a good presentation of the three cases, will you please give them your close attention, and let me know at your earliest, how it is that only one of these mines pays the company, while the other two are a "dead" loss, and be careful to say which mine pays, and show the reasons why it does so.

ANS. I vote for the superintendent at A. For pillar and room workings, no doubt B's policy would be good, but for *longwall* you cannot help having "plenty of pit room" if you are working the right way. In longwall, you have water and falls to provide for, and if you had not more face than that immediately required, you would not employ more than two-thirds of your men. A can, therefore, always be depended on for a full day's work and an increased output at a moment's notice. After longwall is opened up and settled, it is easily and cheaply kept open.

I am therefore sure that B and C could not by any means make their longwall pay, for longwall cannot be worked to profit when the face is crowded for coal.

WILLIAM HODGE,
Forbush, Appanoose Co, Iowa.

Second, JOHN FLETCHER,
428 Tonti St., La Salle, Ill.

[A very great number of competitors sent in answers to question 204, and they all except, the two gentlemen just mentioned, went in for B. Now had the workings been room and pillar, no doubt B was the man; but as they were longwall, B and C must have been working with fast sides in longwall panels, and therefore chopping and pounding the coal into slack, with the result that the mines could not pay. Again, you cannot have a circular or semicircular longwall face, and restrict the length of the face to the requirements of your men, for if you do, you must work with fast sides, and stand by the consequences. We hope our friends will be more careful to read the conditions of the questions in future. —ED.]

Examining Boards for Mine Inspectors

Owing to the illness and continued absence of Hon. Mason Weidman, Judge Bechtel, of Schuylkill county, postponed action on the appointments for the several examining boards until late in January, hoping that Judge Weidman would reach home in time to participate in the selection of the appointees. These appointments should have been announced on the first Monday in January. On Jan. 31st Judge Bechtel announced the following appointments:

Board to examine applicants for the offices of mine inspectors for the Sixth, Seventh and Eighth districts:

Engineers.—Heber S. Thompson, Pottsville; John R. Hoffman, Pottsville.

Miners.—James Roberts, Girardville; Frank Kessler, Forestville; James J. Brennan, St. Nicholas.

The only change on this board was the substitution of Mr. Brennan, who succeeds Mr. John W. Dempsey, of Minersville, whose recent promotion renders him ineligible.

To examine applicants for mine foremen's certificates:

Sixth District.—William Stein, mine inspector, *ex officio*, Shenandoah; William H. Lewis, superintendent, Shaft P. O.; Frank Wilcoxen, miner, Shenandoah; M. J. Brennan, miner, East Mahanoy township.

Seventh District.—Edward Brennan, mine inspector, *ex officio*, Shamokin; Andrew Robertson, operator, Shamokin; Robert Muir, miner, Mt. Carmel; Adam Bachman, miner, Ashland.

Eighth District.—John Maguire, mine inspector, *ex officio*, Pottsville; Thomas Doyle, superintendent, Pottsville; Thomas Holahan, miner, Middleport; David Tucker, miner, Pottsville.

The Lehigh Valley Coal Co. Absorbs the Interests of L. A. Riley & Co.

For some months past negotiations have been pending which culminated Feb. 15th in the absorption of the interests of the firm of L. A. Riley & Co. by the Lehigh Valley Coal Co.

The firm of L. A. Riley & Co. have, for a number of years, been the operators of the Centralia and Logan collieries, at Centralia, Pa., and more recently of the Big Mine Run colliery, near Ashland, Pa. The firm also controlled the lease of what is known as the Germantown tract. All of these interests will on March 1st pass into the hands of the Lehigh Valley Coal Co. The collieries included in the transfer are large ones, producing in 1894 294,790 tons. They afforded employment to nearly 1,200 people. The acquisition of the Germantown tract by the Lehigh Valley Coal Co. in all probability means the early development of it. Surveys have already been made and a preliminary route laid out for a railroad to this tract. The location adopted is said to run from a point near the old Continental colliery northwest to the point of Locust mountain, thence along the mountain side touching Byrnesville, thence into the tract. The immense store at Centralia was not included in the deal, but the business will be carried on by a separate company with Mr. Theodore F. Riley as general manager.

The money consideration involved in the transaction has not been made public.

(Continued from page 177.)

wearing down of the Upper Silurian and Devonian rocks. The geological survey in 1852 determined the existence of gold-bearing alluvions over an area of 10,000 square miles in Quebec and Nova Scotia, also along the Chaudiere river.

In British Columbia gold was discovered on Frazer river in 1858, causing a great "rush" of prospectors. San Francisco was nearly depopulated. Gold was traced 300 miles up the river to Cariboo. On Peace river, 250 miles still further north, gold was also found. In 1872 discoveries in the Cassiar district, 800 miles north of Victoria, caused the "Stickeen river rush." The Frazer river deposits paid only to a limited extent and were soon worked out. The workings were principally in shallow placers and river bars, but at Cariboo there are channels beneath the bed of the present watercourses. Shafts are sunk from the surface to the gold-bearing channels through a covering of clay and gravel. The bed of the ancient stream when reached is followed and worked by drifts. The expense of working owing to a superabundance of water to contend with has caused operations almost to cease. North of this the climate is an obstacle, as work can be carried on only during a few months of the year. Gold is found in the Leech river, in Vancouver Isle. From 1858 to 1880 $45,140,889 has been extracted from the placers of British Columbia.

To the other gold placer deposits in North America we shall devote a special article, after this general sketch of the distribution of gold deposits over the world, for the materials of which we are largely indebted to Bowie's admirable treatise on hydraulic mining.

MODERN STEAM PLANT FOR MINES.

An Economical High Pressure Water Tube Boiler Plant Erected by the Lehigh Valley Coal Co.

In mining, as well as in every other industry, the profits depend entirely on the degree of economy secured in production. In anthracite coal mining, and, to a great extent, in bituminous coal mining, the conditions are such that in many cases the profits on mining and preparing coal are *nil* or "*minus*" unless advantage is taken of every opportunity to reduce cost of production. No persons realize this more than the practical men at the heads of the larger companies engaged in the business. This necessity for greater economy, together with the necessity for more effective steam power at engines and pumps located at a distance from the boiler plants, has resulted in a marked improvement at colliery steam plants. The old wasteful cylinder boilers which carried but 70 or 80 pounds of steam, and which only furnished a distant pump or engine steam at 40 or 50 pounds pressure, are rapidly being superseded by improved high pressure boilers, which generate steam more economically and which are capable of supplying steam to distant points at a more efficient pressure.

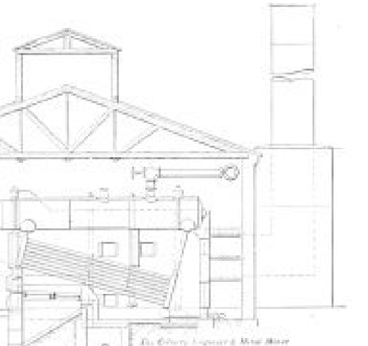


Fig. 1. Side Elevation.

One of the latest of these improved plants is the one illustrated herewith.

The Figures 1 and 2 show the general outlay of 1,500 horse-power Babcock & Wilcox water tube boilers as installed for the Lehigh Valley Coal Co. at their Hazleton No. 1 colliery, Hazleton, Pa. The plant consists of six boilers of 250 horse-power each, arranged two in a battery, so connected that each 250 horse-power can be run independent of the other. Each 250 horse-power is connected to two steam and water drums 42 inches in diameter and 23 feet 3 inches long, providing a steam disengaging surface and steam storage capacity perfectly in accord with the heavy demands of colliery work. The boilers are designed for a working pressure of 175 pounds to the square inch.

The boilers are of special design, built for burning very low grades of anthracite fuels. They have a grate area of 68 square feet for each 250 horse-power, each grate being 9 feet 8 inches wide by 7 feet deep, having three fire doors, with an uninterrupted fire surface the full width of the boiler without any intervening brick arches to necessitate constant renewals. The furnace is made low to secure the best results from the short flame incident to the combustion of the fuels now being generally used throughout the anthracite district, which fuels contain as high as 52 per cent. ash. The fuels used at this plant consist of the chippings and dirt from the breaker rolls, conveyed from the breaker direct into the boiler room, thus saving all handling of fuels.

There is provided throughout the entire front of the plant an ash-tramway (see A, Fig. 1). The ashes from the grates dump directly into the car, and removable plates in the floor provide a dump for ashes when boilers are being cleaned. The connecting duct from the inclined chute from the grates to the ash car is closed with a damper, connected to the front of the boiler.

An underground air duct running the entire length of the plant is shown at *B*, Fig. 1. This duct is connected through the bridge wall with hollow blast boxes controlled by a lever from the front of each boiler, by means of which the introduction of air can be regulated to suit the conditions of running the plant.

On plan view, Fig. 2, is shown a duplicate fan system (see *A* and *E*) for the introduction of forced blast under the grates. In combination with the blast the exhaust steam from the breaker is conducted into the underground duct (*B*, Fig. 1), and takes the place of the old system of utilizing live steam under the grates to prevent clinkering. The latter practice entails a usage of not less than 8 per cent. of the steam generated.

The plans as shown have been modified by the adoption of a single blast fan of larger capacity, to work separately or in combination with an induced draught system. The stack used in connection with the induced draught is but 40 feet high from the boiler room floor, and is provided with dampers by which the fan can be closed off entirely from the system and the stack used for a natural draught in connection with forced air blasts under the grates. Both the forced blasts and the induced draught system are of sufficient capacity to be run independent of the other. The feed water is passed through an American Fuel Economizer installed in the flue leading to the stack, thus utilizing all the heat in the waste gases and passing them at a very low temperature out of the stack. The economizers are fitted with an automatic cleaning device, which prohibits any collection of fine dust on the surface of the tubes. The working of the whole plant, both as to induced draught and forced draught, is automatic, and the speeds of the fans are regulated to suit the demands on the boilers.

The operation of the 1,500 horsepower is conducted by eight men, four to a shift of twelve hours each, making an actual saving in labor over past practice at this plant of over seven thousand dollars per year.

The plant as installed was under the immediate supervision of the designer, Mr. Samuel D. Warriner, Mechanical Engineer, Lehigh Valley Coal Co.

Mine Equipment.

That steam pumps form a very important part in mine equipment and operation is well attested by the number of advertisements of same by prominent pump builders regularly appearing in The Colliery Engineer and Metal Miner. These advertisements are worthy of careful note by mine superintendents and operators, for, as now arranged, they show almost at a glance the salient characteristics of design of nearly all the leading builders in such a way as to afford easy comparison of patterns.

One steam pump advertisement, for the first time appearing in this issue, is that of the Fred M. Prescott Steam Pump Co., of Milwaukee, Wis. This advertisement during the course of its publication will be something more than an "illustrated business card" of the concern named. It will be noted that in this issue is shown a photographic reproduction of a pump constructed for mining service, and notes appended stating where and under what conditions it is in use. This advertisement is virtually a news item and a good one at that. In our next and succeeding issues the same practice will be followed. The Prescott Co. have thus far made a specialty of pumps for mining service, and their ability to cope with the severe conditions imposed in this work needs no other testimony than the "repeat" orders (some several times repeated) they have received from large mining concerns. By means of these advertisements mine superintendents and operators will be kept informed on "Prescott" pumps and it will be worth while to note each carefully as they appear, for each one will show a pump actually built, where it is in use, and conditions of service.

The Edward P. Allis Co., of Milwaukee, Wis., is another new advertiser in The Colliery Engineer and Metal Miner. In what may be termed heavy mine equipment, the list of what the Allis Co. does not build would be far shorter than a catalogue of what they do put out. In their advertisement they simply group it all under "Mining Machinery," including in this everything from power plant to special machinery for treatment of ores of all classes.

In no class of engineering are better measuring instruments required than in mine surveying. For this service steel tapes have, very properly, superseded the chain. The number of makers of steel tapes for engineers' use is comparatively small, however. The Lufkin Rule Co., of Saginaw, E. S. Mich., is the largest in this country making these goods exclusively, if not in the world. They make everything in measuring tapes from the little ones of a single yard in length to those of 2,000 feet and upwards for artesian well measurement, and of qualities guaranteed unsurpassed. Some of their specialties in tape reels and cases are marvels of convenience in use. This concern begin with this issue an advertisement of their goods, and hereafter will keep "Lufkin" rules and tapes prominently before the mining fraternity. It will be worth the while of every civil and mining engineer to send to the Lufkin Rule Co., for their catalogue and inform himself concerning these goods.

In the line of machinery for elevating and conveying coal, ore or other heavy material the Brown Hoisting and Conveying Machine Co., of Cleveland, Ohio, has for years enjoyed an enviable reputation. The appearance of their advertisement in this issue will make their specialties known to mine managers throughout the country who will find it to their interest to send for catalogues of their machinery, and to bear them in mind when erecting new plants or remodelling old ones.

Adequate steam pressure at points of utilization, economy in steam production and safety, are prime requisites of the boiler plant at every mine. A cheap boiler that is cheap only in first cost is expensive in every instance. Heine Safety Boilers, which are advertised in this issue, are fast gaining in favor for mine use. The manufacturers guarantee their superior merits.

The Foster Engineering Co., of Newark, N. J., are manufacturers of superior types of reducing valves, pump governors, and in fact a large number of most excellent steam specialties, some of which we hope to describe in detail in future issues of this journal. Their specialties are of such a nature that every mine manager should know all about them. One of their catalogues should be in every mine manager's hands.

Lumber is a mine supply that is in constant demand. Among the number of other advertisers making a specialty of mine trade in lumber, is the Commonwealth Lumber Co., of Scranton, Pa. Their advertisement appears for the first time in this issue.

An Efficient Type of Boiler.

H. E. Collins & Co., Pittsburg, Pa., sole sales agents for the Cahall Vertical Water Tube Boiler, manufactured by the Aultman & Taylor Machinery Co., Mansfield, Ohio, report the following recent sales of Cahall boilers: National Chemical Co., Cleveland, O., 150 H. P. Republic Iron Works, Pittsburg, (fourth order) 250 H. P. Municipal Electric Lighting Plant, London, Ohio, 250 H. P. Voight Brewing Co., Detroit, Mich., 500 H. P. Michigan Alkali Co., Wyandotte, Mich., (fourth order) 300 H. P. Jefferson Coal Co., Coal Glen, Pa., 500 H. P. Ohio Iron Co., Zanesville, Ohio, 500 H. P.

The boilers for the Republic Iron Works are for the utilization of waste heats from heating furnaces; those for the Ohio Iron Co., are for blast furnace gas and the balance of the orders mentioned are for boilers of the direct coal fired type.

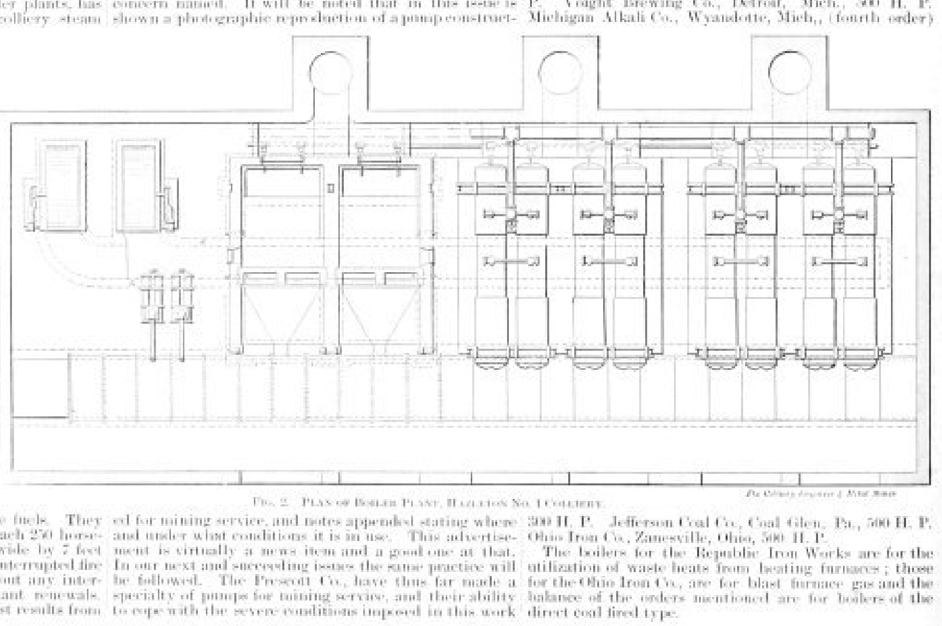

Fig. 2. Plan of Boiler Plant, Hazleton No. 1 Colliery.

THE PROGRESS IN MINING.

Abstracts From the Proceedings of the Mining Societies

And Journals of Europe and America, Illustrating the More Modern Developments in all Branches of the Mining Industry.

WATER CARTRIDGES FOR BLASTING.—The following article by L. Jaroljmek was translated from the German for the *Colliery Guardian* :

To Minimize the Danger of Blasting.—It has all along been the predominant idea in the minds of all connected with the technology of explosives, to minimize the danger of blasting operations. They can, however, only be considered safe provided the cartridges fulfil the following requirements:—(*a*) Abolition of manipulation in igniting; (*b*) rejection of the present detonating materials; (*c*) absence of the necessity of tamping as now understood; (*d*) substitution of a perfect tamping material; (*e*) effective cooling of the gaseous products of explosion. A new process to comply with these conditions must be automatic, requiring neither fire nor spark to produce ignition—*i. e.*, must effect this object by chemical action in the interior of the cartridge. It will further need to abolish existing methods of tamping and employ instead a naturally more resistant material. This may be accomplished, as experiments with plaster, &c., have shown, by the use of liquid or semi-fluid substances, and if the fluid be employed, not only as a tamping but also as the igniting agent—so that it becomes absolutely necessary for firing the shot—it cannot be neglected by the workmen, and will therefore become available for satisfying the condition (*c*).

The Jaroljmek water cartridge is said to fulfil all the foregoing requirements, being automatic, and requiring no spark or light for ignition. Briefly described, it consists of a cartridge of dynamite, into which is imbedded one end of a cap containing in its lower extremity a charge capable of ignition at between 100° and 120° Cent., the part fitting into the dynamite being loaded with an exploding charge of fulminate sufficient to produce the requisite initial impulse. The base is formed by a cartridge of pressed quicklime covering the lower end of the cap, and when the cartridge is surrounded by water the lime absorbs a portion of the liquid, becoming thereby hydrated and evolving sufficient heat to fire the inflammable cap, which thereupon ignites the fulminate and initiates the explosion. The whole cartridge is surrounded by a cover of cotton cloth.

In order to regulate the absorption of water by the lime, the lime cartridge is covered by a capsule of metal foil, the rate of absorption depending on the surface left exposed by the capsule. The lime cartridge is, for the purpose of insuring the unimpaired maintenance of its quality during storage and transport, provided also with a tight-fitting lid, to be removed before the cartridge is attached to the dynamite charge, and the cartridges are timed to produce explosion at any desired interval after insertion in the borehole, from 1 to 2½ minutes and over. The last-named figure represents the minimum interval for cartridges in coal mines, the former sufficing only for quarries and similar cases.

Advice of Committee on Fire-Damp.—The Ostrau-Karwin special committee on fire-damp advises the following procedure for fixing and firing the cartridge: In holes sloping downward the explosive charge is inserted first and the water poured in after adjusting the igniting cartridge. Where the holes are horizontal, or with but a gentle slope, it will be necessary to make a small dam of clay in order to cover the cartridge properly with water. For holes leading in an upward direction, a small spring is affixed to the bottom of the cartridge to prevent slipping back, and in such cases a water-cartridge must be used. This is made of a paper cylinder about 40 cm. long, closed at the lower end (paper soaked in paraffin will be sufficient for this purpose) and large enough to hold an amount of water equal to three or four times the weight of the blasting charge. It should have a diameter slightly less than that of the borehole, so that it may be easily inserted in the latter. When placed in position the conical base of the lime cartridge comes in contact with the water, this contact being insured, and the spilling of the water prevented by a wad of cotton inserted in the mouth of the water-cartridge. This latter can also be employed in downward holes, if there is likelihood of the water escaping through fissures, or may be replaced by a tamping of moss soaked in water.

The apparatus was subjected to a series of tests in May and July, 1895, with the special object of ascertaining how far the timing of the lime cartridge (or cone) could be relied on as accurate. In these tests, both uncovered and "timed" cones of different sizes were used, and the porous material for enveloping the cartridge was subjected to comparative examination. Shots were fired with different caps and varieties of dynamite—true and imitation—as well as blank cartridges (caps only). From the tables of results furnished it is deduced that where the lime cones are partly enclosed by a cover, the time elapsing between the application of the water and the firing of the shot is in inverse ratio to the amount of absorbent surface exposed, and that, furthermore, the texture of the cotton tissue in which the whole cartridge is enveloped exerts a similar effect, viz., the closer and denser the cloth the longer the interval before the explosion ensues.

The practical results to be drawn from the table are: (*a*) That shots timed to at least one minute can be obtained by the use of the small lime cones covered over with cylindrical cotton wick, but surrounded by a band of metal foil only so far as their cylindrical portion is concerned, the cone being unprotected. (*b*) Reliable shots timed to 2½ minutes, and not varying by more than 1 minute, can be produced by means of lime cones enveloped in foil except on the face, and encased in a cylinder of cotton tissue. In neither case were there any delayed shots observed in these tests.

The examination was extended to the effect of unfavorable surroundings on the efficiency of the cartridge. For instance, such as firing shots:—(*a*) In very wide wet boreholes or water-bearing rock; in free-lying blasting charges under water; to dislodge misfires by inserting a new cartridge in the water tamping. (*b*) In upward-sloping holes. (*c*) In holes pointing vertically upwards (roof shots). Here also favorable results were obtained leading to the following conclusions:—First, that when a blasting charge fitted with a "timed" lime cone is inserted into the water tamping of a wide borehole, or even merely dropped into water, the shot will be fired at the interval to which it is timed. This allows boreholes sloping in a downward direction to be filled the simplest and safest way, a point of particular importance in quarrying and surface blasting. In submarine work the cartridge, enclosed in a lead pipe, merely requires lowering till it rests on the spot to be blasted. Secondly, that the angle at which an upward hole is inclined has no effect on the timing of the cartridge. The difficulty of supplying the water decreases as the angle of inclination falls below 45 degs., and with the timing of the shot, but the removal of misfires in upward holes requires more care on the part of the miner when water cartridges are used than in the case of moss tamping.

The Flame of the Shot Completely Stifled.—As regards the behavior of the cartridge in fiery pits or air containing coaldust, it is claimed that communication between the igniting flame and the air is altogether excluded by the mass of lime surrounding the detonator. The lime being impregnated with water vapor, contact with methane or coaldust is prevented. Furthermore, the presence of water in the borehole is, as is well known, sufficient to prevent flame accompanying a blown-out shot; and, in the case of the present cartridge, additional security is afforded by the lime, which expands owing to the combination it enters into with the water, sufficiently to fill the borehole before the charge is exploded, and this, too, even if only the smaller lime cones are used, a still greater amount of security being afforded by the larger sizes. In fact, the lime cone, even when but little water is at hand, is by far the most effective tamping for preventing blown-out shots, a matter of particular importance for upward holes, which are mostly tamped with wet moss only.

The blasting charge is surrounded, so far as concerns the igniting cartridge, by means of the water absorbed into the lime and into the porous envelope. As for the remaining portions of the cartridge, it is manifestly only feasible to surround these with water in the case of downward holes, except in so far as the water is taken up by the porous envelope. The filling the annular space surrounding the cartridge with water is a special feature of the method, as it is considered that if the cartridge were pressed tightly into the borehole in the manner usually practised, a good deal of the security against ignition of gas afforded by this system would, under unfavorable circumstances, disappear. Of course, in upward holes it is impossible to envelop the cartridge with water; but it must not be forgotten that holes of this character are comparatively rare, particularly in fiery mines, where they should be carefully avoided. The occurrence of blown-out shots in these holes is very rare, but in extremely risky cases safety dynamite or similar explosive could be used in place of the ordinary charge.

Test Explosions with Blown-out Shots.—Test explosions with blown-out shots were made in a gallery of the Wilhelm shaft at Poln.-Ostrau, with a 6.8 per cent. mixture of fire damp and finely-powdered coaldust kept in constant circulation in the chamber, the cartridges being inserted in a hole bored in a large steel ingot until this burst, whereupon a block of cement was used and arranged to give a blown-out shot. Various modifications of tamping were made, sand and coaldust being used as well as water. In no case, however, was the gas in the chamber ignited. Similar results were obtained by the Rossitz-Oslavan special committee, explosive mixtures of fire-damp not becoming ignited, although ordinary dynamite was exclusively used and minimal quantities of water put into the holes. Both these committees reported favorably on the cartridge, the first named stating that the Jaroljmek cartridge is a central-fire apparatus, and offers greater security against the ignition of firedamp than the electrical fuses in use, the expansion of the lime cartridge being very effective in increasing the action of the explosive and preventing blown-out shots. Only water or moss tamping is required, and the operation is cheaper and no more complicated than electric fuses. For fiery mines it is particularly to be recommended. The Rossitz committee state that it is evident from the result of the tests that it is possible to adjust the lime cone to prevent the ignition of the detonating cap before a definite time. The fact that water is necessary in order to make the cartridge explode forces the workman to use water tamping, thus obviating the danger occurring from the employment of explosives in boreholes in fiery pits. Furthermore, the lime in the Jaroljmek cartridge forms a second tamping in the borehole and offers additional security against the escape of flame, so that the committee consider the method an absolutely safe one for use in gassy mines.

EXPERIMENTS WITH EXPLOSIVES.—From the Transactions of the Federated Institution of Mining Engineers, England. Some important experiments with explosives were recently made at the experimental station of the Ince Hall collieries near Wigan, Lancashire, England. This station has been fitted with all the requisite appliances for testing explosives by the owners, Messrs. Pearson and Knowles. The apparatus consists of a boiler 30 feet long and 5 feet 10 inches in diameter. One end of the boiler is open, and provision has been made for forming when necessary a gas chamber at the closed end, and this is done by fixing in an air-tight partition eight feet from the end. Along the sides of the boiler are three windows for making observations. On the bottom of the boiler at the closed end a mortar is fixed in masonry for firing the charges, and the shots are fired by electricity. Such in short is the fit up that is called the experimental station. The experimentists now under notice were Messrs. E. W. Thirkell, A. A. Atkinson and M. Hall.

One set of experiments were tried as strength tests and these were done by setting the mortar outside in the open, and firing it in every case at an angle of 55° elevation, and using a 35 pounds projectile with a charge, in each case, of 10 grammes, or .35 of an ounce of the explosive tested, and the exploding was done with No. 6½ detonators, and disregarding the order in the succession in which the shots were fired the following were the distances in feet to which the projectiles were thrown by the charges of the different explosives:

Name of Explosive.	Weight of Projectile.	Weight of Charge.	Distance the Projectile was Thrown.
	Pounds.	Grammes.	Feet.
Bellite	35	10	316
Dynamite	35	10	408
Roburite	35	10	192
Westphalite	35	10	402
Ammonite	35	10	324½
Tonite	35	10	219
Carbonite	35	10	241½
Blasting powder	35	10	165
Ardeer powder	35	10	84

The following table gives the results of the inflammability of the different explosives tested. Half a cubic foot of fine coal dust was thrown near the mortar just before the charge was fired in each case:

Name of Explosive.	Weight of Charge.	Exploded. Yes or No.	Flame. Yes or No.
	Ozs.		
Ammonite	12	Yes, Violently	Yes, Large
Carbonite	12	No	No
Roburite	12	Yes, Violently	Yes, Large
Bellite	12	Yes, Violently	Yes, Large
Westphalite	12	No	No
Tonite	12	Yes, Violently	Yes, Large
Ardeer powder	12	No	No
Compressed powder	8	Yes, Violently	Yes, Large
Dynamite	2	No	No

All the shots were fired without stemming to imitate the results of a blown-out shot.

FATAL ACCIDENTS IN THE MINES AND QUARRIES OF GREAT BRITAIN IN 1895.—We have to hand from the Under Secretary of State, the tables of "Fatal Accidents in and About the Mines, of Great Britain and Ireland," (including those on private branch railways and tramways, and in washing and coking coal) during the year 1895."

The total number of fatal accidents in and about the coal mines, for the year, was 1,033, and the following is the order of the classification of the causes:

EXPLOSIONS.	
Explosions of firedamp or coal dust	55
FALLS IN MINE.	
Falls of sides	88
Falls of roof	330
IN SHAFTS.	
Overwinding	2
Ropes and chains breaking	1
Whilst ascending or descending by machinery	36
Falling to shaft bottom from surface	6
Things falling from surface	2
Falling from part way down	17
Things falling from part way down	12
Miscellaneous	21
MISCELLANEOUS UNDERGROUND.	
By explosions	21
Suffocation by natural gases	5
Irruptions of water	94
On inclined and engine planes	59
By trams and tubs	84
By machinery	2
By underground fires	12
Ropes and chains breaking	18
Sundries	29
ON SURFACE.	
By machinery	17
Boilers bursting	3
Railways and tramways	62
Miscellaneous	37
	1,033

The classification of the causes is well done, and cannot but be appreciated by practical men.

* * *

DAMPING COAL DUST IN MINES.—The following is copied from the Continental Notes of the *Colliery Guardian.* Arrangements for damping coal dust in the Hibernia Colliery, Westphalia, are now extended to all the seams; and for collecting the water supply there is a lodge at the level of 340 m. (186 fathoms) with a capacity of 552 cubic metres, or three times the quantity necessary for a day's use. When the mine water becomes insufficient the reservoir is filled by two pumping engines, erected at the level of 610 m. (333 fathoms), that work alternately, the water in either case being filtered through a layer 2 m. (6 ft. 6 in.) thick of broken slag, held in place by planks bored with holes. The outlet branch pipes in the cross-cuts have a diameter of 52 mm. (2 in.); and the pipes leading from the latter to the working places, half that diameter, while the whole length of piping is about 45,820 m. (50,110 yards). The pipes, which are in lengths of 5 m. (16 ft.), are of wrought iron, galvanized to protect them from rust, and jointed with loose flanges and india rubber washers. In order to permit of thoroughly damping all the workings, every 50 m. (54 yards) three-flange unions are introduced, each of which is fitted with a hydrant carrying shut-off cock and union joint. In front of the working faces there are also hydrants with shut-off cocks and union joints, the total number of hydrants being 1,016. In addition to the shut-off cocks on the hydrants there are 140 others, by means of which the branch pipes may be shut off for repairs or lengthening the service pipes. The damping is effected by india rubber hose screwed onto the hydrants, and their nozzles consist of short pieces of gas pipe with a 3 mm. orifice. The sprinkling of the coal dust is effected, in front of the working places, by men appointed for the purpose, of whom there are at present thirteen; and the faces of stone drifts are also regularly provided with sprinkling apparatus. In some places, for ventilating separate workings, as well as preventing collections of fire-damp where cavities have formed in the roof, ten fixed roses and also Peltzer fans are provided. Up to the present time, states the *Zeitschrift für Berg und Hüttenwesen*, no injurious influence of any consequence has been noticed in the workings of this colliery; and the total expenses of the damping arrangements, including erection, extension and maintenance of the plant, and also the work in connection with it, has not quite amounted to 178,800 marks (£8,940) for the five-yearly period ending with last June.

* * *

IMPROVED MODES OF WORKING COAL.—From the "Continental Notes of the Colliery Guardian" we learn that the German miners are making great advances in the adoption of better modes of working to increase their output of coal, as the following extract shows:

Last year, 162 collieries in the Dortmund Superior Mine Inspection district put out 41,145,745 tons, with a mean of 154,638 hands, against 40,613,073 tons, with a mean of 152,698 hands in 1894, thus showing an increase of 532,672 tons. Of the ninety-five collieries which have joined the Rhenish-Westphalian Coal Syndicate, whose collective participatory output for the present year is limited to 41,631,243½ tons, it is the Centrum Colliery which will supply the odd half ton over 758,301 tons, and six collieries will contribute more than one million tons each—viz., the Ahrenbergische Aktien-Gesellschaft 1,233,916 tons; the Consolidation, 1,169,578 tons; Gelsenkirchener Bergwerks-Aktien-Gesellschaft with Monopol, 3,455,753 tons; Harpener Bergbau Aktien-Gesellschaft with Mont Cenis, 3,465,988 tons; Hibernia, 2,034,195 tons, and Zollverein, 1,395,507.

* * *

SAFETY EXPLOSIVES.—A Paper Read Before the North of England Institute of Mining and Mechanical Engineers. The secretary (Mr. M. Walton Brown) read a paper contributed by Bergassessor Winkhaus on the subject of "Safety Explosives." He said the efforts of manufacturers to render their explosives less and less dangerous in the presence of fire-damp and coaldust were all directed to the one end of reducing as much as possible the temperature of the gases evolved on explosion—that is, the so-called temperature of detonation. It was sought to effect this in one way by mixing high explosives, such as dynamite, with substances containing water in mechanical or chemical combination, and with easily-vaporizing substances, whose vaporization and decomposition was intended to capture a part at least of the heat evolved on explosion. Among the substances thus used were damp sawdust, soda-crystals, sulphate of magnesium, carbonate of ammonia, &c.; and these mixed in various proportions with kieselguhr constituted the so-called wetter-dynamite. To this group also coal-carbonit belonged. Another way of reducing the temperature of the gases evolved on explosion consisted in making the explosives of such substances as had of themselves a relatively low detonating temperature. Such were the explosives belonging to the so-called securit group, preceded as they were by the Sprengel explosives, mixtures of nitrated hydrocarbons with nitric acid. In practice only the first of these latter were in actual use; they were invented by Dr. Schoeneweg, a pharmaceutical chemist at Dudweiler, and consist mainly of intimate mixtures of nitrate of ammonium with the nitro-compounds of the aromatic hydrocarbon series, or with non-nitrated carbonaceous substances. Among these may be reckoned the multifarious explosives, so many of which had recently been brought out—securit, roburit, westfalit, dahmenit, dahmenit A, progressit, rhenalit and the Cologne-Rottweiler safety blasting powder. (A table accompanied the paper giving the composition of these different explosives so far as it had been possible to obtain them in the course of the investigations carried out in the experimental gallery of the Westphalian Miners' Provident Society).

The writer then refers to the definition of a safety explosive, and mentions that in France regulations are laid down as to the properties which must characterize any explosive intended for use in fiery or dusty mines, and only such explosives as yield a temperature of detonation not exceeding 1,500 degs. Cent. (3,212 degs. Fahr.) are allowed in working coal, and 1,900 degs. Cent. (4,000 degs. Fahr.) in working stone. In accordance with statements set forth in an appendix, this temperature must be calculated from the various constituents of the explosive, and in order to make that calculation possible the explosive must be enclosed in a cartridge which bears on its cover an indication of the character and quantity of the said constituents. Personally the writer does not consider it possible to express numerically such a standard of safety for an explosive as will imply its absolute harmlessness in all circumstances, and he fails, moreover, to see that such is needed. Sooner or later in all fiery and dusty mines only such explosives will be used as would be shown by the results obtained in various experimental galleries to possess an unquestionably high degree of safety. After dealing with the manner in which the conditions of the mine differ from those of the experimental galleries, the writer says if the values obtained in experiment are made use of in practical work they must be revised in accordance with the results of actual experience in the mine. The remainder of the paper deals with the experiments made with various explosives, and extensive tables are given showing the results obtained.

* * *

THE BANKET FORMATION AT JOHANNESBURG, TRANSVAAL.—A paper on the above subject was recently read by Mr. A. R. Sawyer before a meeting of the members of the Federated Institution of Mining Engineers, England. The aim of the writer of the paper is to establish four conclusions, and his claims and arguments are so novel and startling that you are struck with the daring of the man that ventures to diverge from the lines of all the favorite theories of his time.

First conclusion: The Banket formation at the end of the period of its complete deposition consisted of a series of coarse sandstones and conglomerates 10,000 feet in thickness, and covered the whole of South Africa. Further he claims that in the order of time the Banket formation was of the age of the old red sandstone, and that the enormous supply of detritus for the deposition of this thick and widely spread mass, was derived from an immense mountain system that is now submerged with the floor of the Indian Ocean. This is a great conclusion, but it is not without collateral evidence, because he notices the wide diffusion of its outliers, and the faultations and depressions and elevations in them that account for both the portions of the rock masses that remain, and those that have been denuded.

Second conclusion: The overlapping of the strata and the common direction of the lines of force by which the strata has been crumpled, and the direction of the planes of faulting, all support the conclusion of the first claim, that the detritus came from the site of the Indian Ocean, and that the folding of the Banket series was the result of a force directed also from the same region.

Third conclusion: The gold in the reefs and their leaders, found in the Banket rocks in the vicinity of Johannesburg, seem to have had an electrolytic origin, and to prepare the minds of his judges for his conclusions he supports them by further arguments, and cites a novel experiment made by Mr. Andrew Crosse. A porous pot filled with kneaded clay was placed in a vessel of water, and funnels were stuck in the clay and filled with various metallic solutions. The clay was then connected with the negative pole of a small voltaic battery, and the porous pot containing the clay was next set in an outer vessel filled with water, and this water was then connected to the positive pole of the battery. After two years had passed cracks began to be formed in the clay, and various minerals were artificially produced within the fissures, and it was observed that the electric current caused the water from the outside vessel to circulate through the fissures, and to rise to the top of the clay. He claims what all know right well is incontrovertible, namely, that the artificial depositions of metal by electrolysis, or the accidental depositions of metal on the outer sheating of ships, are only the analogues of natural depositions on a grander scale, and this he sustains in a wonderful way in his

Fourth conclusion, by showing that the deposition of the precious metal always occurs in the interstices of coarse grained rocks, such as pebbly quartz or conglomerates, and especially the coarse grained conglomerates of the Banket series in the Transvaal, for it is through the partings of such rocks, that the solutions can circulate that are subject to the electrolytic deposition, and he finds that as a general rule, but not an invariable one, the best deposits are found in the larger boulder conglomerates, instead of those of the smaller shingles. The subject is to the observing miner, that loves his geological sequences, one of the most practical interest.

* * *

MEASURING THE PRESSURE OF GAS IN COAL AT LIEVIN COLLIERY.—The following is a translation that appeared in a recent issue of the *Colliery Guardian*, and it is taken from a communication to the *Annales des Mines*, France.

Although no sudden outburst of gas has occurred at the Lievin colliery, the coal is impregnated with a considerable quantity of fire-damp; and it appeared interesting to make some observations, as to its pressure, in the nature of those communicated by other observers. At the beginning of 1893 some experiments were undertaken in No. 1 seat of working; and the results are here recorded, with the view of adding to the general store of knowledge on the subject, although the number of experiments is too slight for permitting any definite conclusions to be drawn from them.

Arrangement of the Experiments.—Holes 6 cm. (2 in.) in diameter and of variable depth were bored in the seam by a hand drill; and a flexible copper tube, 1 cm. (0.39 in.) inside diameter, was introduced into each hole, leaving about 20 cm. (7⅞ in.) between its inner end and the bottom, while its outer end was put in connection with an ordinary pressure-gauge or a gas meter. The annular space between the tube and the hole was stemmed with damp clay, which constituted a strong tamping terminating outside at the mouth of the hole, but leaving a variable distance between it and the bottom. The thrust of the tamping was received by a wrought iron collar brazed to the pipe, a few india rubber rings being interposed between the clay and the collar. A copper pipe has this advantage over one of iron, as generally used, that it may be introduced into the hole in a single length, on account of its flexibility, whereas iron pipes are rigid, and must be used in 2 m. or 3 m. lengths (the joints of which may leak), because of the often slight distance between the face and the opposite wall. The stemming was effected by a special rammer following the form of the tube. The clay gave good results, leakage being rarely noticed; but it has the disadvantage of causing difficulty if occasion should arise for drawing the tamping, which becomes necessary if the hole has to be deepened after an observation.

For reading the pressures, a Bourdon gauge with large dial was used, and both mercury and water gauges had been prepared, although they were not used, because the pressures observed always exceeded 1 kilog. per square centimetre (14 lb. per square inch). The volumes of gas issuing from the holes were measured by a gas meter giving indications in cubic decimetres (1 cubic decimetre = 61 cubic inches).

Selection of Places for Experiments.—As all the seams in Lievin No. 1 seat of working are fiery, and almost equally so, it did not much matter what seams were chosen for the experiments. At the level of 475 m. (260 fathoms), where the experiments were made, the split return-air currents showed fire-damp contents not differing greatly one from another for the same state of the workings. It was, however, important to determine the position of the field of experiment with reference to the state of working; and in this respect two separate series of experiments were carried out—the first in a district where working had not been commenced, so that there was no doubt of the coal being hard and compact, and the second in one where the measures were fissured by neighboring workings.

"What influence," asks the author, "is exerted on the pressure and volume of gas by the depth of the tamping—or, in other words, the vacant space at the bottom of the hole?" All the experiments, he continues, show that pressure increases with the depth, so that there is the maximum pressure when the tamping reaches to nearly the bottom of the hole; and in proportion as the tamping is far from the bottom, a pressure is encountered so much the less, for an equal area of disengagement, as the permeability is greater. The results attained in the Frederic seam warrant the conclusion that the coal there is not particularly permeable, and that the pressures observed for the four holes are not much lower than what would have been found at the bottom. As regards the volume of gas disengaged, it is, for a given pressure, proportional to the area of the vacant space at the bottom of the hole.

The Pressures Measured.—On February 7, 1893, a hole 12 m. (39ft. 4 in.) deep, was put in between No. 2 *bis* and No. 4; and a space of only 1 m. (3 ft. 3⅜ in.) was left between the bottom of the hole and the tamping. This hole, No. 6, when compared with No. 4, gives an idea of the influence exerted by the position of the tamping in holes of equal depth. Other things being equal, arranging the tamping 7 m. (23 ft.) further from the bottom of the hole only altered the pressure by 1 kilog. per square centimetre (14 lbs. per square inch). The following table summarizes the particulars of the five holes, No. 1 having, as already stated, been abandoned on account of its leaking, and No. 2 having been plugged for the same reason:

Hole.	Total length. Metres.	Length of tamping. Metres.	Length of space. Metres.	Disengagement area. Sq. m.
No. 2 *bis*	9.25	4	5.25	1
3	9.25	4	5.25	1
4	12.00	4	8.00	1.52
5	12.00	4	8.00	1.52
6	12.00	11	1.00	0.19

Each hole was provided with a pressure-gauge; and daily observations were made regularly up to April 15, *i. e.*, during a period of three months, at the end of which the pressure was not appreciably diminished. Only one hole, No. 4., showed any considerable diminution of pressure, viz., 1.5 kilogs. per square centimetre (21 lbs. per square inch), which is explained by the fact that the gas was allowed to flow through the meter from the 5th to the 25th March. Two years after these observations, in March, 1895, without the arrangements having been in any way modified, the following particulars were noted:

Hole	Pressure in kilogs. per sq. cm. In March 1893.	In March 1895.	Diminution of pressure. In Kilogs. per sq. cm.	In lbs. per sq. in.
No. 2	5.5	4.2	1.3	18½
3	4.2	2.5	1.7	24
5	5.7	3.75	1.95	27

General Results.—The maximum pressure observed at Lievin was 7.5 kilogs. per square centimetre (105 lbs. per square inch) in a hole 12 m. (39 ft.) deep, whereas the maximum in England was found by Mr. Lindsay Wood to be 31 kilogs. per square centimetre (441 lbs. per square inch) and in the Couchant de Mons, Belgium, 42.5 kilogs. per square centimetre (604 lbs. per square inch), while at the Treuil Colliery, Saint-Etienne, they were found to be less than at Lievin. The observations made in the Frederic and Alfred seams of that colliery show that fire-damp is not regularly distributed through the mass of coal. The pressure increases with the depth of the holes, which is self-evident, and confirmed by all the experiments; but the results obtained at Lievin do not coincide with those of Mr. Lindsay Wood, nor do they bear out Mallard's formula.

The heading in the Frederic seam only drained the gas very slowly, since, after more than two years, the pressure was only reduced by one-third at the outside. It would therefore appear that, for draining off fire-damp, headings which cause no subsidence are but slightly efficacious, and this also explains why the utility has so often been questioned of holes for draining the seam of gas. Mallard considered that the volume increases with the pressure; but the author (M. A. Simon) found that, for equal pressures, the volume per unit of disengagement area was fifty-six times greater in the Alfred (disturbed) seam than in that of Frederic (undisturbed.)

Must Not Hold Public Office.

In accordance with an order recently issued by the Superintendent of the Philadelphia and Reading Coal and Iron Co., all persons occupying official positions under this company must not hold or become candidates for election to public office. This order applies only to township offices. An inside foreman and a fire boss in the Heckscherville valley both received nominations for township offices at the recent primaries, but were obliged to withdraw from the contest. During the presidency of the late Franklin B. Gowen no employe of the company was permitted to hold any public office.

ANTHRACITE STATISTICS FOR 1895.

From advance sheets of the Reports of the Inspectors of Mines of the eight anthracite districts of Pennsylvania, we are enabled to compile the following tables, which will be found to contain a complete summary of the usual statistical reports. For purposes of comparison the statistics for 1894 are also given. This is the first time the complete statistics for the anthracite districts have ever been published in this form, and so soon after the close of the year. The credit for the compilations is due Mr. Baird Halberstadt, mining engineer of Pottsville, Pa., our special representative for the anthracite regions:

Table Showing Total Production, Shipments, the Increase in Production in 1895 Over That of 1894, Number of Employes, Fatal and Non-Fatal Accidents, Kegs of Powder and Pounds of Dynamite Used, Number of Horses and Mules, Number of Steam Boilers in Use, Tons of Coal Mined Per Life Lost and Per Non-Fatal Injury, in the Anthracite Collieries in 1895.

District.	Total Production. (Tons.)	Total Shipments. (Tons.)	Production Increase Over 1894. (Tons.)	Persons Employed.	Fatal Accidents.	Non-Fatal Accidents.	Kegs of Powder.	Pounds of Dynamite.	Number of Horses and Mules.	Number of Steam Boilers.	Tonnage per Life Lost.	Tonnage per Non-Fatal Injury.

LEGAL DECISIONS ON MINING QUESTIONS.

(Reported for THE COLLIERY ENGINEER AND METAL MINER.)

Dangerous Appliances—Blasting.—In an action by an employe for injuries caused by a premature explosion of dynamite while blasting, where it was shown that the company knew that the tools furnished the employe were unsuitable and dangerous, and the evidence to contributory negligence was conflicting, a verdict against the employer will not be disturbed by the court on appeal.

Ohio Valley Ry. Co. v. McKinley (Ct. App. Ky.) 33 S. W. Rep. 186.

Negligence in Blasting.—Blasting by "breasts" or rows of holes from 14 to 20 feet deep, charged with dynamite, and simultaneously exploded, making blasts so powerful that the surrounding earth for a considerable distance was shaken, and logs placed on the blast were thrown 200 feet, and over the tops of houses, shows a want of due care and regard for the interests of others on the part of the operators, for which they are liable, where it appears that the work could have been accomplished by smaller blasts, though not so expeditiously. The method adopted was the one usual for excavating rock, and the one most profitable to the operators; but it is very evident that in conducting the work they had regard only to their own interests. Reasonable care, however, required a due regard for the interests of the adjoining property owners.

Newell v. Woolfolk (Supreme Court 2d Dept.) 36 N. Y. S. Reporter, 327.

Contract for the Manufacture of Mining Machinery.—A contract for the sale of a mining and pumping plant to be manufactured in accordance with special specifications, which require the furnishing of special engines and pumps, connected by shafting specially fitted, the specially manufactured parts of which would be of little value except in connection with the plant, is not within the statute of frauds, requiring contracts to be in writing, etc., though the bulk of the plant was made up of articles purchased as merchandise by the seller from other parties.

Puget Sound Machinery Depot v. Rigby (Supreme Court, Washington) 43 Pacific Reporter, 39.

Inspection of Roofs and Use of Props in Mines.—The Supreme Court of Iowa recently said: The evidence shows beyond all question that there are many places in the roofs of mines that do not require props or supports, because of the roofs being composed of slate or stone. But there is evidence tending to show that such places in the roofs, by lapse of time, may become dangerous and require props. It appears that the mining company was in the habit of making daily inspection of the roof by tapping it with the dull end of the pick. Whether daily inspection was required, we do not determine. Of course, we do not hold that the fact that the roof was not propped at the place of the accident authorizes a recovery. The men working in the mine know that props are only used where they are thought to be necessary, and by their employment they take the risk of the service with the roofs in that condition, but with the obligation of the operators to make proper inspection of the roofs, and to remedy defects in it. But where the testimony in a personal damage case as to whether a miner was injured through his own negligence in blasting and removing coal, or through the negligence of the company in not properly caring for the roof, the issue should be left to the determination of the jury.

Morris v. Excelsior Coal Co., 64 N. W. Reporter, 627.

Contracts as to Oil in Land.—A contract recited that the first party granted to the second party "all the oil and gas in and under" certain premises, "together with the right to enter thereon at all times for purposes of drilling and operating for oil * * * and to erect all buildings * * * and lay all pipes necessary to the production and transportation of oil or gas taken from said premises. Excepting and reserving to the first party one-eighth of all the oil produced, * * * to be delivered in the pipe line with which second party may connect his wells." First party "leases one acre anywhere out of this above described land for a test well, and if oil or gas is found, then second party has the balance of the above land to drill at the same royalty as the within lease. To have and hold said premises on the following conditions: If gas only is found, first party is to receive $100 for each well." Second party "agrees to commence operations within 30 days, and to complete a well in 30 days" thereafter, and failing therein, is to pay first party annually $5 per acre till said well is completed. The court held that the right granted was absolute to take all oil and gas under the entire tract, and that failing to make the test well, $5 per acre thereof was to be annually paid to the first party.

Columbian Oil Co. v. Blake (App. Court, Ind.) 42 N. E. Rep. 234.

Measure of Damages in Failing to Make Mining Operations.—Where, in consideration of extension of time to pay purchase money of mining property, the buyer gives notes secured by deed of trust on the property, and agrees with the seller that he will, till the payment of the debt, work the mine in mine fashion, the measure of damages for breach of such contract, for which the seller only has a cause of action, is the injury to the security.

Belmont Mining and Milling Co. v. Costigan (Supreme Court Colo.) 42 Pacific Reporter, 647.

When a Court of Equity Will Not Interfere With Mining Proceeds.—Certain parties entered into a contract with a mining company whereby they conveyed to the latter a perpetual easement and right of way through a tunnel upon certain mining claims belonging to them, to be used by the company in developing and working its own mining properties, etc., in consideration of a cash payment "and the residue out of the proceeds of the first ore shipped from the company's property." The company not fulfilling its contract, the parties filed a bill in chancery praying for a temporary injunction restraining the company from using any money payable to it for ore, except for the purpose of paying them the amount due, and for a decree making the injunction mandatory, by requiring the company to pay them the first money received by it for ore, within the limitation of the contract. The court held that there were no words in the agreement which could operate to transfer any specific fund, or an interest in any specific fund. No right was conferred upon these parties to receive the money, except as it might be paid to them by the company. The ore belonged to the company. It extracted, shipped and stored it, or sold it, and when it received the price of its ore, the proceeds were its own. The agreement gave these parties no interest in the money as such. It was simply a promise by the company that, when it received the money, it would apply it on the payment of the debt; and until it should do so no title in the money could pass to these parties. If it failed in the fulfillment of its promise, their remedy was an action at law against the company for breach of contract. In other words, a promise to pay a debt out of proceeds of ore to be mined is not an equitable assignment of such proceeds, and a court of equity will not enforce the agreement.

Silent Friend Mining Co. v. Abbott (Ct. App., Colo.) 42 Pacific Reporter, 318.

Agent or Attorney May Locate Mining Claim.—An agent, or attorney in fact, may locate a mining claim for his principal, and may do everything necessary to perfect such location, including the making of the affidavit required by the laws of Idaho.

Dunlap v. Pattison (Supreme Court Idaho) 42 Pacific Reporter, 504.

Risk of Employment—Mining.—On a trial in the Circuit Court of the United States, it appeared that one T. was the foreman of a mine, which was owned by a corporation having large interests in various places under the general charge of a superintendent; that T. had power to hire and discharge the men, direct their work, and generally to control all the ordinary operations at the mine, and upon one occasion, upon the complaint of F., had promised to remove a dangerous obstruction in the tunnel, and had afterwards caused it to be removed. There was evidence that F. had complained to T. of the dangers from the projecting bolts on the revolving shaft, and that T. had promised, a few days before the accident, to have the coupling covered with a box for protection. The Circuit Court of Appeals held that it was within the apparent scope of T's authority to promise to make the coupling safe, and that F. did not, by continuing in the company's employment in reliance on such promise, assume the risks arising from the dangerous condition of the coupling. Also, that the rule that an employer is not bound to replace an appliance, such as is in common use, because it is possible to get a better one, did not apply to relieve the mining company from the duty of protecting the exposed coupling as promised.

Homestake Mining Co. v. Fullerton, 69 Federal Reporter, 923.

Who Cannot be Served as Official Representative of Mining Company.—The Supreme Court of South Dakota holds that, an attorney in fact (one created by deed) authorized by a mining corporation to apply for a patent to mining ground claimed by it and to execute such papers as may be necessary for that purpose, is not by virtue of such employment a "managing agent" within the meaning of the statute of that state in relation to service of process upon corporations.

Mars v. Oro Fino Mining Co. 65 N. W. Reporter, 19.

What is Included in Deed to Minerals.—The meaning of the words "minerals" and "ores" in a deed cannot be limited or explained by declarations of the parties as to what was intended, to be covered by the deed, when reformation of the same is not sought.

Though the words minerals and ores in a deed, standing alone, would include granite, where the surface rights granted are only sufficient land to erect suitable buildings for machinery and other buildings necessary and usual in mining and raising ores, they will be held to include only minerals obtained by underground working.

Armstrong v. Lake Champlain Granite Co. (Court Appeals, N. Y.) 42 N. E. Reporter, 186.

Questions of Negligence Must Be Determined by the Jury.—Where, in an action for personal injuries to a miner, there was evidence that the superintendent of the company knew of a loose stone over the place where the miner was put to work by him, and that the superintendent had made an unsuccessful attempt to dislodge it, and that he told the workman of that fact, and that the place was safe, but the stone afterwards fell upon the workman, the question of the company's negligence and the employe's want of care is for the jury. As is also the question of whether the employe assumed the risk.

In such an action it is not competent to show that no accident had ever happened there before that.

Burgess v. Davis Sulphur Ore Co. (Supreme Judicial Court, Mass.) 41 N. E. Reporter, 501.

Contract of Conveyance of Mineral Rights.—An instrument conveying the mineral interest in certain land, after reciting a nominal consideration, declared that the grantee should have full power to convey, and the grantee stipulated that he would examine the land and if he found valuable minerals, would pay the grantor one-half the net proceeds of same, or should such grantee convey to third persons he would pay the grantor $200, and one-half the net proceeds of the sale. The Supreme Court of North Carolina held that the rights of the grantee under such an instrument were forfeited by his failure, for eight years, to open the mine, and prepare it for sale. Also, that where a conveyance of mineral rights in land is defeated by the grantee's failure to perform the particular acts stipulated to be done by him in the instrument itself, and which forms the real consideration for its execution, a re-entry by the grantor is unnecessary.

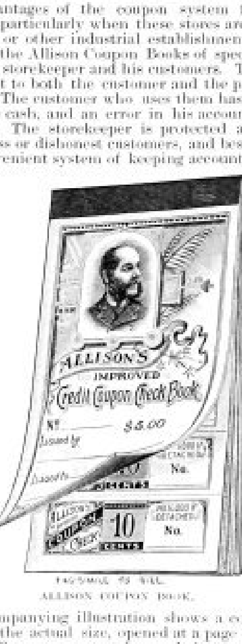
Hawkins v. Pepper, 23 S. E. Reporter, 434.

Sufficient Description of Premises for Mining Lien.—Where the same persons own two mining claims only one of which has improvements on it and it appears that the mines are known by the names of the parties working them, a notice of lien reciting that it is for work done within a designated period of three months on a mining claim, with improvements, located in a particular mining district of a certain county, owned by the persons (naming them) who had the work done, does not identify the claim with the improvements with sufficient certainty to creat a lien upon such property. The description must be such as will enable one to identify the mining claim to the exclusion of any other premises. An incorrect description in a notice renders such notice invalid.

Fernandez v. Burleson (Supreme Court, Cal.) 42 Pacific Reporter, 566.

Allison's Coupon Books.

The advantages of the coupon system for general stores, and particularly when these stores are connected with mines or other industrial establishments, are such as to make the Allison Coupon Books of special interest to both the storekeeper and his customers. These books are a benefit to both the customer and the proprietor of the store. The customer who uses them has practically the same as cash, and an error in his account is an impossibility. The storekeeper is protected against loss from careless or dishonest customers, and besides he has a most convenient system of keeping accounts.



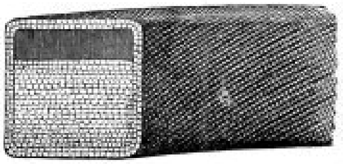
FAC-SIMILE 3/5 SIZE.
ALLISON COUPON BOOK.

The accompanying illustration shows a coupon book three-fifths the actual size, opened at a page of ten cent coupons. The coupons can be made in any denominations from one cent up. The method of using them and keeping exact accounts is very simple and easy. In fact by their use the least possible amount of book-keeping is required. To really appreciate the Allison coupon book it should be examined and the directions for its use read. These directions are not complicated in the least and can be readily understood by any man able to count money. A sample book and a very small pamphlet showing the advantages of the system are sent free to any person interested, on application to the Allison Coupon Co., Indianapolis, Ind.

Garlock High Pressure Packing.

It is but a few years ago that steam at six atmospheres was considered a high pressure and was about the limit on steam plants. To-day on the modern steam plants, with triple expansion or compound engines 150 pounds is a common pressure, and on many of the larger engines a pressure of 225 pounds is used.

The Garlock Packing Co., ever alive to the requirements of the times, have produced a High Pressure Packing, made of selected fibre and metal, in combination with the celebrated Garlock packing compound, which has successfully withstood the trials and hardships of stuffing box life on the largest engines for many years.



GARLOCK HIGH PRESSURE PACKING.

This packing is especially adapted to high pressure work on locomotives, stationary and marine engines. The construction is without question designed to *insure long service*.

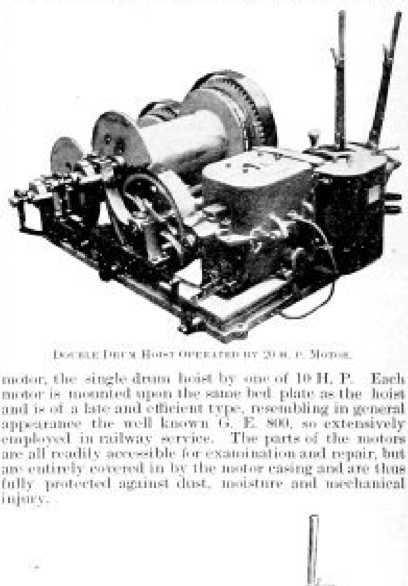
The method of guaranteeing this packing is to ask customers to try it and judge for themselves.

If you are in want of a high pressure packing send for sample.

Made in sixteenth and eighth sizes from ¼ in. to 2 in. square.

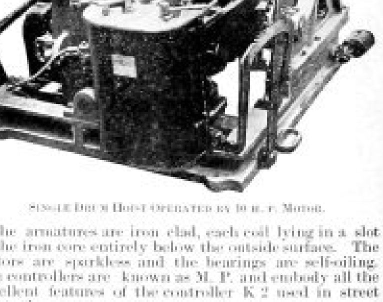
Electric Portable Hoists.

The application of the electric motor to portable hoists for derricks is illustrated admirably in the two hoists which the General Electric Company has lately furnished the United States Government, in connection with an important electrical installation. These hoists are of the double drum and single drum type respectively; the double drum hoists being operated by a 20 H. P.



DOUBLE DRUM HOIST OPERATED BY 20 H. P. MOTOR.

motor, the single drum hoist by one of 10 H. P. Each motor is mounted upon the same bed plate as the hoist and is of a late and efficient type, resembling in general appearance the well known G. E. 800, so extensively employed in railway service. The parts of the motors are all readily accessible for examination and repair, but are entirely covered in by the motor casing and are thus fully protected against dust, moisture and mechanical injury.



SINGLE DRUM HOIST OPERATED BY 10 H. P. MOTOR.

The armatures are iron clad, each coil lying in a slot in the iron core entirely below the outside surface. The motors are sparkless and the bearings are self-oiling. The controllers are known as M. P. and embody all the excellent features of the controller K 2 used in street car work.

The levers for the brakes, controllers, etc., are so arranged that full control of the entire mechanism is had without change of position by the man in charge.

The hoists themselves are from the works of the Lidgerwood Company. The drums are 14 inches in diameter and 26 inches long.

One of the early difficulties with steel pens was the stiffness, which Perry removed in 1830, by perforating the pen at the top of the slit, an improvement very valuable for producing "soft pens."—*Electric Power*.

EASY LESSONS ON MINING.

This Department contains articles to assist ambitious Miners to educate themselves, and obtain Certificates of Competency as Mine Foremen, or to become Mine Superintendents.

The articles are written to be understood by the unlearned and the learned alike. Plain language is used, no obscure terms are employed, and each subject treated, is made as clear and easy to understand as possible.

Further: The Questions asked at the different Examinations for Mine Foremen and Mine Inspectors, are printed and answered.

☞ The Series of Articles "Geology of Coal," "Chemistry of Mining," "Mining Methods" and "Mining Machinery" was commenced in the issue of March, 1894. Back numbers can be obtained at twenty-five cents per single copy, $1.00 for six copies, and $2.00 for twelve copies.

CHEMISTRY OF MINING.

The Diffusion of the Light of a Safety Lamp—The Correct Elevation for the Light—The Correct Angle of Diffusion—The Diameter of the Glass Cylinder—The Lamps Miners Prefer—Refraction of Light—Good Light in Safety Lamps.

89. **The Diffusion of the Light of a Safety Lamp.**—This is a matter of prime importance and there can be no doubt concerning the enhanced value of a lamp in which the right angle for the diffusion of the light has been provided.

The writer has seen lamps that were faultless, in so far as the insulation of the flame and the simplicity of the details of construction were concerned, rejected by mine foremen and superintendents after they had tried them, and found they "did not like them because they gave a bad light." "Bad light" does not refer here either to the qualities of the oil or the wick, but to the angles of the diffusion of the light. It may be said with assurance that no miner likes a lamp he has to raise to the level of his face to see his friend's eyes, and he always does so with a twitch of anger, for his feelings say: "This is a horrible lamp."

It is remarkable, that too little attention has been given to the investigation of the principles of action of the lighting fittings of the safety lamp, and the result is, many of the details are wrongly proportioned, and this is especially so in the case of the glass cylinder, for we find it too short, too wide, the glass shell too thin, and the flame within it set at the wrong elevation. It is true the proportions are better in some makes of the lamp than in others, but in many, as we all know, the proportions are unfavorable to the production of a good light. For example, different makers of the Marsaut lamp give different lengths and thicknesses to the glass cylinder, and it is interesting to notice how these variations affect the acceptance of the different productions; and stranger still, is the fact, that in the judgment of the different lamps you invariably find practical men come to the right conclusion although they never assign any reason for their preference, yet they are right on principle, "for by their fruits ye shall know them." These men carry a lamp one shift, and they actually judge the lamp by its potential, and by them the potential is guaged by their feelings, and if they say the lamp does not please them, rest assured it is not right, for they are seldom wrong.

To prove this just examine one of the Marsaut lamps they condemn, and you will find that the wick pipe sets the flame too high or too low, or the shell of the glass cylinder is too thin, or too short, or too large in diameter, or else the frame of the lamp is made to protrude so much as to cut off a high percentage of the light, but be assured something is wrong if these men say they "do not like the lamp."

Let us then try to discover how the diffusion of the light of a safety lamp is affected under proper and improper conditions, and to begin, let us consider first:

90. **The Correct Elevation for the Light.**—We will proceed with the assistance of Fig. 128. Here it will be seen by reference to the section that the light it represented in two extreme and opposite positions, in one

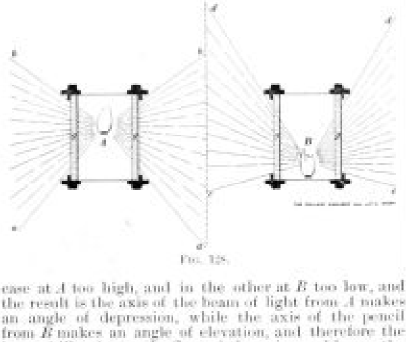


Fig. 128.

case at *A* too high, and in the other at *B* too low, and the result is the axis of the beam of light from *A* makes an angle of depression, while the axis of the pencil from *B* makes an angle of elevation, and therefore the lamp *A* illuminates the floor of the mine and leaves the roof in darkness, while *B* illumines the roof and leaves the floor in darkness. Both these elevations are, therefore, objectionable, and rather suggest that the axis of the beam of light should be in a horizontal plane, but experience teaches that the light should be thrown rather more upward than downward, and it will be noticed that the term "rather more" is not calculated to lead us to a reliable conclusion, and should be qualified by the statement of a definite value. The center of the light then should not be elevated any less or more than one-third of the height of the glass cylinder; and this statement being accepted from the teachings of experience, it suggests another provision that should be made to secure the required height of the wick pipe, and this should never exceed one-fifth of the height of the glass cylinder. Now be it understood that the height of the glass cylinder here spoken of, is not the total height, but the height through which light can pass, and which is uncovered within the flanges of the top or bottom rings that keep the glass in position. If the top of the wick pipe has an elevation of about one-fifth of the height, the top of the wick, in its adjusted position for burning the oil, must have an elevation of one-fourth of the height, and as the center of the flame will occur above the top of the wick, these proportions will bring the center of the flame to an elevation of one-third the height of the available surface of the glass cylinder, and therefore, so far as the elevation of the light is concerned these values will secure the best results.

91. **The Correct Angle of Diffusion.**—The limits of the beam of light whose axis makes an angle of elevation are for *B*, *d c*, and it will be seen that the light of *B* is more thrown upward than that of *A*, by the vertical length *d b*, and the beam of light from *A* that makes an angle of depression, is more prolonged downward than that of *B*, by the vertical length *c a*. The proportion given for the height of the top of the wick is for a short glass, but where a long glass of 3 or 3½ inches is used then the height of the wick pipe should be adjusted for the center of the light to occur at one-third the available height.

92. **The Diameter of the Glass Cylinder** greatly affects the diffusion of the light of a safety lamp, and a mere glance at Fig. 129 sustains this conclusion. It will

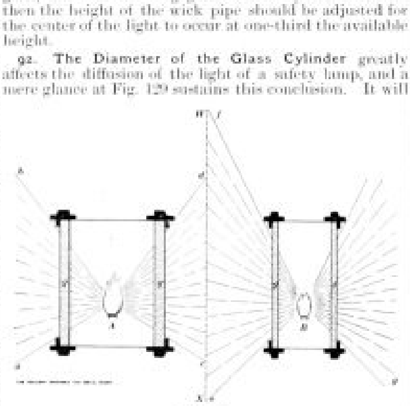

Fig. 129.

be seen by the sections before us that a wide cylinder reduces the angle of diffusion, whereas a narrow one increases this angle. The reason for this difference in the angles of diffusion is found in the fact that when the actual lengths of two chords are equal, and their radians are different, then their angles are different. Now the actual lengths of the radians of *A* and *B* are different, the result is the angle of diffusion of *B* is much greater than that of *A* in the proportions of the chords *d c* and *W X*. The actual angles of diffusion are *A* 100 degrees, and *B* 130 degrees. We cannot, therefore, set aside the fact that a greater volume of light is diffused by a lamp with a glass cylinder small in diameter, than with a lamp in which the diameter of the glass is relatively large; and another fact is of equal importance and interest in the investigation of this matter, and that is, a short cylinder of small diameter will diffuse as much light as a longer "glass" with a larger diameter, because if the radius of a small glass is one inch and its disposable height two inches, the angle of diffusion will be the same as that of a glass 1.5 inches in the radius and three inches in available height, therefore, when we assign any diameter to the glass cylinder of a lamp, we cannot do otherwise than co-relate the diameter with the length. Looking at many makes of the lamp, we are struck forcibly with the impression that the glass is *short*, and that there must be, or has been, some particular reason for this and other defects in the construction of the safety lamp in so far as its potential of illumination is concerned, and digressing for a moment, let us notice that the word *potential* here used, has in relation to the lighting *power* of the lamp a very significant meaning; for example, lights are of high and low tension, or if you please, of greater and lesser intensity, and another factor of a light is its volume. Now in mechanics if you multiply the pressure by the volume, the product is the power, so if you multiply the intensity of a light by its volume, you obtain its *potential*.

93. **The Lamps Miners Prefer.**—Again, let us come back to the consideration of the practical reason for the shortening of the glass cylinder of a safety lamp. Practical miners have been heard to say, and how often have we said the same ourselves, "Give me a Davy lamp to test for gas," and this special preference was the reason of the Clanny gauze and the Clanny glass being both made as short as possible, because the shorter these parts were made, the better was the lamp adapted for immersion in a stratum of gas floating under the roof of the chamber, and the result was a *short* lamp was said to be very *sensitive*. What is true of the Clanny is equally true of the Marsaut, but now with improvements, such as we find in the Gray lamp, a stratum of gas only one inch in depth can be detected under the roof, as the air to feed the flame at the period of testing has to pass down tubular poles *a b* and *c d* shown in Figure 130. This lamp is bonneted, and when used for other than testing purposes, the down-flow of air through the poles is cut off, and the supply of air is then admitted near the bottom of the air tubes, and strange to say, as seen in the figure, the glass cylinder is here lengthened, with the object of showing the gas cap on the flame, but as the only object of this elongation of the glass is to show the "blue tail," the conical glass is so fixed that it cannot increase the diffusion of the light.

Fig. 130.

In fixing what should be the dimensions of the glass cylinder, there are several great principles that should guide us; and for the present, let us notice two of them. First, then, the glass should be as long as possible, and the diameter as short as possible. Or the length of the glass shell should be 1½ times its diameter.

Having given attention to the diameter and length of the glass cylinder of the safety lamp, a principle of construction of equal importance confronts us and demands an answer, and it is this: What should be the thickness of this glass shell?

As we cannot evade the question, we must provide an answer, and the reader must assist us with his forebearance while we try to make interesting a problem that is somewhat involved, for we have now to consider the refraction and interference of light in relation to the practical requirements of the miner. However, "to patience and faith the prize is sure," and with the help of Fig. 131 we cannot fail to secure the solution of the problem.

Light, in common with other modes of motion, is most active along the lines of least resistance in its path, and as a result of this, it is subject to refraction. For example, when light strikes a plain glass surface obliquely, the ray suddenly alters its course in passing through the glass, as in the case of the ray *a b*. It now takes the path of least resistance *b c*, and then leaves the glass nearly parallel to its course at the moment of incidence; that is to say, *a b* is parallel to *c d*.

There is much that might be said about refraction, if we were treating on physical science alone, but our subject is lamp glasses, and we, therefore, only require to know for the present how the refraction of light effects our subject.

The reader should, however, make himself familiar with the effects of refraction, such as are within his reach, to enable him to better understand this subject. For example, light cannot pass through air without resistance, and therefore refraction as found in the atmosphere where the sun's rays have to pass through different depths and densities of the atmosphere. Water, however, furnishes the most convenient illustration for our present purpose, and all can practice the experiment here introduced.

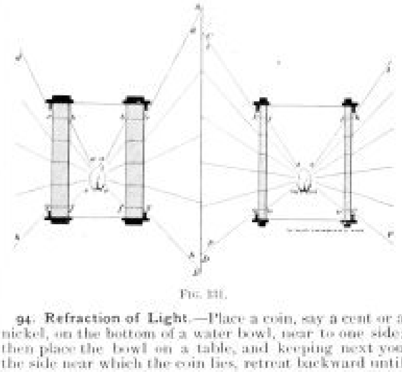

Fig. 131.

94. **Refraction of Light.**—Place a coin, say a cent or a nickel, on the bottom of a water bowl, near to one side; then place the bowl on a table, and keeping next you the side near which the coin lies, retreat backward until the top edge of the bowl just conceals the coin. While standing here, let an assistant gently pour water into the bowl, and as the surface of the inpoured water rises, the coin will come more and more into view, until the coin and the bottom of the bowl will appear to have been upraised. Now we have here an example of an invisible body being rendered visible by the refraction of the reflected light from its image in passing through water, and indeed what here takes place is the analogue of the increase in the angle of diffusion of the light of the safety lamp. Having made clear what we mean by refraction, we have now to consider the relationship of the thickness of the glass to the angle of diffusion, and

the figure is designed to furnish the required solution, and therefore we see at a glance that the thick glass gives a greater angle of diffusion than the thin one, for *m n* is parallel to *o p*, just as *e f* is parallel to *g h*; and *i j* is parallel to *k l*, just as *a b* is parallel to *c d*. The reader will find that the coin experiment sustains the same conclusion, for as the depth of the water in the bowl increases, the angle of diffusion increases, and therefore a greater depth brings the coin more into view than a less one, and in the same way we see that the chord of the arc *C D* is considerably less than the chord *A B*, or the arc due to the thick glass.

We may then conclude that the thick glass is the one best adapted to the requirements of the safety lamp, but before accepting this dictum, let us notice, a high refraction is the result of a high resistance, and a correspondingly great diminution in the intensity of the light, and therefore we can get a high angle of diffusion with a thin glass if we reduce the diameter of the cylinder. There is without a doubt a thickness at which the glass shell gives the best results, but it will require the teachings of the next lesson to furnish other facts that must figure as witnesses in the trial.

95. Good Light in Safety Lamps.—There are other matters of importance beside the thickness of the glass shell that deserve our notice, and not the least of these is the question of a motive column to bring live air to the flame of the lamp, and we must all admit that with the exception of the Gray lamp, very little has hitherto been done to obtain a motive column commensurate to the requirements of the case. On examining some of the best modern lamps the first thing that strikes us is this, little or no provision has been made for the complete combustion of the oil and we continue to say these lamps will give a bad light. As a case in point let us consider the Mueseler lamp as illustrated by Fig. 132, and here we find the only approach to a motive column is furnished by the conical funnel; but, say you, "good oil should burn like an open candle;" our reply is, so it should, but if you interpose between the flame of the candle and the open air two gauze diaphragms for the feed air to pass through, then the candle flame will pour off a column of sooty smoke and then you will admit that the naked light is best, or otherwise you must provide a motive column to overcome the resistance the air is subject to in its passage to the flame.

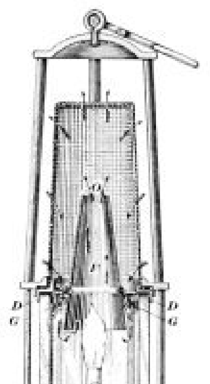

Fig. 132.

This is exactly the case in the Mueseler lamp; the air has to first pass through the meshes of the gauze cylinder, and after that it has to force a passage through the meshes of the horizontal gauze diaphragm that supports the funnel, and the result of this is, not only is the glass cylinder badly adapted for the diffusion of the light, but the conditions of combustion are under such restraint, that the light is subdued and the lamp loses favor with the miner. Let the reader observe that in the Gray lamp in its most recent form, as we find it in the United States, the air feed takes place at the bottom of the lamp, after the original idea of Stephenson, but in the case of the Mueseler the feed air enters above the glass cylinder, with the result of losing a portion of the elevation that should be disposable for a motive column.

This brings us to the consideration of the claims of the Marsaut lamp, Fig. 133. Here the motive column is a little longer, and all men who have used this and the Mueseler know, that it has been preferred for its superior light, but the air here enters as in the common type of the bonneted lamps above the glass cylinder, and in addition, the feed air has still to be drawn through the meshes of a double system of gauze walls with a great loss of motive column with the result, that all this type of lamps are easily extinguished, and give a very bad light where the air contains a small percentage of carbonic acid gas. The entering air must pass through some medium like one gauze, or better still, two gauze barriers, but some moving pressure is required to overcome the unavoidable resistance, and the only source of this factor in the feed potential of a lamp is in a motive column due to the rarefaction produced by the heat of the lamp flame. From all this and what is to follow, we have so far found, and will further know, that all future improvements in the safety lamp must conform to the requirements of a good light, as only secondary to the best provision for the perfect isolation of the flame.

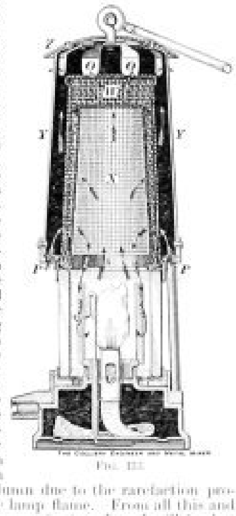

Fig. 133.

(*To be Continued.*)

MINING METHODS.

Underground Fires—Chemistry and Chemical Action—Chemical Changes of Carbon—Extinguishing Underground Fires—An Underground Fire in the Workings—The Effect of High Pressure in Gob Fires.

87. Underground Fires.—These can only be kept under subjection and ultimately extinguished by correct methods of treatment, and to explain such is the object of this and the other lessons on the subject.

Fire is a manifestation of very active chemical action, and as this action is the resultant of well known forces, it is capable of being restrained or rendered passive by cutting off the supply of one of the components of the resulting energy; for example, if while a candle is burning in a can the lid is put on and tightly closed, after the expiration of a moment or two the flame of the candle will die out, or, in other words, chemical action will cease, because combustion is the result of oxygen combining with inflammable substances, and the moment the supply of oxygen ceases, that same moment combustion ceases, because the fuel burns the oxygen as surely as the oxygen burns the fuel, and to one who has not studied the laws of chemical combination such a statement will no doubt be in conflict with his preconceived notions. To the chemist it is as correct to say that a piece of paper burns the oxygen of the air, as it would be to give the common rendering of the operation and say the oxygen burns the paper. This is proved by fixing a bracket and gas burner in a tank, and then filling the vessel with coal gas. To the burner is fixed a platinum wire, and this is put in circuit with the generator of an electric current, and the moment a current of oxygen gas or even atmospheric air is forced through the pipe and out of the burner, the same moment the electric current is turned on, when it lights the oxygen jet at the gas burner, and we now witness oxygen gas or air, burning and giving off light and heat with a veritable flame in an atmosphere of coal gas, thus fully sustaining our conclusions.

88. Chemistry and Chemical Action.—That variety of chemical action called fire is the result of certain elements combining, while in a *nascent* state, or in a state in which they actively devour each other, and produce new substances totally unlike themselves. Now the reader may think that the writer cares more for the science of chemistry, than for the suppression of underground fires, but let him wait for further explanation, and he will discover the need of these preparatory remarks. On looking back a few lines in the lesson the word *nascent* is seen, and before we proceed further with the suppression of underground fires we must know properly what this word means, and its bearing on our subject. If we mix two parts of oxygen gas with one part of coal gas, we obtain a very explosive mixture, and yet if no flame is brought into the mixture, the gases will never combine and produce light and heat, but the moment a light is introduced, the gases in the mixture combine with explosive violence, because the flame made them *nascent*. Still we do not know what the word means. Well let us have another try, and this time we will take a piece of cinder, coke, charcoal or carbon, and we will find that this piece of carbon or cinder may be exposed to an atmosphere containing oxygen, as the air does, for a thousand years, and yet it will not change or oxidize. The writer was present when some excavations were being done to unearth an old Roman military station at South Shields, England, and at the intersection of the *Via Principia* or Main street, with the *Via Transepta* or Cross street of the station, the excavators unearthed the office of the Commandant and here were the remains of his last *coal fire*, and the coals were as bright as if they had been newly taken from the mine, and the cinders were as perfect as if the fire had just died out. The carbon had lain on that hearth for 2,000 years without undergoing any change. Now if by some means a few pounds of the Roman cinder were put on a burning fire and there raised to a *red heat* they would burn or oxidize, until after the lapse of two or three hours nothing would be left but a small quantity of incombustible ash, for in this case the heat would make the carbon *nascent*. Still we do not know what this word means. Then let us have another try to unearth the right definition. Well, all the chemical elements are positive and negative to each other, and a positive will not combine with a positive, nor will a negative combine with a negative, but in all cases the moment two or more elements that are in a high degree positive and negative to each other, are brought together, they combine so greedily, that they devour each other, and produce a body unlike its originators, and it so happens that some bodies, such as carbon, are negative below a *red heat* and cannot therefore combine with oxygen that is also negative, but red hot carbon is positive, and at a white heat it is very positive and therefore *nascent* and consequently intensely quick in combining with oxygen.

89. Chemical Changes of Carbon.—Now, then, we see that carbon is in a nascent condition when heat has changed it from the negative state in which it cannot combine with oxygen, to the positive state in which it combines savagely with that gas. This explanation is of great value to the miner because by it he learns why the flame of his lamp has to be insulated with wire gauze, for otherwise the flame would make the firedamp chemically active or *nascent*, and it is for this reason that coal dust becomes *explosive* in air, where flame makes the hydrogen and carbon of the coal chemically active, or *nascent*, and it is for this reason that *red-hot* coals or cinders are so dangerous in underground fires, because they are so *nascent* that even air containing only a trace of oxygen is sufficient to feed the greedy monster.

Now that we understand the tactics of the enemy, we may assail him with success.

90. Extinguishing Underground Fires.—Then let us resume the subject of the subjection of underground fires with the help of Fig. 129. Here a fire has occurred at *F*,

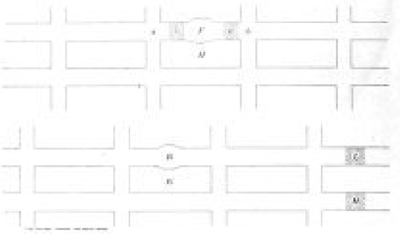

Fig. 129.

and it has been decided to cut it off at its very seat by a stopping at *a* and another at *b*, and let us watch and see what will occur.

First.—The heat will cause such a great expansion of the small volume of confined air, in such a restricted space, that by its great pressure it will force its way through the stoppings, and joints in the roof, floor and sides.

Second.—The heat will convert any water in the roof rock, floor rock, or the coal sides, into steam at a very high pressure, and aided by the expansion of the hot rock, the roof, floor and coal sides will be split and broken, and thus a great number of vents will be made for the breathing of the fire.

Third.—The fire will at once spread into the very heart of the pillar *H*, because the coal will be cracked by the heat, and at the same time its temperature will be raised to the nascent point, and unless checked by a better mode of treatment the whole mine will soon be on fire.

Had the stoppings been built in at the points *L* and *M*, the following results would have followed:—

First.—For a few days the fire would burn fiercely and crack the roof and the coal.

Second.—The temperature of the enclosed air would never rise very high, nor would the pressure of the confined air ever be much above the normal pressure of the atmosphere, because the combined areas of the rooms and headings would prevent compression, and the great extent of the combined surfaces of the roofs, floors and walls would present an enormous surface for the absorption of the heat.

Third.—After the oxygen, in the large volume of air, that made the fire burn fiercely at first, was all consumed, the breathing of the fire would be very slow, because the pressure would be too low, and the volume of the enclosed air too great for rapid exhaustion; again, the heat of the fire could not extend to the rock and coal in which the stoppings were built, hence the vents for exhalation would be of a very constricted character. It is then manifest from the examples before us, and they are the outcome of the writer's experience, that it is a dangerous experiment to constrict the region of an underground fire.

91. An Underground Fire in the Workings.—If a fire occurred in a room as at *F*, Fig. 130, we now know that it would be altogether a serious mistake to stop it off

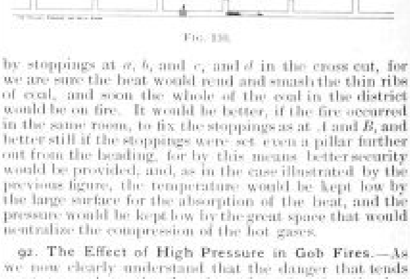

Fig. 130.

by stoppings at *a*, *b*, and *c*, and *d* in the cross cut, for we are sure the heat would rend and smash the thin ribs of coal, and soon the whole of the coal in the district would be on fire. It would be better, if the fire occurred in the same room, to fix the stoppings as at *A* and *B*, and better still if the stoppings were set even a pillar further out from the heading, for by this means better security would be provided, and, as in the case illustrated by the previous figure, the temperature would be kept low by the large surface for the absorption of the heat, and the pressure would be kept low by the great space that would neutralize the compression of the hot gases.

92. The Effect of High Pressure in Gob Fires.—As we now clearly understand that the danger that tends most to prolong the duration of a mine fire, is that variation in the pressure of the confined air, in which it rises sometimes and falls at other times below the pressure of the atmosphere, we should be careful to take steps when this occurs to prevent it, or otherwise nitrogen will be expelled at the period of compression, and oxygen inhaled at the period of depression, and the fire will thus be kept permanently active.

There is one condition of the confined air that will prevent breathing, and that is, to sustain in the region of the fire a pressure above that of the external air. There are many cases in which this would be very difficult to carry out, but where it can be done, it secures the best results. By the sections of a mine, we could determine the height to which water should be raised in the shafts or slopes to sustain a pressure that would be above that of the atmosphere, and if such a pressure could be maintained for a sufficient period the gob could not inhale, and the result would be that the necessary oxygen for combustion would cease, and the hot coal would cool and thereby loose the heat that promotes

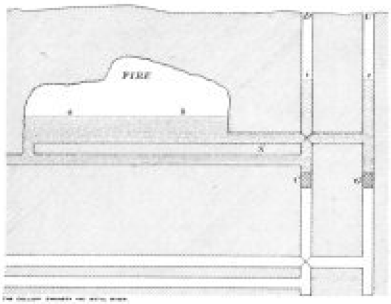

FIG. 131.

chemical activity. Such a case is illustrated by Fig. 131. Here dams have been fixed in the slopes as at *C* and *G*, and the water in the slopes has been raised to the elevations *i* and *e*, while the air is compressed in the region of the fire to the extent of the difference of the water level elevations *a b* and *i e*. But how can we tell that the air is compressed in this case. There is only one way of making the compression in a case like this sure and reliable, and that is to maintain the water levels in the slopes at an elevation above that of the highest point in the gob, and then should any leakage occur, or should the water used for flooding find a downward vent into the lower workings, we could rest assured that the pressure could not be removed from the fire, otherwise should the flooding water find a way of escape, it might cause a depression at the seat of the fire and at the same time produce an inflow of fresh air that would rekindle the fire. Safety then can only be secured by maintaining the water levels in the shafts or slopes at the required

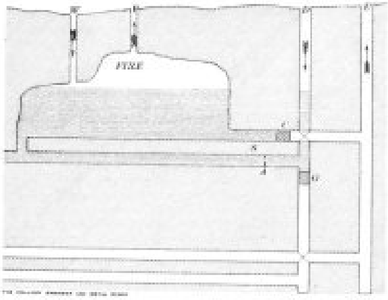

FIG. 132.

height. It is no easy matter to extinguish a mine fire; the whole problem is beset with difficulties that require the utmost care and calculation to secure the successful arrest of the enemy.

Fig. 132 furnishes another mode of treating a mine fire. Here large bore holes, *W*, *W*, have been put down to the crown of the fire region, and a dam has been built in the airway at *C* and in the downcast slope at *G*. The object of this plan is to drown the fire, and no doubt in some cases this is the best mode of proceeding that could be adopted, especially where a copious flood of water can be obtained, and where this water can be quickly and cheaply lifted again. The inflow of the water is indicated by the downward pointing arrow, and the course of the outflowing air is indicated by the upward arrow. There are many cases, however, where this method of drowning the fire could not be applied, and it is for this reason that we must still continue our lessons on the subject.

(*To be Continued.*)

GEOLOGY OF COAL.

The Life Indices of the Coal Period—Geology a Registering Thermometer—The Pentagonal Characteristic of Animal Life.

55. **The Life Indices of the Coal Period.**—There can be no doubt that life is real, and with the successful man life is earnest, but a life without recreative pleasure is like a garden without a rose, and as the miner requires a befitment of technical knowledge much more comprehensive than that of men in many other professions, he should have something to do that would ease the tension of hard study, and at the same time be playfully in line with his daily pursuits. Now we are happy to say that no other professional man is more favorably situated in this respect than he, for geology provides him a magnificent play garden in which he may gather stone lilies for his cabinet, just as a child gathers flowers for a wreath, or he may dig shells out of the rocks, as a child picks them out of the shingle on the ocean's shore. The man's pleasure, however, may outstrip that of the child, because he has scope for his imagination to revive, in mental pictures, a past so mighty that the man who looks into it feels divine. For gauging heat we have registering thermometers that leave at the ends of the thermal range for any period, little index rods, and by looking at the instrument you can by this means tell what has been the highest temperature of the day, or the lowest temperature of the night. Or, if you set aside the instrument for twelve months, at the end of that time the indices show the highest and lowest temperatures of the whole period, and from this we may see that if registering thermometers when placed at a great number of points on both hemispheres of the earth and allowed to remain for a cycle of, say 10 years, we could by this means determine the mean temperature, approximately, for the whole surface of the earth. Now in nature we find indices of heat far more exact than the readings of the best thermometers that man can make; for example, ice melts at an invariable temperature, and never alters, and indeed the scales we use are simply divisions of natural ranges. In the Fahrenheit thermometer the range between the freezing and boiling points is divided into 180 equal parts called degrees, and in the Centigrade thermometer the same range is divided into 100 equal parts that are also called degrees, but the big degree, that is the range between freezing and boiling, is the same in all thermometers. As the laws of nature are constant then, the past would be no exception to the present, and we may be sure, therefore, that lead would melt at the same temperature in Carboniferous times as it does now, and if all this is granted, we may with perfect faith take the figures that are the subjects of this lesson, as *real* indices of the temperatures of the seas in which these creatures lived.

56. **Geology a Registering Thermometer.**—Now this is certainly making geology a registering thermometer, which it is, and the fossils furnish the means of determining with exactness the temperatures of the air or water in which the plants or animals lived. For example, the

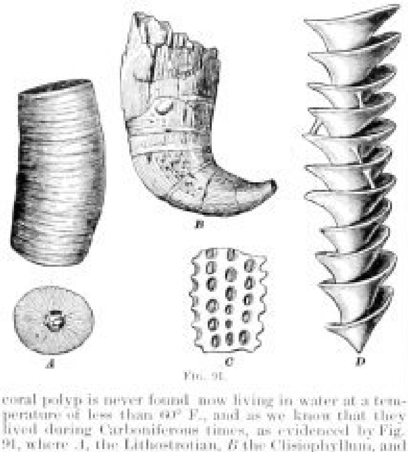

FIG. 91.

coral polyp is never found now living in water at a temperature of less than 60° F., and as we know that they lived during Carboniferous times, as evidenced by Fig. 91, where *A*, the Lithostrotian, *B* the Clisiophyllum, and *C* and *D*, different examples of the Archimedes, were all varieties of coral polyps that lived in the Carboniferous seas. What then is true now is equally true of the Carboniferous period, because we know that the laws of inorganic and organic chemistry cannot change. How, then, can it be said that geology is a profitless study, when it can be made at once a source of pleasure and useful knowledge.

57. **The Pentagonal Characteristic of Animal Life.**—On the floors of the warm seas of the Carboniferous period there grew a lowly budding variety of crinoids

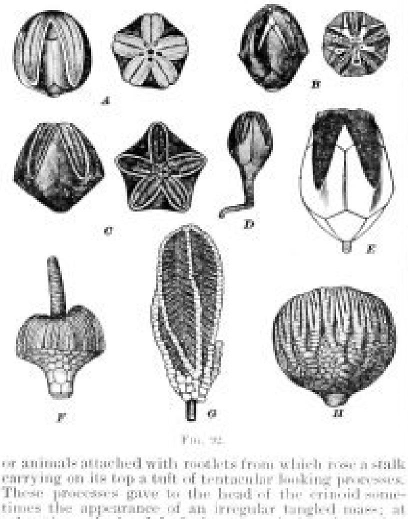

FIG. 92.

or animals attached with rootlets from which rose a stalk carrying on its top a tuft of tentacular looking processes. These processes gave to the head of the crinoid sometimes the appearance of an irregular tangled mass; at other times the head looked symmetrical, and at other times it was so beautiful in the order and repetition of its coronal parts that when it is seen now by a geologist, it is to him an object of wonder and admiration.

The crinoid is somewhat allied to the corals, hence their structure was calcareous, and so varied has been their development that each succeeding geological age has produced its characteristic crinoids, and this was especially so during the Carboniferous period, for its deep, warm seas were especially favorable to the growth of these strange forms of animal life; and so true is this, that this period was distinguished above all the preceding ones for its beautiful crinoids called asteroids. (See Fig 92.) These star-like crinoids are shown at *A*, *B*, *C*, *D* and *E*, and we cannot pass them by without showing

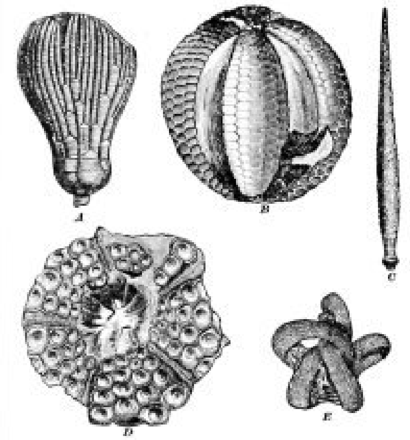

FIG. 93.

how, in a particular manner, they were related to all the higher life forms, for these stone flowers of the sea had their pentagonal plumes and petals, that is, their radiation was in the order of fives, and in this respect they are somewhat related to the radiata, because the star fishes have their five rays, and therefore the pentagonal order of the asteroids of these ancient seas was not singular. The head is so beautiful that in looking at it you can fancy you see the corolla and the calyx of a flower, and it does appear that there is some directive principle in nature that has associated the radial arms of the asteroid with the digits of man, and the rays of a star fish, for the order of five is so common throughout the whole series of simple and complex organisms that the correlation seems complete.

We see, then, that the crinoids are to the miner geologist a matter of engrossing interest. Fig. 93 furnishes more examples of these beautiful pentagons. At first sight *A* appears not to be an asteroid, yet by closely looking at the bottom of the tuft, three of the five bunches of tentacles can be distinctly seen. In the cases of *B* and *D* the asteroidal structure is clear enough. At *C* is shown one of the five tentacles of *E*, where the creature is seen folding its arms as a cuttle fish does its true tentacles.

MINING MACHINERY.

Mine Drainage—Correction of the Pump Balance—Is There Such a Principle as Suction?—The Hydrostatic Balance of Pumps—Diagrams of Water and Mercury Balance.

104. **Mine Drainage.**—This is a subject of so much importance to the mining engineer that he is by force of circumstances obliged to understand, among other kindred appliances, the principles of action and the mode of construction of the common pump, and therefore we are going to make it one of the subjects of our Easy Lessons.

The first principle to be understood in the action of the pump is that by which water is made to rise in the upright tail pipe with the appearance of doing so defiantly of the laws of gravitation. For the water to thus rise, however, two conditions are necessary, and the first is, there must be an equivalent reduction of pressure above the water column in the pipe; and the second is, that the pressure of the atmosphere shall so lift the water that the weight of water in the column lifted, added to the reduced pressure above the water, shall be equal to the pressure of the atmosphere. The case has been no doubt correctly stated, but still some obscurity may enshroud the reader's understanding, and we must therefore continue the explanation until the mist that conceals the truth of the matter has been cleared away.

To the definition of the balance given let us add an illustration, and suppose that the piston of the pump has moved upward to an elevation of 20 feet, and further let us suppose that the transverse area of the pipe is equal to one square foot, then if the piston has moved upward from the level of the intake water, or from the surface level of the water lifted, 20 feet, it is clear that if one cubic foot of water weighs 62·5 pounds, 20 cubic feet must weigh 20 × 62·5 = 1,250 pounds, then the weight that will hang on the piston will be 1,250 pounds. Now, if the pressure of the atmosphere has lifted this weight, it is clear that for it so to act, 1,250 pounds pressure per square foot has been removed from the top of the column of water under the piston, and therefore the remaining pressure under the piston must be 2,118 − 1,250 = 868 pounds per square foot, and this is exactly what is the case, for the pressure of the atmosphere in pounds per square foot is 2,118. Now, to prove this, let us suppose that in a vertical pipe 40 feet high and closed at the top perfectly air-tight, while the open end of the pipe dips into water, the liquid will rise into the vacant or vacuum space to an elevation of $\frac{2,118}{62.5} = 33.888$ feet, and we discover by this that 33·888 feet of water column exactly balances the pressure of the atmosphere, and this being so, if 33.888 cubic ft. are equal to the pressure of the atmosphere, or 2,118 pounds per square foot, it follows by a simple proportion that a water column of 20 feet will be the proportion of the whole atmospheric pressure that is represented by 1,250 pounds per square foot, as

33·888 : 20 :: 2,118 : 1,250 exactly.

Or if 33·888 feet of water column balances the pressure of the atmosphere, by a simple proportion we can find what height will balance 1,250 pounds, for

2,118 : 1,250 :: 33·888 : 20 feet.

Now we stated in the beginning that if the weight lifted was added to the pressure beneath the pump piston the sum would be equal to the pressure of the atmosphere, and for a 20 feet lift the weight or strain on the pump rod is equal to $20 \times 62.5 = 1,250$ pounds, therefore $2,118 - 1,250 = 868$ pounds, or to present the case in an easy way,

Pressure of the Atmosphere.		Pressure Under the Piston.		Weight Hanging on Piston Rod.
2,118	=	868	+	1,250.

From this example we clearly discover that the whole matter resolves itself into a question of a balance.

105. Correction of the Pump Balance.—Sometimes clear presentations of a case engender mistaken conceptions of the qualifying merits of the case. Then let it be understood that the equation given is purely *theoretical* and is *not true* in practice for the following three reasons:—

First.—The pressure of the inflowing water has to lift the suction valve and keep it up, and gurgle through the constrictions due to the port way of the valve.

Second.—Water moving through pipes is subject to resistance arising from the wave motion of the fluid, which is known as the friction of the moving fluid.

Third.—The *vena contracta* introduces a resistance at the intake or port of entry.

Further on these causes of resistance will be duly allowed for, but in the mean time let us not lose sight of the fact that so far as suction is concerned the pressure of the atmosphere remains constant, and it may happen, as it sometimes does, where the valve way is constricted or the tail or intake pipe is too small in diameter in relation to the diameter of the piston, that with a 20 feet lift the theoretical pressure beneath the piston is lost by the abnormal resistances being equal to it, and when this is the case we have the following singular equation:—

Pressure of the Atmosphere.		Weight Hanging on Piston.		The Sum of the Resistances.		The Pressure Under the Piston.
2,118	=	1,250	+	868	+	0.

106. Is There Such a Principle as Suction?—There is such a principle as suction in the action of pumps and other kindred appliances, and the word is expressive of what takes place when a fluid *falls* from a higher to a lower pressure, and if the use of such a word was disallowed, then we would be compelled to use modes of expression that would not be half so explicit. Some say the inhalation of a pump takes place by pressure, but this is not correct, because the piston must first act and set up a depression, or reduced pressure, and the word suction refers to the action of the something that makes the depression; if, therefore, we discontinue the use of the word suction, we must invent another word that means suction.

We grant that many persons use the word suction in a mythical sense, and think all the while that it is some peculiar vital action that is outside of the principles of mechanics, but this view of the matter is quite a mistake, for the sucking of the young of mammals is the result of the action of a pump that produces a depression in the mouth. Watch the movement of the lower jaw of the offspring sucking, or experiment on yourself, and you will find that you cannot suck while the teeth in your upper and lower jaws are touching. The milk, then, in the act of sucking, falls from the pressure of the atmosphere into a depression. We will therefore continue to use this correct and most expressive word in this and the future lessons.

107. The Hydrostatic Balance of Pumps.—With the help of the explanation already given we can now take in hand Fig. 140, and we hope the reader will enjoy the

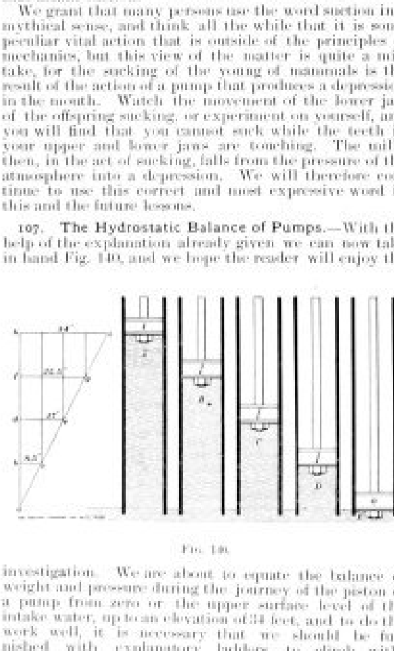

Fig. 140.

investigation. We are about to equate the balance of weight and pressure during the journey of the piston of a pump from zero or the upper surface level of the intake water, up to an elevation of 34 feet, and to do the work well, it is necessary that we should be furnished with explanatory ladders to climb with. All the way up the long stroke we will find *theoretically*, that the atmospheric pressure is equal to the pressure under the piston, plus the weight of the column of water lifted. At the left hand side of the figure a triangular diagram is shown, and the object of this is to show that the amount of mechanical work done at each step is equal to the area of the triangular space below the line of elevation; and starting from the zero height or no elevation at all, we will find that during the first one-fourth or 8.5 feet of the stroke, very little work is done, for it is only equal to the area of the triangle *a b c*, but during the second quarter of the stroke three times as much work is done as in the first quarter, and, therefore, if the work done in the first quarter is proportionate to the triangle *a b c*, the work done in the second quarter of the stroke is proportionate to the area of the trapezoid *b d e c*, and so on with the rest.

Now, let us begin the upward journey of the piston from zero, or 0 to *D*, and here we observe that the under side of the piston has risen one-fourth of the stroke or 8.5 feet, and as a column of water one square foot in the base and 8.5 feet high weighs $62.5 \times 8.5 = 531.25$ pounds, we find the theoretical balance is

Pressure of the Atmosphere.		Weight of Water Hanging.		Pressure Under the Piston.
2,118	=	531.25	+	1,586.75

The work done will be equal to the weight of water lifted multiplied by the height of its center of gravity, and as the center of gravity of the column of water will occur at half the height, we have $531.25 \times \frac{8.5}{2} =$ 2,257.8125 foot-pounds, or the work done in the first quarter of the journey, is equal to $\frac{1}{16}$th of that done during the full stroke.

Next, let the piston rise to *C*, or to half the height of the stroke. We now obtain an instructive equation, because the weight of water hanging will be exactly equal to the pressure under the piston, for if we take the pressure of the atmosphere at 2,125 pounds, to balance, under a vacuum, a vertical column of water 34 feet high, then

Pressure of the Atmosphere.		Weight of Water Hanging.		Pressure Under the Piston.
2,125	=	1,062.5	+	1,062.5

And the work done for one-half stroke will be equal to $1,062.5 \times \frac{17}{2} = 9,031.25$ foot-pounds.

Now, let the piston ascend to the elevation at *B* and the theoretical balance will be, when a column of water one square foot in the base and 25.5 feet high, weighs $62.5 \times 25.5 = 1,593.75$ pounds.

Pressure of the Atmosphere.		Weight of Water Hanging.		Pressure Under the Piston.
2125	=	1593.75	+	531.25,

and the work done for three-fourths of the stroke will be $1593.75 \times \frac{25.5}{2} = 20320.3125$.

Now, to complete the stroke, let the piston rise to *A*, and here the weight of a column of water one square foot in the base and 34 feet high will weigh $62.5 \times 34 =$ 2125 pounds, and therefore the theoretical balance will be:

Pressure of the Atmosphere.		Weight of Water Hanging.		Pressure Under the Piston.
2125	=	2125	+	0

The work done throughout the stroke will be $2125 \times \frac{34}{2} = 36125$ foot pounds.

From the standpoint of the calculated results, the diagram of work cannot fail to be interesting, as by it we can see in a graphic manner the reason why the work done in the different quarters is so divergent that in the first quarter it is only $\frac{1}{16}$, and in the first half of the stroke $\frac{4}{16}$; making the second quarter $\frac{3}{16}$, the first three quarters are equal to $\frac{9}{16}$, thus making the work done during the third quarter $\frac{5}{16}$ of the whole, and the entire work being $\frac{16}{16}$, we find the work done during the last quarter stroke was $\frac{7}{16}$ of the whole.

108. Diagrams of Water and Mercury Balance.—Notwithstanding the fact that a column of 30 inches of mercury balances a column of 406.656 inches, or 33.888

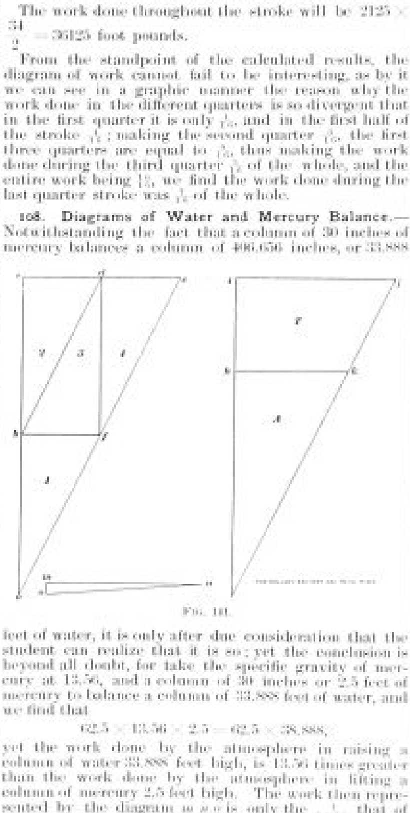

Fig. 141.

feet of water, it is only after due consideration that the student can realize that it is so; yet the conclusion is beyond all doubt, for take the specific gravity of mercury at 13.56, and a column of 30 inches or 2.5 feet of mercury to balance a column of 33.888 feet of water, and we find that

$$62.5 \times 13.56 \times 2.5 = 62.5 \times 33.888,$$

yet the work done by the atmosphere in raising a column of water 33.888 feet high, is 13.56 times greater than the work done by the atmosphere in lifting a column of mercury 2.5 feet high. The work then represented by the diagram *m n o* is only the $\frac{1}{13.56}$ that of the work done in raising the water.

The work done, however, in raising water into a depression, varies directly as the squares of the heights of the column in its ascension, and this is clearly shown by the diagram, where for half the height *o b* the work done is 1, or it is equal to the area of the triangle *o b f*, and the work done for the entire height is 4 times that done at half the height, as shown by the four triangles 1, 2, 3, 4. Again, the square root of $.50 = .707$, is equal to the height *o h*, if the whole height be taken at 1, and the area of the triangle *o h k*, is equal to the area of the trapezoid *h i j k*; therefore, at an elevation of .707 or $33.888 \times .707 = 24$ feet, one-half of the work, has been done in raising the column of water.

109. The Velocity of Water Entering a Pump.—As was shown at first, the velocity of the water entering a pump was such that the result in practice was very

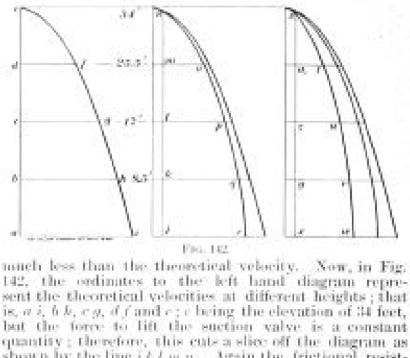

Fig. 142.

much less than the theoretical velocity. Now, in Fig. 142, the ordinates to the left hand diagram represent the theoretical velocities at different heights; that is, *a i*, *b h*, *c g*, *d f* and *e*; *e* being the elevation of 34 feet, but the force to lift the suction valve is a constant quantity; therefore, this cuts a slice off the diagram as shown by the line *i k l m n*. Again the frictional resistance still further reduces the velocities, and therefore we pare another margin off the diagram and the ordinates of the relative velocities are now reduced from *a i* to *j z* and from *b h* to *k q*, and so on. Again the *vena contracta* still further reduces the velocities from *j z* to *z w*, and from *k q* to *q v* and so on.

These three diagrams then show clearly the relationship of the theoretical and practical results.

(*To be continued.*)

Large Electric Locomotives.

The Westinghouse Electric and Manufacturing Company has received the first electric locomotive manufactured under the arrangement entered into some time ago between the Westinghouse Company and the Baldwin Locomotive Works of Philadelphia. In appearance the locomotive is much different from the steam locomotive, and it also shows radical departures in construction from every electric locomotive hitherto manufactured. It is 38 feet long and 9 feet across. All the operating parts of the locomotive have been placed on the truck and the body of the car will only contain the controlling apparatus, and can be utilized as a receptacle for such appliances as are usually carried by any train. It may also be used as a freight or baggage car.

One of the characteristic features of the locomotive is the truck, which has eight wheels, and is constructed in a very substantial manner. The wheels are 42 inches in diameter. There will be four motors of 200 h. p. each connected to the axles of the locomotive. Thus the entire weight of the locomotive will be placed upon the truck, thereby becoming available for adhesion. This feature of construction will be readily recognized as a very advantageous one over other locomotives, where only a small percentage of the weight is available for adhesion.

The locomotive completely equipped will weigh 160,000 pounds. The motors are geared, which method has been decided upon so as to enable the company to use more efficient and durable motors, and also greatly reduce the cost or the locomotive. It is stated that while the electric locomotive used in the Baltimore tunnel cost $50,000, the Baldwin-Westinghouse locomotive will cost less than one-third of that amount, and yet it will be able to accomplish the same work. The Baldwin-Westinghouse combination is constructing engines for all kinds of purposes. The one described here is the regular passenger engine, rated at 1,000 h. p. capacity. Then there will be locomotives made to be used in mines. The latter will have six driving wheels and the superstructure will consist of a sheet iron cab. The switching locomotives will also have a cab as a superstructure. There will also be manufactured locomotives for tunnel work, suburban traffic and rack locomotives, as well as for elevated railroads.

It is expected that within a few days the second locomotive, as completed by the Baldwin people, will be received at the East Pittsburgh factory of the Westinghouse Electric and Manufacturing Company. This last one will be of the elevated railroad type, and is an example of a motor car of the Manhattan Elevated Railroad of New York.

As far as the speed of these new locomotives is concerned, it may be stated that the motors have been geared to produce a speed of 75 miles an hour, although it may reach 125 miles an hour, if it were demanded. All Westinghouse-Baldwin locomotives will be equipped with air-brakes, which will be operated in the usual manner by an air pump, which is underneath the car, and which will be driven by an electric motor.

The Westinghouse-Baldwin locomotives have been designed so as to be utilized with any method of electric traction. They can be used with the trolley system, the third rail system, the Westinghouse electro-magnetic system and they can also be utilized in connection with the Tesla polyphase system.

Since it has become known that the Baldwin-Westinghouse companies are constructing electric locomotives, inquiries have come from all over the world for such machines, indicating the wonderful demand there is for such engines when they are manufactured by such well known firms as the Baldwin Locomotive Works and the Westinghouse Electric Manufacturing Company.

MISCELLANEOUS.

THE GREAT EMERGENCY MAN.

The Vice-Presidency is essentially an office of dignity. No other office under the government has such lofty possibilities for its occupant, while at the same time being so utterly bereft of influence either to wield patronage or to affect legislation.

The Vice-Presidency requires a man fitted to fill the highest office under the government, one whose broad information will make him equal to coping with any national question that might come before Congress, and whose information and position among men would qualify him to preside over the conservative branch of Congress. He is an emergency man. Should death remove the President, it is he who is called upon to occupy the White House. Should there be a tie in the vote of the senate, he, then, has the deciding vote, but, except in this emergency, he is without influence to affect legislation. While the Speaker of the house of representatives assigns all the representatives to places on committees, and in that way virtually determines what legislation shall be enacted, the Vice-President, not being a member of the senate, has nothing to do with the formation of committees, and is not even admitted to the caucuses of his party, in which, if that party have a majority, committee assignments are determined and the policy of the party is mapped out.

The patronage of the Vice-President consists in the appointment of a secretary, a messenger, a telegraph operator, and a telegrapher's page. That is all. The presiding officer of the senate occupies a handsome room, opening on the senate lobby, and he is accorded all the respect which goes with his high office, the chief function of which is to preside over the deliberations of the United States senate.

Because of the peculiar character of the duties of the Vice-President, the daily routine of his life is very different from that of a United States senator. His social life in Washington is just what he chooses to make it. His invitations would not be disregarded by any one in official or social life here, but whether he entertain much or little is a matter purely within his own pleasure. While certain social functions are a part of the official duties of the President, the Vice-President is free to entertain or not, as he sees fit.

But the Vice-President is sought by many visitors to the capital. He is one of the sights of the capital, and visitors from Illinois especially do not like to leave Washington without having sought an introduction to the Vice-President and the man who is regarded as a presidential possibility. But the chances of the Vice-President for the nomination at the hands of the next national convention are rendered smaller because of the fact that since his election his hands have been tied and he has had no opportunity to show the qualities of a leader of his fellow Democrats. Of course, this fact renders the Vice-President free from all responsibility for the acts of his party, although it is probable that in the minds of the masses of the people he is regarded as equally responsible with all Democratic senators for the acts of the last congress.

The duties of the Vice-President do not require him to burn any midnight oil in the consideration of public questions. He has ample opportunity to keep himself informed on all matters that come before Congress by being a good listener, and he has no occasion to prepare any speech for delivery in the senate. He is relieved from all committee work, of course, and even the task of presiding over the senate is rendered an easy one because of the fact that that body is a very docile one to govern, and is not fraught with the perplexing parliamentary problems that are constantly occurring in the house of representatives. The fact that the senate is so largely run by "courtesy" makes it an easy body to preside over.

Perhaps no man connected with the United States senate is so apt to be bored as is the Vice-President. Without power to influence legislation, his office being such that even any suggestion from him would be apt to be regarded as an unwarranted interference, he is yet obliged to attend the sessions of the senate daily, and to recognize this or that one who happens to have a bill to present or a suggestion to make.

From 12 until 2 o'clock is known in the senate as "the morning hour," and during that time all the business of introducing bills, making reports from committees, presenting petitions and memorials, &c., is done. The vice-president is seldom absent from the chair during the "morning hour," but when that expires the "regular business" is taken up, which practically means a continuation of speaking on the pending bill. Then the Vice-President has an opportunity to leave the senate, which he does if there is not in prospect some very interesting debate which he wishes to hear. He seeks his private office, where he frequently holds a reception, for his friends know the hour when he is at leisure and can see them. He generally is on hand when the senate adjourns, and then he has nothing in the nature of official duties to occupy his attention until the day on which the senate is next to meet.—*Washington Evening Star.*

SNOW SHEDS OF THE CENTRAL PACIFIC RAILROAD.

The line of the Southern Pacific Company lying between Blue Canon and Truckee, a distance of 41 miles, is thickly studded with an extensive system of snow sheds costing nearly, if not quite, one and one-half million dollars. During the winter months these sheds are protected from fire by the snow, but in the summer they become very dry and are readily ignited. A spark from a passing engine, or a forest fire, or a match lit by a malicious tramp, may do great damage, not only costing thousands of dollars for repairs, but blocking the road with debris, so that all trains are stopped for several days at a time. Several years ago the railroad company reduced the danger of fires being set by tramps by issuing orders to trainmen to let those gentry of the road ride through the sheds whenever they boarded a freight train, and under no consideration to put them off until the sheds were passed, but other dangers threaten which do not offer so easy a remedy. In spite of spark arresters on the locomotives sparks will rise. Nor does there seem to be a way to keep the camper from breaking camp and leaving his fire burning behind him.

All of these dangers have been reduced to a minimum. The necessities of the occasion demanded a remedy, and this has been found in a system of fire alarms, patrols and fire trains that probably surpasses anything of the kind in the world. Situated at a distance of a mile apart throughout the entire length of shed-guarded track are placed unlocked electrical call boxes similar to those in use in the cities. On the face of these are inscribed the words: "East—west—rock on track—shed down—train wreck—car off slide—fire." Besides these there are 34 fire alarm boxes, which are kept locked. These are used exclusively for fire. When an alarm is rung in on one of these a gong strikes the number of the box in Sacramento, 100 miles away, and at the different points where the fire trains are situated.

The forty miles of shed are constantly patroled by men selected for that purpose. Each man's beat is less than three miles long, and is so arranged that he passes over it a short time in advance of every train. The most important of all, however, are the duties performed by the fire trains, of which there are three. These trains consist of an engine and tender and two flat cars, upon which there are mounted immense boilers filled with water. These boilers are decked to afford room for the crew when at work on a fire. The regular crew consists of three men—the engineer, fireman and brakeman. But when an alarm is rung this is enhanced by picking up the nearest section gang. Of these fire trains one is stationed at Blue Canon, another at Summit, and a third at Truckee.

Whenever a patrolman discovers a fire in a shed he hurries to the nearest box and turns in the alarm. Instantly the number is sounded on a huge gong in Sacramento and at fire stations. The crew of the fire train nearest the point of danger spring to their places and await orders from Sacramento. At the latter place the train dispatcher seizes his key and sends his orders along the road to side-track all trains. A few minutes pass and the word comes flying over the wire that the last train is out of the way. The dispatcher then strikes the key again, and the fire train receives the word "track clear; box 28; go." The engineer seizes the throttle, the fire train moves out on the main track and starts for the scene where it is to do battle.

When the scene of a fire is reached the train is stationed as near as possible to the burning timbers, and the battle begins. The method pursued is the same as is used by the city fire departments. Two streams of water are thrown against the flames, and it is rare that the fire is not under control in less than twenty minutes. If the wind is against them the engineer must be careful not to let his train get too close, and the axe and pickaxe men who toss aside the burning timbers must look alive that the weakened sheds do not fall upon them. It has been a number of years since there has been a fire of any consequence in the sheds. The largest fire that ever occurred was in 1878, when 5,000 feet one mile west of the summit went up in smoke.

During the intervals between fires in the summer the trains are used in wetting down the sheds, so as to reduce as far as possible the chances of their being ignited by sparks from passing engines. For this purpose the fire trains are rigged with spray nozzles, which completely deluge the interior of the sheds as they steam slowly through them.—*San Francisco Chronicle.*

INDIA PAPER.

The marvelous Oxford India paper was first introduced in 1875. Since then it has revolutionized the Bible and prayer book trade, and it is now used for all the more popular devotional books throughout the world. In the year 1841 an Oxford graduate is said to have brought home from the far East a small fold of extremely thin paper, which was manifestly more opaque and tough for its substance than any paper then manufactured in Europe. He presented it to the Clarendon press. The late Thomas Combe, who had only recently been appointed printer to the university, found it to be just sufficient for 24 copies of the smallest Bible then in existence—diamond 24mo—and printed an edition of that number, which bore the date of 1842. The books were barely a third of the usual thickness, and, although as much as $100 apiece were offered for them, no copies were sold, and they were presented to the queen and other distinguished persons.

All efforts to trace the paper to its source were futile, and as years rolled on the circumstance was forgotten. But early in 1874 a copy fell into the hands of Arthur E. Miles, who showed it to Mr. Froude, and experiments were at once set on foot at the Oxford university paper mills with the object of producing a similar paper. The first attempts were failures, but success was achieved, and Aug. 24, 1875, an edition of diamond 12mo Bible, similar in all respects to the 24 copies printed in 1842, was placed on sale. This was the first Oxford Bible published by Mr. Froude. The feat of compression was looked upon as astounding, the demand was enormous, and before long 250,000 copies had been sold. The paper when subjected to severe rubbing, instead of breaking into holes, assumed a texture resembling chamois leather, and a strip only 3 inches wide was found able to support a quarter of a hundredweight without yielding. The secret of its manufacture, it may be said, is known to only three living persons.—*Book Review.*

THE ORDINARY EARTHWORM.

The common earthworm, despised by man and heedlessly trodden under foot, fulfils a part in nature that would seem incredible but for the facts revealed by the patient and long-continued researches of Darwin. "Worms," says Darwin, "have played a more important part in the history of the world than most persons would at first suppose." Let us follow Darwin and see how this apparently insignificant creature has changed the face of nature. We will first consider the habits and mode of life of the earthworm. As every one knows, the worms live in burrows in the superficial layer of the ground. They can live anywhere in a layer of earth, provided it retains moisture, dry air being fatal to them. They can, on the other hand, exist submerged in water for several months. They live chiefly in the superficial mould less than a foot below the surface, but in long continued dry weather and in very cold seasons they may burrow to a depth of eight feet. The burrows are lined by a thin layer of earth, voided by the worms, and end in small chambers in which they can turn round.

The burrows are formed partly by pushing away the earth, but chiefly by the earth being swallowed. Large quantities of earth are swallowed by the worms for the sake of the decomposing vegetable matter contained in it, on which they feed. The earth thus swallowed is voided in spiral heaps, forming the worm castings. In this case the worm obtains food and at the same time excavates its burrows.

In addition to the food thus obtained, half-decayed leaves are dragged into the burrows, mainly for food, but also to plug the mouths of the burrows for the sake of protection. Worms are also fond of meat, especially fat; they will also eat the dead bodies of their relatives. They are nocturnal in habit, remaining, as a rule, in the burrows during the day and coming out to feed at night.

The earthworm has no eyes, but is affected by strong light if exposed to it for some time. It has no sense of hearing, but is sensitive to the vibrations of sound. The whole body is sensitive to touch. There appears to be some sense of smell, but this is limited to certain articles of food, which are discovered by the worm when buried in earth, in preference to other bodies not relished. The worm appears to have some degree of intelligence from the way in which it draws the leaves into its burrows, always judging which is the best end to draw them in by. This is remarkable in so lowly organized an animal, being a degree of intelligence not possessed by many animals of more complex organization. For instance, the ant can often be seen dragging objects along traversely instead of taking them the easiest way.

As we have seen, vast quantities of earth are continually being passed through the bodies of worms and voided on the surface as castings. When it is stated that the number of worms in an acre of ordinary land suitable for them to live in is 53,000, we can imagine the great effect which they must have on the soil.

They are, in fact, continually ploughing the land. At one part of the alimentary canal of the worm is a gizzard, or hard muscular organ, capable of grinding food into fine particles; it is this gizzard which is the main factor in triturating the soil, and it is aided by small stones swallowed with the earth, which act as millstones.

In consequence of the immense amount of earth continually being brought to the surface by worms it is not difficult to understand how objects, such as stones, rocks, &c., lying on the surface, will in course of time become gradually buried in the ground. Owing to the burial of stones and other objects by the action of worms, ancient monuments, portions of Roman villas, and other objects of antiquity have been preserved. These have been gradually buried by the worms, and so preserved from the destructive effect of rain and wind. Many Roman remains were studied by Darwin, and traces of the action of worms found, to which action their preservation was mainly due. The sinking of the foundations of old buildings is due to the action of worms, and no building is safe from this unless the foundations are laid lower than the level at which the worms can work, namely, about eight feet below the surface.

Another useful effect produced by worms is the preparation of the soil for the growth of seedlings. By their agency the soil is periodically sifted and exposed to the air, and in this way is able to retain moisture and absorb soluble substances of use for the nutrition of plants.—*Knowledge.*

FIRING A BIG NAVAL GUN.

There will take place in a very short time a test which will mean much to the United States navy, and which will be watched with interest by armament and naval experts the world over. It will determine whether or not the firing of the 13-inch gun on the first of the United States' three battle ships, the Indiana, will or will not cripple that magnificent floating fortress. It is a matter regarding which few people are informed and which has, therefore, not attracted public attention.

During the forty-eight hour ocean run which she will take, and which will be the government's test of her capabilities, she will discharge the 13-inch guns with which she is equipped, this being the first time in the history of our government that so large a gun has ever been fired from a vessel.

Few people understand the seriousness of this feat. Let us first understand what a 13-inch gun is, and the Indiana, by the way, carries four of them in addition to a large number of weapons of smaller calibre. Each of the 13-inch guns on the Indiana is 39 feet 11½ inches in length—one-half inch less than 40 feet. Each weighs about 67 tons. Each fires a solid steel shot or shell 13 inches in diameter and about 4 feet in length. Each of these weighs 1,300 pounds, and is composed of a quality of steel that costs 23 cents a pound, making the valuation of each shot exactly $299. To fire this projectile, when in war action, requires the use of 500 pounds of powder, so that it will readily be seen that each discharge of the gun costs a pretty penny. With that amount of explosive force back of it the 13-inch gun will throw one of these steel messengers of death to a distance of about twelve miles. Imagine a projectile of that size—we are speaking now of solid shot—striking the side of a vessel, say, only two miles away. It would require a wonderfully perfect condition of armor to withstand the shock of the impact.

But the question of cost and the question of force do not involve the most serious aspect of the trial of the 13-inch gun which will take place in the near future.

Some time ago the English government experimented with a 13-inch gun on a ship of the Royal Sovereign class. At the first firing of the gun the entire upper deck was lifted from its position and sprung along its entire centre, so terrible was the shock. The Indiana has been specially equipped to provide against any such disaster, and her decks have been constructed in such a manner that naval experts agree that no such damage can befall her when the 13-inch guns send out their flaming messages. Naval experts are agreed, however, that when she is in action and the four 13-inch guns are performing their deadly work the explosions will shatter and destroy every piece of woodwork and glass in every portion of the vessel. That is expected and prepared for, and for that reason the battleship Indiana is composed almost entirely of iron and steel. She has been aptly described as an enormous floating steel fort with a ship built around it for purposes of navigation. Fully one-half of her could be shot away and she would still float and retain her unequalled fighting power.

But it is not Uncle Sam's wish that this grand marine monster should have her exterior furnishings wrecked before there is any necessity for it, and therefore the officers who will have charge of the approaching test, instead of placing a charge of 500 pounds of powder behind one of the 1,300-pound projectiles, will use only 300 to 350 pounds, and thus it is hoped that while they will satisfy themselves as to the working of the gun they will not wreck the interior woodwork of the vessel.—*Philadelphia Times.*

THE BRONCHO.

A few words about this horse, the horse of the plains. Whether or no his forefathers looked on when Montezuma fell, they certainly hailed from Spain. And whether it was missionaries or thieves who carried them northward from Mexico, until the Sioux heard of the new animal, certain it also is that this pony ran wild for a century or two, either alone or with various red-skinned owners; and as he gathered the sundry experiences of war and peace, of being stolen, and of being abandoned in the snow at inconvenient distances from home, of being ridden by two women and a baby at once, and of being eaten by a bear, his wide range of contretemps brought him a wit sharper than a street Arab's, and an attitude toward life more blase than in the united capitals of Europe. I have frequently caught him watching me with an eye of such sardonic depreciation that I felt it quite vain to attempt any hiding from him of my incompetence; and as for surprising him, a locomotive cannot do it, for I have tried this. He relishes putting a man in absurd positions, and will wait many days in patience to accomplish this uncharitable thing; and when he cannot bring a man to derision, he contents himself with a steer or a buffalo, helping the man to rope and throw these animals with an ingenuity surpassing any circus, to my thinking. A number of delighted passengers on the Kansas Pacific railway passed by a Mexican vaquero who had been sent out from Kansas City to rope a buffalo as an advertisement for the stock-yards. The train stopped to take a look at the solitary horseman fast to a buffalo in the midst of the plains. Jose, who had his bull safely roped, shouted to ask if they had water on the train. "We'll bring you some," said they. "Oh, I come get," said he; and jumping off, he left his accomplished pony in sole charge of the buffalo. Whenever the huge beast struggled for freedom, the clever pony stiffened his legs and leaned back as in a tug of war, by jumps and dodges so anticipating each move of the enemy that escape was entirely hopeless. The boy got his drink, and his employer sent out a car for the buffalo, which was taken in triumph into Kansas City behind the passenger train. The Mexican narrated the exploit to his employer thus: "Oh, Shirley, when the train start they all give three greata bigga cheers for me, and then they give three mucha bigger cheers for the little gray hoss!"—*From "The Evolution of the Cow-Puncher," by Owen Wister, in Harper's Magazine.*

DOCTORS IN CHINA.

The life of a medical missionary in China is filled with difficulties, any one of which may become a source of positive danger at any time.

In the making of a diagnosis many perils lurk. The fever thermometer, the tongue depressor or the stethoscope may be remembered as an evil implement in the hands of the foreigner, calling down upon the patient a bad spirit, if he should happen to die even at some far distant time, while the use of more complicated instruments in examining the throat, nose or eye is advisable only in selected cases.

In prescribing medicines not only is the fear of a future accusation of poisoning ever present, but the possibility that it may prove to be a reality. Thus a bottle of liniment curing the venerable grandmother of rheumatism may be lent to a neighbor stricken with small pox as an infallible remedy, or the entire contents of a vial of toothache medicine be administered in one dose to a teething infant. And, without exception, the heathen Celestials reason that if a small portion of medicine is of any benefit, the whole bottleful, taken at once, multiplies its usefulness in a corresponding ratio. Therefore, if not previously warned, experience soon teaches the missionary to make it an infallible rule never to dispense a poisonous remedy or one which could do harm if the entire quantity were taken at once.

When it is absolutely necessary to administer a powerful remedy several times or for several days in succession, the doctor puts each dose up in a separate vial, powder or capsule, and, leaving them at the dispensary with a trained American nurse or other foreign helper, directs that a servant or child of the patient be sent there for one every three hours, or three times a day, as the case may require; otherwise it would all be taken at once or divided among ailing neighbors.

The complications and responsibilities usually attendant upon grave operations are, in China, multiplied a thousand-fold. An operation must never be done in private, but in a room where it is possible for the natives to observe the mysterious rites from outside posts of observation. It is possible that they may take alarm at any stage of the proceedings, to be appeased only with great difficulty, and the death of the patient may be followed by an open revolt. On the contrary, if the operation is successful, people afflicted with all sorts of irremedial surgical ailments in nowise resembling the preceding one are brought to the little hospital with the demand that they also be relieved.

Against the administration of an anæsthetic there is the greatest prejudice, the condition of temporary unconsciousness produced by it being beyond Chinese comprehension. In the majority of cases, however, it is easily dispensed with, the stoicism or the insensibility to pain of the average Chinese being remarkable. He or she will open the mouth and submit to having every tooth extracted without a grimace or a groan.

The dread of smallpox and cholera displayed by foreigners fills the Celestial mind with surprise, and any show of absolute fear, with the utmost contempt. "Why be afraid of smallpox," they ask, "when thousands of Chinamen die from it every year? We know there is nothing to fear from it." In these cases the forlorn hope of the Chinese leech is the famous red pills, globules of the bigness of a pin's head, whose composition is secret and whose curative properties are in Chinese eyes unequaled.

During an epidemic of either of these contagious diseases patients so afflicted are daily brought to the hospital, asking for admission, but the reasons for their rejection fall upon uncomprehending and dissatisfied minds. It is utterly impossible to establish any form of quarantine, or to prevent members of the affected families from going wherever they desire, while the physician has great reason to congratulate herself if she succeeds in excluding them from visiting the dispensary and hospital wards.—*Philadelphia Times.*

ENGINEERING BY A MOUSE.

"While digging holes for telegraph poles at Byron, Me.," said a Western Union man, "I became interested in watching the ingenuity and perseverance of a mouse. He fell into one of the holes, which was 4½ feet deep and 20 inches across. The first day he ran around the bottom of the hole, trying to find some means of escape, but could not climb out. The second day he settled down to business. He began steadily and systematically to dig a spiral groove round and round the inner surface of the hole with a uniformly ascending grade. He worked night and day, and as he got further from the bottom he dug little pockets where he could either lie or sit and rest. Interested witnesses threw in food.

"At the end of two weeks the mouse struck a rock. This puzzled him. For nearly a day he tried to get under, around or over the obstruction, but without success. With unflinching patience he reversed his spiral and went on tunneling his way in the opposite direction. At the end of four weeks he reached the top and probably sped away to enjoy his well-earned freedom. His escape was not seen. When his food was put in in the morning, he was near the surface, but at night the work was seen to be complete, and the little engineer, whose pluck and skill had saved his life, had left."—*New York Sun.*

HOW THE GOVERNMENT BORROWS MONEY.

The announcement recently made that for thirty days the Secretary of the Treasury would receive bids for United States bonds means that our government proposes to borrow money. The amount named is one hundred million dollars.

In general, it may be said that a nation, like a railway or other corporation, borrows money by selling its written promises to pay. Indebtedness may be contracted in the ordinary course of affairs when services or commodities obtained by the government are not paid for at once. Such liabilities are called a "floating debt." But the contraction of this sort of indebtedness could hardly be called borrowing.

In the case of voluntary loans, now by far the commonest way in which a nation borrows, the debtor government usually pays interest to its creditors at a fixed rate on the par value of its paper. On some of its obligations, however, which are redeemable on demand, our own government pays no interest at all. Such, for example, are the United States notes, commonly called "greenbacks," which circulate as money, and are legal tender in payment of debts. Not many years ago the greenbacks were not redeemable on demand, and their legal tender quality, therefore, gave them the nature of an involuntary or "forced" loan.

On bonds, such as those now about to be issued, the government promises to pay interest until it redeems them. It also names a certain term of years which must elapse before it will even have the right to redeem them; that is to pay off the principal of the debt now incurred. The rate of interest and the number of years the bonds are to run may usually vary widely; but at present our laws permit only three kinds of bonds to be issued, viz., those running ten years with interest at 5 per cent., those running fifteen years with interest at four and one-half per cent., and those running thirty years with interest at four per cent. This issue is to be of the last-named class.

How to place the bonds on the market is a question which the President and the Secretary of the Treasury are called on to decide. There are several ways. A private contract may be made with a syndicate or group of capitalists, without any public advertisement of the issue. An advantage claimed for this method is that conditions such as the government desires to impose, but which are not described in the bonds themselves, may be prescribed in the contract.

Another plan is to employ a syndicate, or perhaps a single great banking house, as the agent of the government in floating the loan. A fixed commission is paid to the agent, who can employ, in selling the bonds, business machinery which the government may not possess, and so secure better terms. This method is frequently employed when it is desirable to dispose of the loan abroad. It was largely resorted to when we were borrowing the money needed for prosecuting the Civil War.

The government may, however, dispense entirely with the use of agents, and deal directly with the entire mass of purchasers, as in the present case. Offers are received from anybody, and in large or small amounts. This is a "popular" loan. The term may also properly be applied even to a loan contracted through an agency, provided there is an opportunity for all who so desire to invest money in the bonds.—*Youth's Companion.*

DWARFS IN THE PYRENEES.

There has long dwelt in the heart of the Pyrenees, on the old Catalonian border of Spain, a curious race of dwarfs, supposed by some to be of Tartar origin. A writer in a recent issue of *Cosmos* describes them and advances a theory of their origin in consonance with modern anthropology.

They inhabit the valley of the Ribas in the northwestern part of the Spanish province now called Gerona. They never exceed 51¼ inches in height and have short, ill-formed legs, great bellies, small eyes, flat noses, and pale, unwholesome complexions. They are usually stupid, often to the verge of idiocy, and much subject to goitre and scrofulous affections. The chief town of the Ribas Valley is Ribas, a place of 1,500 inhabitants, about 800 feet above sea level. The mountains rise about the town to a height of 6,000 to 8,000 feet, and command an amazingly beautiful panorama of mountain, plain, and river, with Spanish cities visible upon the one side and French upon the other. The region is rich, both agriculturally and minerally, and is famous for its medicinal springs. In this paradise dwell the dwarfs, perhaps as degraded a race of men and women as may be found in any civilized community. They are almost without education, and inhabit wretched huts when they have any shelter. The most intelligent are employed as shepherds, and in summer they live for months at an elevation of more than 6,000 feet without shelter. Here they see no human creature save some of their own kind, often idiots, who are sent up every fifteen or twenty days with a supply of food.

It is said that formal marriage is almost unknown among them. The women in some instances are employed in the village of Ribas as nurses for children, and as such are found tender and faithful. Before communication throughout the region was as easy as it is now it was thought lucky to have one of these dwarfs in a family, and the dwarfs were hired out and even sold to be used in beggary in neighboring cities. There are somewhat similar dwarfs in other valleys of the Pyrenees, but the number is decreasing, and those of the Ribas Valley are reduced to a few individuals.

The writer of the *Cosmos* article rejects the theory of a Chinese origin for the dwarfs, and believes that they are merely the degenerate descendants of the ordinary natives, ill-nourished for generations upon a diet of potatoes and black bread. The fact that with improved means of communication the dwarfs are decreasing helps to confirm the writer's theory, and he believes that with proper nourishment and decent shelter their descendants would gradually return to the normal type. Meanwhile the neighbors of the dwarfs look upon them with a curious mixture of feelings. The fact that the dwarfs drink much at a particular mineral spring has given rise to a superstition that whoever drinks of it will become deformed, and the normal natives are horrified to see visitors experimenting with the dreaded waters. There is reason to believe that the waters of the spring are beneficial to the stomachs of well nourished persons, but injurious to those who are accustomed to an unwholesome diet, and it is entirely possible that the ill-fed dwarfs have been injured by drinking of the spring.—*New York Sun.*

ODD PRODUCTS OF UTAH'S MINES.

Utah, the newest of the states, seems to be a mineralogical freak. Mr. George Eldridge, of the Geological Survey, was sent out there a few weeks ago for the purpose of looking up certain natural resources, and he has returned with a most interesting report. Among other things he found great deposits of mineral rubber—enough to make gum shoes for a large part of the population of the United States. A piece of this substance about eight inches square and one inch thick was lying on his desk. It was black, and looked and felt exactly like ordinary rubber, and was quite elastic. The scientific name for this substance is "elaterite." It may, in the future be put to many valuable uses, and for a roofing material has already proved excellent.

In the mining towns of Utah mineral rubber is utilized commonly for roofing, being prepared in sheets consisting of a layer of burlap, with the rubber on both sides. Nothing could be more thoroughly waterproof.

Another unexplored mineral and one about which very little is known, is mineral wax, or as it is scientifically known "ozokerite." In parts of Utah it is found in veins, like the mineral rubber, though sometimes the ozokerite occurs in pockets between layers of shale. It has not been mined at all but many uses for it are likely to be discovered in the future. To electricians it will be valuable, inasmuch as it is one of the best insulating materials known.

Gum asphalt represents a great mineral resource that has hardly been touched as yet as it has only been mined to a small extent. It is an exceedingly pure kind of asphalt, and its important usefulness is in the manufacture of varnishes. The conditions under which it is found are so extraordinary that nobody has been able to account for them satisfactorily. The deposits are found chiefly within and in the neighborhood of the Uncompahgre reservation. It appears in veins having a tendency to run parallel to each other with a trend from northwest to southeast. These veins vary in width from a quarter of an inch to eighteen feet and they are from half a mile to six miles in length. Nobody knows how deep they are. It is believed that they extend to a depth of at least 1,000 feet, so that the quantity of material obtainable is enormous. The greatest depth thus far reached is 125 feet. Mining for the stuff has hardly got beyond the prospecting stage. The veins are perfectly vertical. For a few feet from the surface the substance is more or less impure, owing to weathering, but lower down it is entirely free from impurities. Digging for it is the hardest work imaginable, owing chiefly to the dust. The atmosphere of the shafts becomes literally loaded with asphalt dust, which is highly explosive. The body heat melts it so that it forms a brown coat all over a person exposed to it. Soap and water are no good for washing it off. The only thing that will remove it is kerosene. A tank of kerosene is kept handy, so that everybody who comes out of the mines may take a bath.—*St. Louis Globe-Democrat.*

EXPERT LONDON DRIVERS.

The majority of the streets of London, at least those on which the principal traffic of the city proper centres, are narrow, and the navigating of the 'buses along these highways, which are always crowded to distraction with every description of vehicle, large and small, is a feat in driving which would turn the hair of a Broad street 'bus driver gray in a day and drive him crazy in a week. But his London prototype does not lose any sleep of nights worrying about it. To him the safe conduct of his 'bus along his route is work of the most ordinary kind.

It is generally acknowledged that these 'bus men, who undergo a course of long years of most careful training, are, when put to it, the finest drivers in the world, but, at the same time, their every-day task is made comparatively easy for them by the punctilious observance of the rules of the road, practiced by every Englishman who drives in London, be he lord or commoner.

There is never the slightest trouble caused by the misunderstanding of these rules by an ignorant driver; the most ordinary costermonger who drives his little donkey cart in the crowded section of the city is perfectly familiar with them, and never evinces the slightest inclination to rebel against their dictates by not pulling up out of the way when a coach or four-in-hand signals its intention to drive by.

The first time an American mounts the steep steps at the back of a 'bus and takes a seat on the roof for a ride along Fleet street or the Strand, or a trip down Cheapside, his attention is riveted for the greatest part of the journey and his breath frequently taken away in watching the manœuvres of the 'bus driver.

The way these men keep their horses under control and steer their clumsy vehicles in and out of the constant crush of wagons and all manner of vehicles is exciting and wonderful. Look ahead of you and the street seems packed, with only a small opening, which to the eye of the uninitiated appears scarcely wide enough for a 'bus to go through, and yet the driver goes ahead unhesitatingly, and, presto, change, in a minute you are through the crush, and have never even scraped the wheels of the wagons on either side of you.

If, however, one of these wagons had suddenly turned into the narrow passageway through which you have passed, the driver bent on getting out before the 'bus, there would have been a crash and a smashup, an accident which very likely would happen under similar circumstances a dozen times in a day in an American city. But between the drivers of the wagons and the 'bus drivers, and all other drivers in London, perfect confidence exists, the 'bus driver, knowing that he has the right of way, going ahead without fear, while the driver of the cart or wagon, being fully aware that he must stand aside so that the lumbering public conveyance can go through, does so without a murmur of discontent at the few minutes of lost time which he is bound to suffer.—*From the Philadelphia Times.*

FATIGUE.

Fatigue is the natural result of labor, and as such is a periodic symptom with which every healthy person is familiar.

It is one of the laws of organic life that periods of relaxation shall succeed periods of activity. The heart itself is normally in repose for about one-third of the time consumed by each beat—a fact in which there is something particularly suggestive and interesting, since physiologists agree that about one-third of the twenty-four hours should be devoted to sleep.

Life is made up of series of vibrations in which tension and rest succeed each other. The heart vibrates about seventy times a minute; the vibrations of the respiratory organs occur about sixteen times in the same period; while the vibrations of the whole organism may be said to complete their cycle once in twenty-four hours.

Abnormal fatigue, a state approaching exhaustion, occurs when one attempts to alter nature's rhythm; when the hours of tension are made to encroach upon those which should be devoted to rest; when muscle and nerve already fatigued are driven to further exertion.

Fatigue of a kind known as overtraining results, in the case of the athlete, in heart-weakness and shortness of breath—"loss of wind," as it is called; while the long-continued fatigue occasioned by excessive application to professional or business pursuits results in nervous prostration, or even in paralysis.

While excessive fatigue is in itself unwise, one of the chief dangers which result from it is that commonly indicated by the term "catching cold." Thus the danger of sitting in a draft or on the damp ground is many times doubled after great exertion. The application of heat to the surface is a more logical procedure after extreme fatigue.

Loss of sleep is one of the first symptoms of abnormal fatigue. Habitual insomnia from this cause is to be treated only in one way, by absolute rest.—*Youth's Companion.*

A MYSTERIOUS CRATER.

About forty miles from Flagstaff, Arizona, in the midst of a great plain, there is a saucer-shaped hollow about three-quarters of a mile across and six hundred feet deep. The rim of this strange crater rises between one hundred and fifty and two hundred feet above the surrounding plain. Rocky fragments are scattered for several miles around the crater, decreasing in number until they disappear. Among these rocks many fragments of meteoric iron, some containing minute black diamonds, have been found. The inner walls show that the crust of the earth was broken when the crater was formed; yet no volcanic rocks exist there. Geologists have recently proposed several theories to account for this singular phenomenon. One theory is that an immense meteorite made the hole, and that the meteoric fragments just mentioned are remnants of the falling star. Another theory ascribes the origin of the crater to a tremendous explosion of steam in the rocks beneath; and a third combines the first two by suggesting that the blow of a falling meteor, striking the earth's crust at a point where subterranean water had accumulated in the neighborhood of heated rocks, was the cause of the explosion.—*Youth's Companion.*

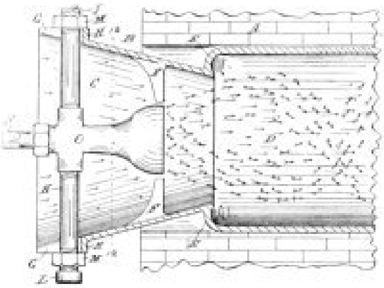
The Telegrapher's Ear.

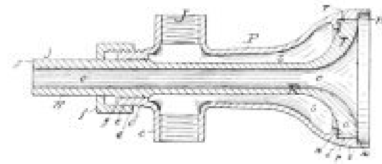
Any operator who is accustomed to work by sound with men every day can tell in an instant just who is working the key. There is something peculiar in the way each operator opens and closes his key. Of course it is entirely a matter of education of the ear. Another evidence of the susceptibility of the aural nerves to education is the fact that an operator can receive and copy a message and at the same time distinctly hear and comprehend everything that is being said by others in the room. He can be very busily engaged at anything, and yet his ear will take in everything that is said near him. Another peculiar thing is the fact that a telegrapher working at night will lay his head within two inches of a working instrument and sleep as soundly as though in bed. He will not be disturbed in the least until his own office call is sounded by the instrument. That will awaken him in an instant. Of course each sound is exactly of the same degree of intensity, and it is only the training of the ear that causes him to distinguish his office call when even asleep.—*Philadelphia Times.*

NEW INVENTIONS.

STEAM BLOWER.

No. 551,927. William A. Eudaly, Cincinnati, Ohio. *Patented Dec. 24th, 1895.*—Fig. 1 is a vertical section of the apparatus; and Fig. 2 is a lengthways section of the steam jet. The steam enters through the pipe *J*, and passes into the space between the shell *P*, and the central tube *R*. This tube has a flange, or head, *T*, at the front end, which is seated, steam tight, upon the shoulder *n* of the shell *P*. The escape





of steam from the chamber *S*, is controlled by screwing the tube *R* forward or back by means of a wrench applied to the shank *j*. The steam jets are made by grooves *r*, which are cut in the rim of the head *T*. These grooves taper in depth as shown, being almost nothing at the front edge. The volume of steam which may be delivered by each jet, may be varied, without changing the pressure, by moving the head *T* forward beyond the shoulder *n*, of the shell, thus increasing the depth of each opening at the point of discharge. Should any dirt lodge in a jet and clog it, it may be blown out by advancing the head *T* still farther forward; this may be done without stopping the blower.

AUTOMATIC COAL BIN.

No. 553,075. Charles S. C. Rock, New York, N. Y. *Patented Jan. 14th, 1896.* Fig. 1 shows the position of the parts before and after the bucket has been filled, and Fig. 2 shows the mode of filling the bucket. This device is designed for the use of tenants in "flats" and tenement houses, where the coal is kept in the cellar or basement. Each floor or tenant

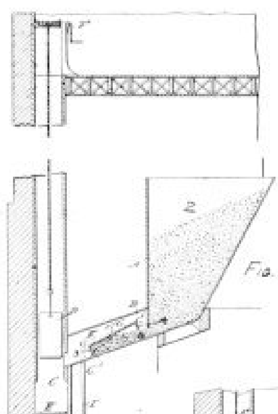


Fig. 1

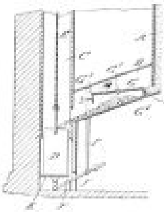

Fig. 2

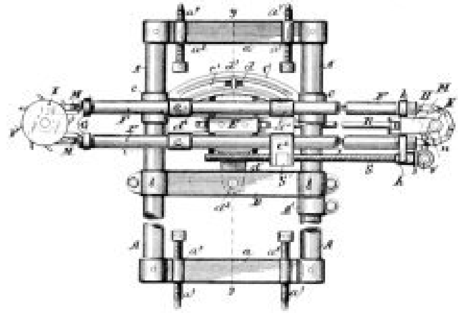
is provided with a hoisting apparatus and bucket, which takes coal from a certain compartment of a general coal bin 2. Each chute is provided with a rocking frame *G*, which has a gate at each end. When the bucket descends upon the balanced platform *K*, the gates are moved into the position shown in Fig. 2 by means of the lever *J*, rod *I*, and arm *H*. As the gate 3 rises, the gate 4 descends and stops the flow of coal from the bin. When the bucket is lifted off the platform, the gates are reversed as shown in Fig. 1. The quantity of coal that may pass into the bucket is thus measured, at each filling, and is limited to the amount which is caught between the gates 3 and 4.

COAL GROOVING MACHINE.

No. 551,140. Edward S. McKinlay, Denver, Colo. *Patented Dec. 10th, 1895.* Fig. 1 is a side view of the machine, and Fig. 2 is a top view of the same. The machine is designed to cut vertical grooves in the coal, along the side walls or "ribs" of a room. The cutting is performed by a pair of wheels *I*, which are armed with cutters, as shown. They are revolved by means of a sprocket wheel *g*, and a chain *M*,



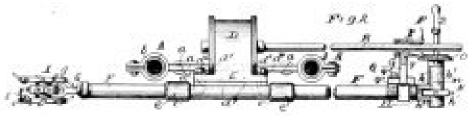


Fig. 2.

which is driven by a sprocket wheel *N*, at the rear end of the frame. The chain runs through the tubular frame bars *F*, and is well protected. Power is applied by means of the rotary engine *D*, square shaft *R*, and bevel gears *P* and *O*, to the rear sprocket wheel *N*. The frame is fed forward by the screw *S*, nut *S'*, gears *s* and *g'*, and handle 2. It slides through bearings *e*, which project from the saddle *E*. The saddle is supported by a pin *d'*, upon the lower bar *B*, and is clamped to the curved top bar *C*, by an adjusting bolt *d*. By slacking off this bolt, the cutter frame may be swung up or down, as desired. The bars *B* and *C*, may be secured at any height upon the posts *A*, by means of the clamp collar *A'*.

MINING MACHINE.

No. 550,283. Edmund C. Morgan, Chicago, Ill. *Patented Nov. 26th, 1895.* Fig. 1 is a side view of the machine, and Fig. 2 is a top view of the same. Fig. 3 is a front end view of the steadying device.

The cutter chain is guided by two sprocket wheels 44, 45, between the plates 42 and 43, in the usual manner, and is driven by means of the sprocket wheel 46, at the rear. The electric motor which supplies the motive power is constructed with a vertical spindle 11, having a pinion which meshes with the gear 13, thus driving the sprocket 46 by spur gears, instead of the bevel gearing usually employed. The frame 9, which carries the motor and working parts, slides upon the

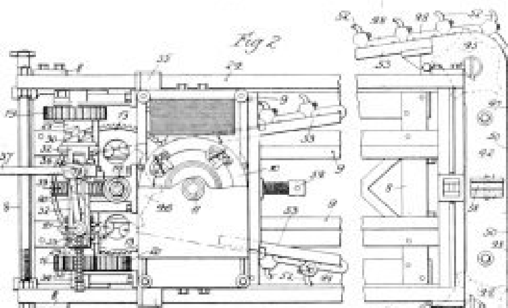

Fig 2

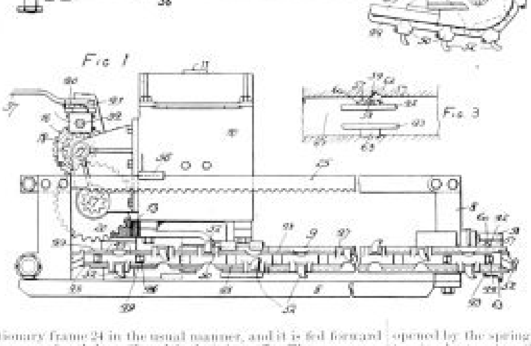

Fig 1

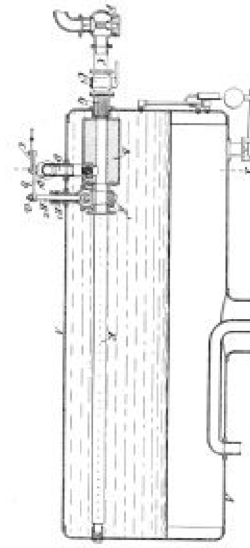
Fig. 3

stationary frame 24 in the usual manner, and it is fed forward by means of rack bars 25 and feed pinions 27. These are connected by suitable gearing to two clutches 28 and 29, on the shaft 17, which is rotated by the worm wheel 30 and a worm on the spindle 14. The clutches 30, 33 revolve with the shaft 17, and when coupled to 28, by means of the lever 37, produce a slow forward feed motion. When 29 and 33 are coupled they produce a rapid backward feed motion. The cutter head frame 42 is held steady against all side strains by means of a guide cutter 58, 59. As shown in Fig. 3, the cutting blade is inclined, so as to cut a V groove in the underside of the hanging coal. By this device the cutter is enabled to produce a guide groove which is smooth and solid upon the side on which the pressure is exerted, the splintering of the coal being confined to the off side of the cutter.

METHOD OF GENERATING STEAM.

No. 550,831. John H. Laird, London, England. *Patented Dec. 3rd, 1895.* In this device, the fuel is burned in contact with the water, and the entire amount of the heat developed by combustion is imparted to the water. The fuel, which may be oil vapor or spray, or any variety of combustible gas, is mixed with a sufficient volume of air to properly burn it, and is forced by suitable pumps through the valve *F* and

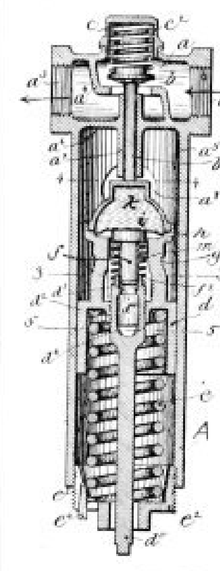


cock *C*, into a firing tube *B*. The hot products of combustion pass through the cock *E'*, into the perforated tube *E*, and escape into the surrounding water. The gas quickly cools to the temperature of the water, and rising through it in streams of bubbles, mingles with the steam. Thus there can be no waste of heat, as the entire operation of combustion and cooling is performed within the boiler.

The gas is ignited, at the start, by closing the cock *E'*, and opening another cock *D*, to the atmosphere, and holding a torch at the orifice *D'*. The lever *C* is connected so as to operate both cocks simultaneously. As soon as they are reversed, the fire passes into the tube *E*, and the generation of steam begins. *G* is a bundle of rods which act as a safety check to prevent fire from passing back into the supply pipe.

REDUCING VALVE AND STEAM TRAP.

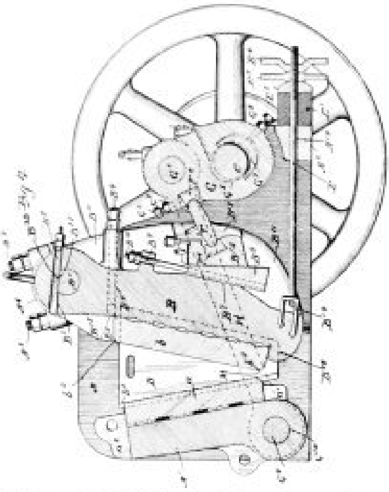
No. 551,778. William B. Mason, Boston, Mass. *Patented Dec. 24th, 1895.* The supply pipe is attached at a^2, and the steam passes through the valve *h*, in the direction shown by the arrows. The steam is throttled, and its pressure reduced



to any extent, as desired, by passing through the valve. The entering steam tends to force the valve to its seat, and the spring c^1 operates in the same manner. The valve is opened by the spring *c*, which may be adjusted to any desired tension by turning the screw plug c^2. The condensed water from the heating apparatus to which this valve is attached, enters the casing at a^6, and collects in the space above the piston *d*. This piston is fitted to move freely within the casing, and is not packed except by the water. The escape of the water is governed by a plug valve *f*, which is attached to the flexible plate *i*, forming the bottom of the cell or cup *k*. This cup is filled with naphtha, which is very sensitive to changes in temperature. When the case is filled with steam, the naphtha expands and shuts the valve *f*, but when the cup is surrounded with water, it contracts and lifts the valve. The opening of the valve may be adjusted by turning the screw $d^1 d^2$. The drip or waste pipe is connected in any suitable manner to the lower end of the case *A*.

ORE CRUSHER.

No. 551,304. Charles L. Carman, Chicago, Ill. *Patented Dec. 10th, 1895.* The movable jaw *B*, swings on a pin B^1, and is held back against the toggle links by the rod *E*, and spring E^1. The front jaw is not movable. Motion is given to the parts by the eccentric *C*, on the main shaft. The upper end

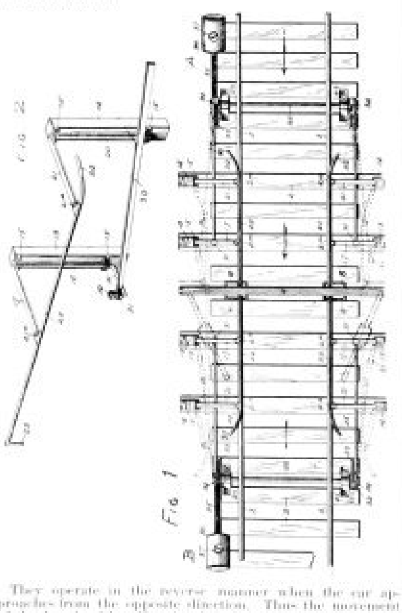


of the pitman *G*, is held by the pin G^1, and heavy side links *H*, which are shown in dotted lines. The pin G^1 thus has an up and down movement, and the bearing block F^2, which drives the toggle bar *F*, has a compound movement. It follows the pin G^1, up and down, and swings to and fro around the pin G^1, and is moved back and forth by the lateral motion of the eccentric. The motion which is imparted to the crushing jaw by this peculiar mechanism, is claimed to be so graduated that it is very efficacious for crushing tough ores.

MINE DOOR.

No. 551,786. Levi S. Minerd, Minden Mines, Missouri. *Patented Dec. 24th, 1895.* Fig. 1 is a top view of a pair of doors with all of the apparatus in place; and Fig. 2 is a perspective of the actuating bar and its supports.

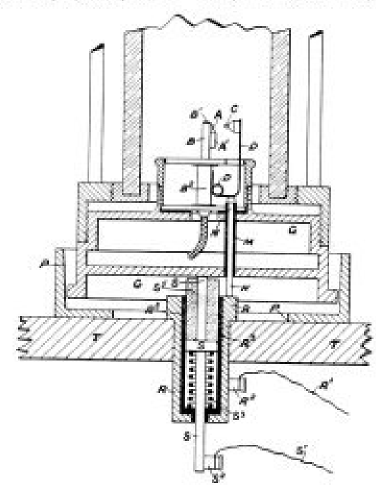
The doors are made in pairs, and are hinged to suitable frames or casings, at their outer edges. Each door is provided with operating bars, 22, there being one on each side. These bars are attached loosely to the doors by means of hooks 23, Fig. 2, which engage with long staples 8 upon each face of the doors. They are supported at a proper height by swinging arms or cranes 17 and 21, which are attached to posts 13 and 14. The doors are held shut by means of balance weights 36, upon the arms 35 of rockshafts 26, which are connected by pitmen rods 30, to short arms 18, at the foot of the cranes 17. Each weight pulls against the other, and they hold the doors firmly at the middle position, tightly closed. When a car approaches, as in the direction of the arrows, it strikes the bars 22, and pushes them forward and outward, as shown by the dotted lines. The weight at *A* is lifted, but that at *B* remains stationary, the pitman being slotted to permit the backward motion.



They operate in the reverse manner when the car approaches from the opposite direction. Thus the movement of the door in either direction is resisted by the full power of one of the weights, except for an inch or so at the middle position, when the weights pull against each other. These doors will yield to extra pressure from shots or explosions, and will promptly close, and maintain the air currents in a proper manner.

LIGHTING SAFETY LAMPS.

No. 550,309. William Ackroyd and William Best, Birkenshaw, England. *Patented Nov. 26th, 1895.* This device is designed for lighting safety lamps in places where explosive gas is present in dangerous quantities, by means of electricity, and without opening them. A carbon block *A* is fastened to the side of the wick tube *B*. A movable carbon *C* is held by a spring *D*, which is attached to a collar B^1, and is properly insulated from the wick tube. A conducting rod *N*, properly insulated by a covering *M*, passes down through the oil chamber *G*, and rests upon the brass cylinder *R*. Another conducting rod *S* touches the bottom of the oil chamber and is held up by the spring S^1. The cylinder *R* and rod *S* are

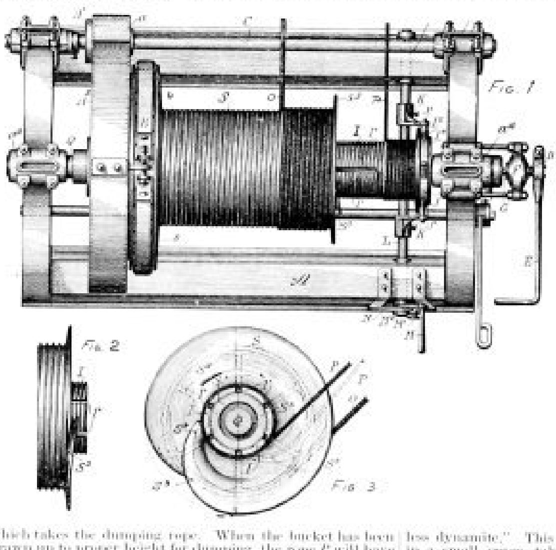


connected to the accumulator or dynamo, by the wires R^1, S^1. When it is desired to light a lamp, it is set down inside the ring *P*. The rod *N* strikes *R* and slides upward, thus bending the spring *D*, and bringing the carbons *A* and *C* together. As the current passes, the end of the wick is quickly warmed. The lamp is then lifted up, and as the carbons separate, the circuit is broken. The flash which occurs at the breaking of the circuit ignites the wick. As the carbons do not project above the top of the wick tube, they do not obstruct the light.

HOISTING AND DUMPING DRUM.

No. 552,513. Charles L. Carman, Chicago, Ill. *Patented Jan. 7th., 1896.* Fig. 1 is a top view of the entire drum and its attachments; Fig. 2 shows a part of the main drum; and Fig. 3 is an end view of the same.

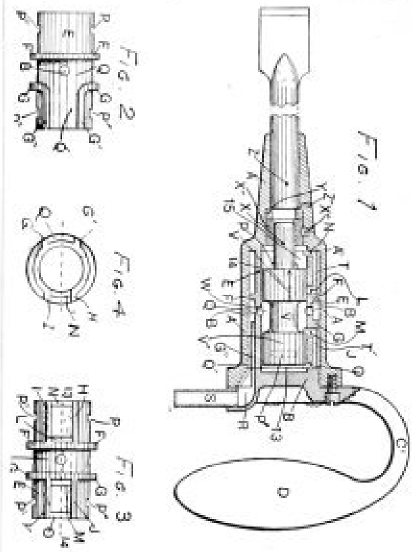
This apparatus is designed for hoisting coal, ores, etc., with a bucket which is to be dumped automatically at a certain point, in each lift. The bucket is hoisted with a "double fall" by the rope *O*, and the dumping is effected by the rope *P*. As the hoisting rope moves twice as fast as the bucket, the main drum *S*, is made twice the diameter of the drum *I*,



which takes the dumping rope. When the bucket has been drawn up to proper height for dumping, the rope *P* will have filled the small drum, and it will then run close to the end of the main drum. As the drums revolve, the rope will mount up the spiral guide S^3, and will wind onto the main drum, thus doubling its speed. The quicker motion thus given to the dumping rope, causes it to pull up much faster than the bucket raises, and enables it to release the catches or other dumping apparatus. The point at which the bucket will be dumped can be adjusted by sliding the small drum within the large one, by means of the collar *J*, arms *K*, rock shaft *L*, and lever *M*. The main drum is driven by a friction clutch in the usual manner.

PNEUMATIC HAND DRILL.

No. 551,687. William B. Murray, Chicago, Ills. *Patented Dec. 17th, 1895.* Fig. 1 is a lengthways section of the machine; Fig. 2 is a view of the under side of the cylinder; Fig. 3 is the top side of the same; and Fig. 4 is an end view. The machine is held up to its work by the handle *D*. The cutter or drill stem *Z*, is hammered upon the inner end, by the piston rod *X*, which is attached to the double piston *V*. The outer shell or casing *A*, is forged in one piece, and the liner or cylinder *E*, is also forged of steel. The exterior surface of the cylinder is formed with grooves and ridges, which serve to enclose passages for the compressed air, between the cylinder proper and the outer shell *A*. Compressed air is admitted through the pipe *S*, and holes *R* to the space between the pistons. The parts being in the position shown, the air will pass through the ports *M* and *O*, to the back end of the



piston. The piston will fly forward and strike the drill bar *Z*, and in so doing, will close the exhaust port P, and inlet port M_1, and will open the exhaust port P^1, and inlet port *L*. The air then passes to the front end of the cylinder and moves the piston back to the position shown. The blows follow each other with great rapidity, thus enabling the drill to cut continuously, as long as the machine is pressed up to the work. The handle bow *C* is elastic, and absorbs most of the shocks.

BLASTING CARTRIDGE.

No. 551,900. Paul A. Oliver, Olivers Mills, Penna. *Patented Dec. 17th, 1895.* It is claimed that this cartridge enables blasting to be performed in the presence of inflammable gas without igniting it.

The drawing shows a longitudinal section through a cartridge and its cap or primer, constructed according to this invention.

A is an outer inclosing cartridge case of any approved material. This case is filled with a flameless explosive compound *B*, preferably the kind commercially known as "flameless dynamite." This flameless explosive compound packs in a small space, takes up less room than ordinary black blasting powder, is a high explosive, and is set off by means of a cap or primer. This flameless explosive compound when exploded, will not ignite the gas in a coal mine, or air mixed with fire-damp or coal dust; but as it requires a powerful cap to set it off, it also becomes necessary that the cap itself should produce no flame; as otherwise the flame of the cap bursting through the blasting charge would ignite the gas in the mine.

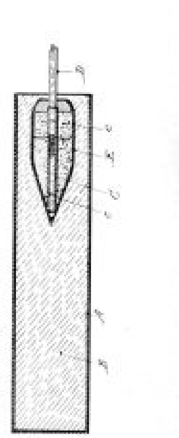
C is a metallic cap containing any approved detonating compound or fulminate, such as the fulminate of mercury *c*.

D is a fuse inserted in the end of the cap *C*. This fuse is preferably an electric fuse consisting of two insulated wires.

E is a case secured to the cap *C* and surrounding it, and *e* is a flame-extinguishing substance in the form of a dry powder, such as borax and bicarbonate of soda or alum and borax, contained in the case *E*, surrounding the cap, and interposed between the cap and the flameless explosive compound *B*.

The front end of the case *E* is preferably pointed to enable it to be thrust into the compound *B*, but it is not necessarily pointed, as the case may be packed in with the flameless explosive compound in a bore-hole, or it may be placed upon a rock and covered with the flameless explosive compound, and an outer layer of clay.

The ends of the case *E* and the cap *C* are plugged up in any approved manner, such as, for instance, with melted sulphur.



The Colliery Engineer

AND

METAL MINER.

VOL. XVI.—NO. 9. SCRANTON, PA., APRIL, 1896. With Which is Combined THE MINING HERALD.

PROSPECTING FOR GOLD.

THE PLACERS OF NORTH AMERICA.

The Location of Placer Deposits in Different Parts of North America and a Description of Their Peculiarities and the Methods by Which They Are Worked.

Written for THE COLLIERY ENGINEER AND METAL MINER by Prof. Arthur Lakes.

PLACER MINING FOR GOLD IN NORTH AMERICA.

As our prospectors are more likely to go prospecting in these days of gold in their own country of North America than elsewhere, we shall devote our time for the present to this country.

Although from an historical point of view the discoveries of placer gold at Sutter's Mill in California practically were the origin and main impetus of gold mining in North America, and would therefore be apparently the right place to begin with an historical and geographical account of placer mining, yet, for practical purposes, we prefer to begin with a geographical distribution of gold, commencing at the extreme Northwest from Alaska downwards.

THE PLACERS OF ALASKA.

In 1870, Dale, the explorer of Alaska, said that gold and silver exist in limited quantities in Alaska. Talcose and chloritic slates with veins of quartz abound in the island of Kadiak (see map). Analysis showed only $1 to the ton in gold and silver; but Newberry observes that "These specimens come from a system which at other points is probably much richer. The mineralogical character of the specimens is precisely that of the most productive gold bearing veins known, although silver will not be found in quantity in such an association of minerals." The gold bearing alluvion of Cook's Inlet was probably discovered from the same rocks or class of rocks.

The gold deposits of Stickeen river are in British territory, and are all placers, though gold veins exist. The head waters of the Taheo river have afforded coarse gold. Fine scaly gold, like iron filings, is found in the sands at the mouth of the Porcupine, or Rat river, a branch of the Yukon. The Kakun river has a yellowish gold bearing clay, and gold has been found in the bay on which the Taku villages are situated, averaging 5 cents to the pan in scales and small nuggets.

The richest deposit was on the main stream four or five miles from the bay, at the foot of a water fall 100 feet high. More recently quartz prospecting has been vigorously carried on in this territory. In parts of Alaska they work the gold gravel out in frozen blocks and pound it up and thaw it out in the spring. They work drift mining in this way all the winter. The gravel beds never thaw out in Alaska.

G. A. Carpenter in the Alaska *Record*, gives an account of the placers around Cook's inlet.

"Six Mile creek is the richest and biggest. It empties six miles east of Resurrection creek, opposite the head forks of the famous Kenai river. It is a large stream, 200 feet across at the mouth and 4 to 6 feet deep, with rapid current. Six miles up the hills the canyon begins to narrow from the bench lands until at the first forks, 12 miles up from the arm, the right hand fork, or Canon creek, foams and whirls between walls of slate. The left hand fork runs more smoothly in an open, rolling country. To the first fork there are large bars, which are hydraulic propositions, and the gold being fine on the water's edge, the worker did not average over $3.50 per day. On Beedy's bar three men took out in August 23 ounces of gold in 13 days with sluice boxes. They had put a wing dam in a short distance from the shore line. This was an immense bar, which to be properly worked, should be by hydraulicing. The largest and best property yet discovered is that of Sanford Mills, a prospector, who, with 100 pounds pack of grub and tools on his back, and no blankets, found gold on the creek at the upper sources, and after thorough prospecting proclaimed that Six Mile discounted Resurrection and Bear creeks for gold. He is at present ground sluicing a channel through the bar above high water mark to turn the creek into it next season and work the creek bottom. At the last end of the bar Sun was making $10 a day per man. There is more or less clay or cement in the gravel, so that the bank stands up from the creek about 30 feet and extends back like a bench land to a height of 150 feet a quarter of a mile from the creek. The creek bottom in front of Sun's claims catches the gold washed through two miles of box canon above, and pieces of gold can readily be seen through two or three feet of water lurking in the crevices. He expects to take out $100 to the man per day.

"Dusez and party, on the next claim below, took 2,000, and claimed that their sluice boxes yielded an ounce of gold per day to the man. The creek is all canyon with good hydraulic banks and small sniping bars to the second forks, 25 miles from salt water. The contents of a pan tied up in the corner of a red bandanna showed $8 in coarse gold, and next day they took out pieces worth $10 and $15, showing what the rich spots will yield. But a man going to Six Mile wants to have an adequate respect for the red and black moose gnats!"

BRITISH COLUMBIA.

From Alaska, next in order we turn to British Columbia. George M. Dawson says, "There is scarcely a stream of any importance in British Columbia in which

BRITISH COLUMBIA GOLD FIELDS (AFTER LOCKE).

the 'color' of gold cannot be found. Gold discoveries made in 1858 led to a great 'rush', and gold ever since has been the chief factor in the prosperity of the country. Between 1858 and 1880 the product, according to Locke, was $45,140,889. The gold yield fluctuates from year to year, due partly to the uncertainty of the deposits worked and to climatic conditions, great quantities of snow perhaps falling one winter, and more than an average rainfall in the summer preventing the clearing of the deep claims from water till late in the season. In Cassiar district the unfavorable spring prevented the miners from reaching their claims till late, and heavy floods impeded their operations during the summer.

"The very general distribution of alluvial gold over the province indicates that several different rock formations produce it in greater or less quantity. The coarse gold is most likely to be near original veins. 'Colors,' as the finer particles of gold are called, travel far along the beds of rapid rivers before they are reduced to invisibility. The gold formation proper, and in place, consists of talcose and chloritic, or greenish schists and slates, and are doubtless a continuation or equivalent northward of some of the rich gold bearing slates of California. From the denudation of these rocks and veins the gold has been concentrated in the placers. The greatest area of these gold bearing schists is in the disturbed region west of the Rocky Mountain ranges known as the Purcell, Selkirk, Columbia, Cariboo and Omineca ranges. Gold bearing rocks also occur near Anderson river and Boston bar on the Fraser, at Leech river, Vancouver Island, and elsewhere. The Cariboo, discovered in 1860, has been the most permanent and productive. The 53d parallel of latitude passes through this district, which has been described as a mountainous region, but is rather a remnant of a great high level plateau, 5,000 feet high, dissected by numerous tributaries of the Fraser, which cut great V shaped valleys. And with lessening slope the rock is concealed by gravel deposits which increase in thickness and extent till the valleys become U shaped, or flat-bottomed, and little swampy glades are formed, through which the stream flows tortuously and with gentle current. The steep banks are densely covered with heavy pine trees. The country is covered by drift or detrital matter, concealing the rock substratum. This description is characteristic of many of our placer localities also in Colorado.

"The shallower placers, as usual, first attracted attention, but later the deep diggings were found by far the most profitable, as in California and Australia. Williams and Lightning creeks have so far yielded the greater part of the gold of Cariboo. They were known from the first to be rich, but have been found to be specially suited for deep work in having a hard deposit of boulder clay beneath the beds of the present water courses, which prevents the access of much of the superficial water to the workings below. By regular mining operations, the rocky bottom of the valley is followed beneath 50 to 150 feet of overlying clays and gravels, the course of the ancient stream being traceable by the polished rocks of its bed and the coarse gravel and boulders which have filled its channel. In the hollow of the rocky channel the richest lead of gold is usually found, but in following the rock surface laterally, rich side ground is discovered of greater or less width." The old stream courses follow the same direction as the new and present rivers, crossing often from side to side of the valley, never leaving the old valley, or running across the modern drainage system, as is so often the case in the deep placers of California and Australia. The Van Winkel mine is a good typical example of the method of mining to reach the buried channels. The claim covers 2,050 feet length of valley, and the deepest part of the channel has been cleared out 1,600 feet long. The workings attain a width of 300 feet; $40,000 were expended before gold was found in the channel. Since, it has produced well, upwards of $15,700 in one week, and weekly "clean ups" of $14,000, $12,000, etc. In 1876 the product had amounted to $500,964. In reaching the buried channel a shaft is usually sunk at the lower down-stream end of the claim (as at Roscoe placer, Colorado) on the sloping side of the valley, where, after having gone through a moderate depth of clay or gravel, the slaty rock of the district is reached. The shaft is continued through this till a sufficient depth is attained, when a drift is started at right angles to the course of the valley. The old channel is thus struck in such a way as to enable the subterranean water collecting in it from the whole upper part of the claim to be pumped to the surface by the shaft. On cutting out of the slate rock, however, into the gravel, so much water is frequently met with that the pumps are mastered, rendering necessary a cessation of work till the dryest part of the season, or the application of more powerful machinery. When the drift is not found to be at a sufficient depth to cut the bottom of the old channel, it is generally necessary to close it, and after continuing the shaft to a greater depth, to drive out again. The old channel, once reached and cleared of water, is followed up its slope by the workings to the upper part of the claim, and where paying side ground occurs it is also opened. The average depth of workings is 70 feet. The water is raised to within 40 feet of the surface, where it is discharged into an adit 3,000 feet long. There are two pumps 10 inches in diameter. The richest pay is obtained in the rock channel of the old stream, but where this is much contracted, the force of the water has swept the gold away to those places where its width is increased. Most of the slates are rotten and crumbling to a considerable depth, and in clearing up in the bottom, a thickness of 1 to 2 feet is taken out with a pick and shovel (as in the Alma placer, Colorado), and sent up to the surface with the overlying gravel for treatment. In the side rock, as in the central channel, the greater part of the gold is found lying directly on "bed rock," and only occasionally are paying streaks seen in the gravel a few feet above it.

The side ground is worked up from the channel in successive breasts parallel to it. The average yield when Dawson visited it was 3 ounces to each set of timbers, the set uncovering about 35 square feet of bed rock with height of 6 feet. The lowest layers of gravel contain many large boulders of quartz and slate, not much water worn, which must have come down from the hillsides. It is a torrential deposit to a depth of 4 feet in the channel, above which the gravel is better rounded and more evenly spread, though still mixed with clay. Owing to the unconsolidated nature of the gravel, the pressure on the supports of the workings is excessive. The sets of timber are only a few inches apart, and workings are lined with complete lagging. The timber is massive, 1 to 2 feet thick, of the country spruce, costing 8 cents delivered at mine.

In many parts water streams from the roof like a heavy shower of rain. The gold gravel is raised to the surface by bucket rope with friction gearing and water power. The whole of the deep workings are annually filled with water at the time of spring floods and it is late in summer or autumn before the pumps acquire the mastery. This account of Dawson's gives an admirable idea of a typical mine of this kind not merely for the country in question, but for others similarly situated in regions far distant. In endeavoring to "bottom" the old channel on Lightning creek, great difficulties were met from the large quantity of the water and the increased depth of sinking required. The lowest part of the channel holding good pay has not yet been reached. Usually the "pay" was taken in these placers from the bottom of the deep channel. In some places, however, the gravel paid clear to the surface. In working over the deep ground in early days much was left that would even now pay handsomely, but cannot be found or reached on account of the treacherous nature of the moved ground filled with old timbering and water. Dawson thinks the quantity of gold still remaining in Williams creek, which has been worked over, is as great as that already obtained.

In most gold bearing countries the placers, though rich, lead up to mining the quartz veins whence the gold came. At present the placers have absorbed the labor of the miner. The Kootenai district, Omineca and New Cassiar are very similar to those of Cariboo. The greater part of the gold range especially toward the north is very densely timbered and covered with moss, peaty swamp, and tangled vegetation, great obstacles to the prospector, differing much from the bare slopes of California. The Cassiar mines much further north are worked at enormous disadvantage owing to being situated in an almost Artic climate where the soil is permanently frozen (as in Alaska) at a small depth below the surface on the shady sides of the valleys, with a short season during which the water courses are liable to floods disastrous to the mines, with supplies at famine prices. Its rich deposits, however, show the continuity of the gold belt of the country. On the Fraser river the gold occurs along the whole course of the river irrespective of the formation over which the river may pass. In Vancouver Isle the Leech river district yielded considerable gold over a short area; the gold rocks are the same as those of British Columbia. In Southern British Columbia the placer deposits lie on or in the vicinity of black slaty rocks, from quartz veins traversing which the alluvial gold appears to be derived. In prospecting, the extent and distribution of these slaty areas is important. The fissile character of these slates renders them easily permeable to waters which have concentrated the minerals of economic value with quartz and other minerals of secondary origin in the veins. These slates are probably metamorphosed mesozoic shales, some of the gold may be derived from igneous Tertiary rocks. On the Tranquille river, flakes and scales of platinum are found together with flakes of gold. In so many cases it is recorded that along these rivers the best paying ground was found where the aforesaid slates crossed the river, that too much importance cannot be given to these slates. Gold has been found in gravels resting on the surface of the old rocks in irregular pockets formed by the uneven hollows into which they are worn. Were the underlying rocks or stream bed a coarse conglomerate instead of a clayey breccia and clays and shales, it would probably form a rich gold bearing horizon.

In the Queen Charlotte Islands in 1849 the Hardas Indians brought rough gold to Fort Simpson; their mode of obtaining it was to light fires over the vein and dash cold water on the heated rock which was thus disintegrated and made to expose the metal.

A correspondent of the San Francisco *Call* writes from Vancouver lately that there is a gold excitement in that region. In the Cariboo, British Columbia, hydraulic companies in finishing up their season's work reported $67,000 from a late clean up at the Horsefly and Cariboo mines. On the Waverley claim bedrock has just been struck after 18 years of quiet steady working by poor miners. Rich placers are reported on the Yukon river. The largest nugget taken out last season in Alaska was on Glacier creek. It was worth $234. The principal jingle on the store counters and bars is gold dust. A miner will go into a place of public resort where dancing is the high carnival and balancing the scales with $50 in dust he will receive dancing tickets at 50 cents each for that amount and the whole house, bums, broke miners and all fill up the sets until this amount runs out, when another miner with a long sack steps up to the bar and lays down his dust for another supply of tickets and thus the long winter hours of darkness are spent.

A PROSPECTORS' ACCOUNT OF THE GOLD REGIONS OF THE NORTHWEST.

The latest and most comprehensive sketch of the mining possibles of all this northwest region was given me by a friend, Mr. A. L. Preston, who has just returned from a general survey and prospecting trip over Idaho, British Columbia and part of Alaska. In Idaho on the Snake river, placers are being worked on bars at the surface line of low water. The gold is fine, light and hard to save. At Spokane many machines of various patterns are in use, the river valley is of barren wastes of sand. The banks are low and they are working long bars washed up on bends and islands down to the water line. The soil is alluvial with no glacial matter. Pumping plants are a necessity, as there is no head or gravity line to the rivers.

In British Columbia it is claimed gold can be found in every stream. The Columbia river is 35 feet deep between high and low water mark during six months of the year. North of Revelstoke the Columbia river rises near the United States boundary line west of the Rockies. It makes a sharp bend cutting through the Selkirk range and goes south 300 miles. The first gold worked in paying quantities is 40 miles north of Revelstoke on small streams coming in from the east, and thence north, every stream from the east side contains placer gold as far north as Gold stream 75 miles north of Revelstoke. The country was first prospected in '59 and has been worked for the last 7 or 8 years. The altitude of Columbia river is 2,000 feet above the sea, the higher ranges 8,000 feet. Glaciers extend down to a level of 4,000 feet and are still working and grinding down rocks and gold. The best pay has been found late in the season at the foot of these glaciers. The side streams as well as the Columbia are raging torrents from June 1 to September, but they are worked between thawing out in April and the floods of May, also in the fall in September after the floods have run off and before the hard freezing of October. This high water is caused by melting of snows by warm weather. Rain usually lowers the water in the streams because it makes the mountains so cold that it checks the melting of snows, and the highest water is during clear, bright hot weather. Thus the snow rather than the rain is the cause of rise or fall of the rivers.

The gold is fairly coarse and found mostly on bedrock near the bed and channel of the present streams, also at the bottom of boulder and glacial debris to a depth of from 20 to 80 feet. In proof of what may be found there, the Last Chance placer worked four years digging down to bedrock, sixty feet, with a river of water to contend with, only a few months in spring and fall available for working, the works drowned out in summer and frozen up in winter. The prospectors made their own wooden wheels and pumps, packed everything over a rough trail 75 miles on mules. They had to make bridges across streams which were liable to be speedily washed away again. For supplies they would make two or three trips in the summer season. They drifted the first season in bedrock, hoisting the dirt to the surface and washing it in a common sluice box. In the brief season they took out $7,000 and the following year $10,000 and the past year the same. On Smith creek on the west side of the Columbia an attempt was made at hydraulicing with canvas hose and an old fashioned brass nozzle like a fire hose and fifty feet head of water power.

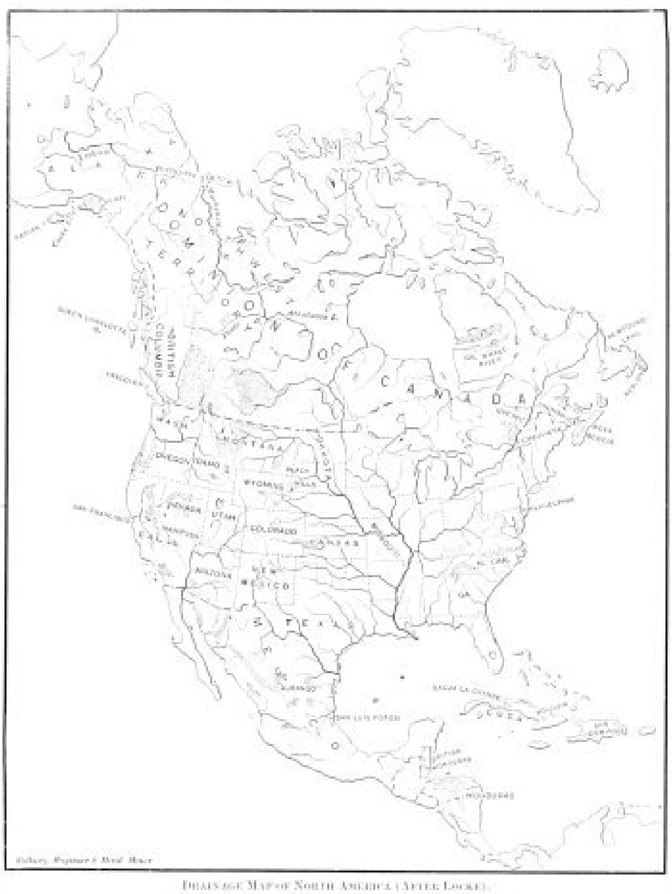
They are working, however, on a bench not a well defined channel and the material is all glacial drift full of immense boulders.

Up to the head of Smith creek there are evidences of remains of quite extensive ground sluicing done in the 60's and they have worked up almost under the present glaciers. Prospecting done here during the last few years has given fairly good returns, but no work of any importance. "Outfits" of 3 or 4 parties are working about a dozen men each on Smith creek and about 60 men on Gold stream trying to get down to bedrock and getting a little pay as they go. North of this a little surface placer work is being done. Mr. Preston met a party of four who had been on a canoeing journey up to Big Bend and Canoe river to latitude 53 N. who reported small prospects and no diggings. The country between Selkirk range and the Rockies is characteristic of mountain ranges. The strike is west of north and south southeast parallel with the Rockies. The formation is like that of our Rocky Mountains consisting of granite, porphyry, rhyolite and other igneous eruptive rocks.

The mountains are steep; the lower slopes are covered with heavy timber, tamarack, fir, etc. Wash and slides and great glacial slides and moraines are characteristic. The first glaciers Mr. Preston met were south of Revelstoke, narrow necks of ice leading up to big basins full of ice. One of these glaciers is 400 feet deep. The veins in this region have not been much prospected. There are a few rich and narrow veins with free milling quartz carrying gold. There are no large mines there. Farther back on the Selkirk range, 30 miles east of Columbia river, arsenical pyrites are found carrying gold and silver, principally gold, and 30 miles on the west side near the top of the range we find galena and silver ores.

Kootenai country lies east of the Columbia and between the Canadian Pacific railway and the boundary at the end of the Selkirk range. Galena and silver ores are principally found north of Spokane country. The region is steep and rugged. It is a great region for snowslides. A number of large mines are being worked here rich in silver averaging from 300 to 500 ounces silver to the ton.

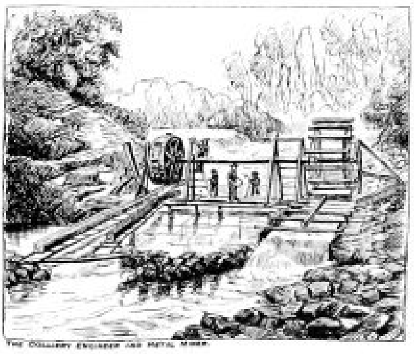
At Pilot bay on the Kootenai lake is a smelter, and another at Nelson and a third at Trail landing on the west side of the Columbia. Trail creek district runs west ten miles and borders on the state of Washington and extends north as far as it has been prospected for 30 miles. The camp of Rossland is the center of this Trail Creek district and is located 6 miles north of this boundary line and some distance west of the Columbia river. The ores are hard, being arsenical pyrites carrying one to three ounces of gold with 10 per cent. copper and some silver. Veins of this ore occur in the granite and the ore is found frozen onto the walls. There is no gouge or gangue and no distinct line between ore and country rock. Only two veins are opened up east and west along low ridges north and south of Trail creek. On the north side the Le Roy mine and War Eagle, the Jose and O K between them, are shipping 200 tons daily principally of gold ore about 2 ounces of gold or $50 per ton. Boundary creek, 40 miles west, reports a number of prospects similar to this Trail Creek district. This mineral belt extends south into Washington and Idaho. The new camps are being pushed ahead. Prospecting is hard work. The country is heavily and closely timbered with much underbrush and fallen timber. The prospector has to pack his tools on his back and cut his own trail through the wilderness; when he finds a favorable location he makes his central camp and works from that. Game is not plentiful. In the veins they find a "cap rock" rusty with oxidized iron broken over



DRAINAGE MAP OF NORTH AMERICA (AFTER LOCKE).
DOTTED PORTIONS SHOW POSITION OF PLACER GOLD DEPOSITS.

and capping these veins; this cap is two to four feet deep. Then the rock passes into hard unoxidized pyrites. Prospecting is hard and slow, for you have to blast from grass roots; caps are poor; the best ore is found with depth.

The Fraser and Cariboo districts lie west of this region. At old Cariboo up to the Fraser this last season a rich company has put in two expensive hydraulic plants, one on the Quesnal, the other in the south fork of the Horsefly, putting forty or fifty miles of ditch on each plant, also several thousand feet of steel pipe and large siphons. Several storied reservoirs are being got ready for extensive hydraulicing next season. They report gravel banks 30 to 60 feet deep and gravel ranging 50 cents to $2.00 per yard. The difficulty outside of the short season is from the immense glacial boulders. Farther south on the Fraser river Indians, white men and Chinese are washing bars every fall and spring at low water, with rockers, sluices, etc., making a living. A San Francisco company have gone on the Middle Fraser north of Yale and have put in dredging plants at



DRAINING A RIVER CLAIM BY A CALIFORNIA PUMP.

an expense of $75,000 per dredge, dredging up sand and gravel fifty feet below the water surface. In Horsefly country which has been worked since 1860 successfully, they will put down a wing dam or caisson to bedrock and clean up well. Throughout British Columbia transportation is by horse; they use canoes where they have lakes or can go down stream, but the streams are too swift to ascend that way. Leaving the traveled trail you have to carry things on your back; trails have to be made and prospectors carry big crosscut saws for this purpose and saw through the timber and fallen logs.

CANADA.

The gold alluvions of lower Canada cover a large region, upwards of 10,000 square miles. The gravels through which the gold is irregularly distributed are covered by vegetable earth and sometimes clay. They lie upon metamorphosed Lower Silurian rocks such as schists associated with diorites and serpentines which are traversed by numerous veins of quartz. On the Chaudiere river at the Devil's rapids, where the river makes a sharp turn, gold has been found in the cavities, fissures and cracks of the clay slates which form the bed of the stream and act as natural riffles. At low water the country people break up these rocks and search them to a depth of several feet. The fissures are filled with clayey gravel in which the gold is met; and metal worth several dollars has been found between the layers of slate. The gold in these slates is sometimes tarnished by a black earthy coating of oxide of manganese. The richest slates lie near a quartz vein and the largest pieces of gold are found in its vicinity along the tributaries of the Chaudiere; it is worth observing that those very gold bearing eruptive rocks, diorite and serpentine (an alterative product of eruptive rocks) pave the stream together with schists, and gold is found in their vicinity. Pans yielded grains of gold and black sand or magnetite, a common accompaniment of the gold here as elsewhere. Dr. Douglas obtained 8 to 9 ounces of gold in 20 days from gravel accumulated in the re-entering angles and cracks of the diorite. If in this region, however, the gravel does not rest on bedrock but on a bluish clay the alluvions overlying the clay are generally barren or poor. A section of a placer shows on the Chaudiere:

1. 1 foot of sandy vegetable soil.
2. A yellowish sand with pebbles.
3. A clayey gravel containing gold.
4. Sandstone bedrock in the fissures of which the largest amount of gold was obtained.

In lower Canada they work subterraneously the alluvions during the winter season when most other placer operations are frozen up and closed.

"By the aid of pits and galleries the miners were able to carry on their search for gold throughout the winter and to extract and wash a large quantity of gravel in which the gold was so abundant as to richly repay their energy and perseverance. A mass of gold weighing over 1 lb. was found on the Gilbert. The pits were opened on the left bank of the river at distances of 50 to 100 feet from the stream and sunk to bedrock a depth of 20 to 25 feet. They were connected by galleries, one of which draining the whole of the works carried the water into a pit whence it was pumped into the river. The gold gravel was washed in rockers at the bottom of each pit, the greater part was extracted from fissures in bedrock, sandstone and clay slates which they break up to a depth of 5 or 6 feet. In its joints and between its lamina, where the gravel has penetrated and become hardened, gold has been found in greatest abundance and largest masses. Here as elsewhere the layers of alluvion which contain the precious metal are not continuous, but occur in sheets or belts of greater or less extent and of variable thickness.

"The proportion of gold in these sheets or belts is far from uniform and regular, the richer portion being met with in patches more or less remote and isolated from each other. The gold gravels result from a general alluvial action. In the veins on the hills from which the gravels are derived gold is often so capriciously and irregularly distributed that the results of a week's working in some favored spot may compensate the miner for months of unprofitable work in poorer ground." It would appear that in Canada the source of most of the alluvial gold is derived from the veins in the Lower Silurian rocks. In these slates quartz veins abound and in the black schists as on Leech river. The veins are very numerous, but generally very small. A vein of slates is often characterized by small thin streaks of quartz and little lenticular bunches through all its layers without showing any well marked large vein. This is characteristic of veins and veinlets in most slate regions, the quartz having a tendency to scatter through the minute cracks and interstices of a slate formation rather than to occupy a broad, well-defined fissure.

In addition to this there are the eruptive diorite or greenstone rocks worthy of observation as undoubtedly a source of gold in this as in many other regions. In Arizona we have ourselves observed such greenstone dykes to be decomposed and traversed by numerous little veinlets of gold bearing quartz. The oxidation of the iron pyrites in such formations yields the rusty surface float or gossan which sets the gold free; and from the wearing down of this soft oxidized material doubtless a large proportion of the placer gold is derived. On Leech river a large mass of these quartz veined slates has been worn down and removed during the excavation of the valley, leaving the heavy gold by a natural process of concentration in a narrow line in the bottom of the excavation. A cement also occurs on Leech river, sometimes far up the slopes, and in the river forms a false bottom with gold on top of it and gold below it on bedrock. Miners should not stop on these false bottoms, however rich, but go through them till they have reached bedrock where the best gold is almost sure to be found.

MANITOBA.

Gold is found along the Saskatchewan river and gold is found scattered over the surface from Lake Manitoba to the Rocky Mountains. On ascending the river granitic and crystalline boulders die out gradually and with them also the gold, showing that the gold is associated with and derived from these crystalline rocks.

NEW BRUNSWICK.

Gold has been found in the Carboniferous conglomerates of the coast. Here is another case of gold occurring in consolidated bodies of pebbles or conglomerates of a far older date than the ordinary placer beds. As these pebbles were originally derived from the granitic rocks the beds may be considered as an ancient consolidated placer. Alluvial deposits of gold have also been found in the counties of Central New Brunswick which show that the gold is derived from quartz veins penetrating the rocks of the district as also shown by the character of the pebbles.

NEW FOUNDLAND GOLD DEPOSITS.

Gold quartz veins are found in serpentine in the Lower Silurian rocks, and where no serpentine exists it is no use to look for ore. Serpentine, be it said, is usually a grass green or purplish rock of magnesian silicate derived from the alteration of certain minerals composing some igneous rocks. The area of this serpentine is 500 square miles. The ore occurs in beds or pockets rather than in veins, or in quartz knobs at the junction of little veins. So far we do not hear of extensive placer deposits.

NOVA SCOTIA.

In Nova Scotia there has been as yet but little placer mining, although there are large areas of drift and a great number of gold bearing lodes to which attention seems hitherto to have been almost wholly confined. The rocks are principally Lower Silurian. It is a curious fact that here gold occurs in spots and bunches up to 60 oz. nuggets in the veins. At Cooper lake a layer of tough clay and glacial drift was met with underneath the mud and vegetable matter and in the under clay small round gold nuggets.

SUMMARY OF NOTES ON THE NORTHWEST.

The principal points to note for practical use in this account of the gold deposits of the Northwest are:

1st. That in Alaska, and generally through this northwest region, talcose and chloritic or greenish and dark schists and slates abound traversed by veins and veinlets of quartz together with igneous dykes of eruptive diorite or greenstone. These rocks seem to be the parents of the placer gold and should be followed and traced with a view to those deposits.

2nd. Rich deposits of gold were found in Alaska at the foot of a waterfall. Singularly enough this is by no means as common an occurrence as one might expect.

3rd. Prospectors going to Alaska will have to encounter frozen soils and an Arctic climate, but their labor may be rewarded by the richness of the soils. They appear there to sometimes turn the course of the creek by wing dams one season to work the bed of the creek the following one. Black gnats and mosquitos are to be expected.

4th. British Columbia seems to be very rich in placers all along its rivers. Here again climatic conditions are a drawback. If you find course gold in placers in this as well as in other regions you are likely to be not far from the original gold vein and should look for it.

Another difficulty to the prospector is the dense forests overlying what he is looking for.

A V-shaped sharp canyon usually has a rapid stream in it which does not deposit much material; this is rather to be looked for when the canyon widens out into the U shape. Shallow placers will first attract the prospector, but it will be well when he has exhausted these to dig down and look for deeper channels and not let up till he has reached bedrock where he may expect most gold; side ground may be rich as well as central channel. The example of the Van Winkel mine is a good one to study and follow.

You may expect to be troubled with water and need pumps.

Do not stop at bedrock, but dig down into it; it may be five or six feet deep till you find no gold. Experience in this region and elsewhere shows that much of the gold is carried down into the chinks and crevices especially in slates.

Moreover the bedrock is liable to be rotten for a depth of a few feet and may pay to take out bodily and overhaul at leisure.

Unconsolidated gravels in the Van Winkel press heavily on the ground below and need thick timber supports.

The workings are annually filled with water and need pumping out every year.

Gold may be only found at bedrock, but may pay clear to the surface.

Work out your placer thoroughly and carefully whilst you are at it. It is very dangerous as well as difficult work to go over an old extravagantly worked ground again, and to work under moved ground, far more difficult than in virgin ground. At the same time it may pay to go over an old placer that was wastefully and carelessly worked by others years ago.

Good pay and placers may sometimes be found at the foot of living glaciers in this region.

The season for work is very short, but big sums may be made at times in a short season or by keeping at it for many years till bedrock is reached.

Prospecting in British Columbia is evidently "no picnic." You will expect to meet in that region enormous slides and moraines of rock from glaciers, as well as huge boulders, the latter are always an obstruction. The value and importance of these placers of the Northwest is shown by the enormous ditches and plants that are in preparation at so great expense.

In Canada the Silurian rocks, slates and schists appear responsible for the placer gold, together with diorite and serpentine.

It is important to notice that the Canadians have been able to carry on certain placer work successfully through the winter months, when elsewhere most placer miners give up.

We must not expect a placer ground to be continuous, or to carry the same amount or even any gold at all, thoughout its extent. Placers are often long, lenticular beds or bodies distributed at intervals, some gold bearing, others barren and others a mixture of both.

Gold quartz veins in slates are apt to be small and much scattered, but such veinlets are usually good indications of gold.

Early prospectors generally pay most attention to placer deposits and later, to veins in place. In Nova Scotia it seems the other way.

Finally it would appear that the Northwest is the paradise of placer deposits. The reason of this is to be looked for largely, in that region being the main area of the great ice sheet of the glacial epoch as well as the locality of many long glaciers and of a vast river and drainage system. We might conclude like Horace Greeley with our advice to the prospector: "Go Northwest young man."

Watt Mine Car Wheels.

The Watt Mining Car Wheel Co. of Barnesville, O., have an advertisement in this issue of our paper to which we wish to call especial attention.

This firm believe it better to do one thing and do that right than to be engaged in a variety of work. Acting on that principle they decided there was a good opening for a wide-awake firm to engage in the manufacture of mining cars and car wheels. They therefore organized a company for this express purpose and their phenomenal success shows they were right, as they today do more business in that line than any other firm in the United States.

The firm is composed of the four Watt Bros. of Barnesville, O., and Rev. W. K. Pendleton of Florida. The Watt Bros. are all practical men, having been brought up in the foundry and machine business, and two of them are inventors of many valuable articles that the firm are now manufacturing, all pertaining to their self-oiling wheel and their cars. They do all their own traveling and watch the interests of their patrons very closely. One of the brothers has especial charge of the foundry department and gives his undivided attention, watching every detail, and with such good results that their work is known all over the United States where there are any mines, with the exception of the anthracite regions. This trade they have never canvassed, but they are well prepared to do anything for this field and at low prices.

Steam Boilers.

The reports we receive from Messrs. H. E. Collins & Co., of Pittsburg, Pa., sole sales agents for Cahall Vertical Water Tube Boilers, manufactured by the Aultman and Taylor Machinery Co., of Mansfield, Ohio, evidences two things: First, that they have an exceptionally efficient boiler, and second, that Messrs. Collins & Co. are "hustlers."

Their latest report states that the following sales were effected within the last few days:

One thousand H. P. for the Pittsburg Plate Glass Co., Kokomo, Ind.; Brown & Co., Pittsburg, 100 H. P.; Jones & Laughlins, Ltd., Pittsburg, 500 H. P. The boilers for the Pittsburg Plate Glass Co. are of the standard direct fired type; those for Jones & Laughlins will be equipped with the chain grate stoker, and that for Brown & Co. is of the waste heat type.

INGENIOUS MINING CONTRIVANCES.

This department is intended for short and plain descriptions of unpatented ingenious contrivances or methods used at mines and found of value. When necessary, articles will be illustrated with cuts, if the writer will send a clear pencil sketch from which our artists can make the necessary drawings.

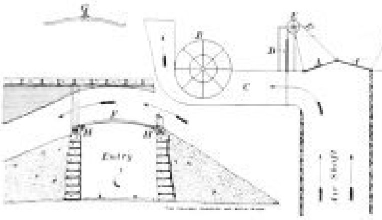
If the ideas are clearly expressed we will make all needed corrections in composition.

All accepted articles will be paid for at the rate of $5.00 per column, payable in any books in our catalogue, or that of any other publishers.

Balanced Doors and Iron Air-Bridges as Preventatives of Disastrous Mine Explosions.

(By Captain Wm. M. Morris, Pueblo, Colo.)

Since the explosion at the Vulcan Mine at New Castle, Colo., in February, when fifty-five men lost their lives through the same old story of carelessness, ignorance and bad discipline, with gas, coal dust and blown out shots, I have given some study to the question of preventing, to a great extent, such disasters. The destruction of the fan and over-casts (or, more properly speaking, air-bridges), by almost every explo-



sion, thereby destroying ventilation and preventing the rescue of the unfortunate workingmen, can be prevented by the plan illustrated in the accompanying sketch.

Balanced doors, *A A*, are set over the top of the air-shaft and the fan, *B*, is set about 50' from the shaft and connected therewith by a fan drift or tunnel, *C*. The balanced doors set over the air-shaft should be connected with the vertical door, *D*, by a wire rope, *E*, over a pulley or wheel, *E* and a rod, not shown in the sketch, should be connected with the throttle valve of the fan engine. When the least extra pressure of air comes up the air-shaft the balanced doors immediately open and the vertical door drops, thereby closing the fan and allowing the force of the explosion to go up straight into the atmosphere, and the lever or rod connected with the throttle valve shuts off the steam and the fan stops. As soon as the force of the explosion is over the doors can be closed by a slight push and the fan started, thereby restoring the ventilation. It will not make any difference whether it is a pressure or exhaust fan, as the explosion will go against the air as well as with it.

The air bridge I propose is shown at *F* and should be of boiler iron cambered to any degree desired. For wide bridges two or more plates can be bolted together with angle-irons, as shown in *G*. For small over-casts one wide plate will be sufficient. The ends should be strengthened by angle-irons spiked to a piece of 8" x 8" timber, which must be secured and fastened into the sides or over-head as shown on the sketch at *H H*. The iron should be from ⅜" to ½" thick, the thickness depending on the size of the bridge or over-cast. This type of a bridge or over-cast can be fastened so that it will take a great power to blow it out and it can be put in place quickly and cheaply even if knocked out. The iron must be tarred to prevent rusting.

Replacing Mine Cars on Track.

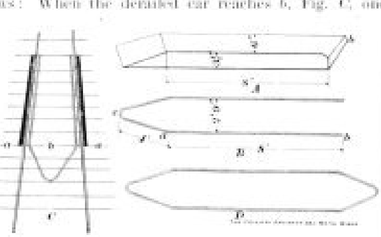
(By S. J. Roulledge, Pratt City, Ala.)

It sometimes happens that at certain points on slopes or haulage roads more wrecks will occur from derailment of cars than at any other point. Such wrecks can be prevented, and much expense and labor can be saved by adopting the arrangement shown in the accompanying illustration. It will work well at any place on a haulage road or slope.

By reference to the illustration, it will be seen that Fig. *A* represents a piece of timber about 8' long, 6" wide, 3½" thick at the outer edge, and 3" thick at the inner edge, or the side next the rail. The end of the stick is wedge-shaped, as shown in the figure. This wedge-shaped end is set in the direction from which the car or cars are being hauled, *a*, Fig. *C*. The entire stick is covered with plate iron 6" wide and ¼" thick.

Fig. *B* represents an arrangement of rail, made from same size rail as the track. The straight sides, from *a* to *b*, are each 8 ft. long. The distance *b* to *c* is 4 ft. The arrangement of the various parts is shown in Fig. *C*. The gauge of the track *b*, or in other words, the distance between straight sides of Fig. *B* is 2 ft. 9 in., for a 3 ft. gauge haulage road. If the gauge of the haulage road is more or less, the gauge of the track *b* must naturally vary.

The mode of operation of this arrangement is as follows: When the derailed car reaches *b*, Fig. *C*, one



wheel will mount the rail at *a*, and the other will mount the block. As the block is ½ in. higher on the outside, and the straight rail of the interior track pushes the opposite wheel, the car will pull on the haulage track. It makes no difference which side of the track the derailed car is, the result will be the same. In tail rope haulage, both empty cars going in and loaded cars going out can be replaced on the rail, by having the pieces of timber wedge-shaped at *both* ends, and making the interior rails as shown in Fig. *D*.

The thickness of timber and iron plate is for 30 lb. T-rail.

ELECTRIC MINE HAULAGE.

That the most economical method of bringing coal from the working face in a mine to the breaker or tipple is by means of some type of mechanical haulage, has long been recognized. The first system employed for this purpose was the steam mine locomotive, which was only applicable in such mines as were free from gas and which used the main haulage road as a return airway. The next system introduced was rope haulage, either of the endless or tail-rope type. These, with compressed air locomotives and electric locomotives, are now in use, reducing the cost of mine haulage very materially.

In many cases electric haulage proves most advantageous owing to the simple manner in which the

JEFFREY ELECTRIC MINE LOCOMOTIVE WITH LOADED TRIP.

motive power can be conducted to any part of the mine, and it can be utilized, not only for haulage, but for running the pumps, inside hoists, mining machinery, etc., etc. The accompanying illustration of an electric locomotive hauling a loaded trip to the tipple, shows very plainly the convenience of this system of haulage. The photograph from which this cut was made was taken at the mines of the Pulaski Iron Co. at Eckman, W. Va., which was recently equipped by the Jeffrey Manufacturing Co., of Columbus, Ohio, with a complete plant of coal cutting, drilling and electric haulage machinery.

This locomotive does the entire hauling and gathering of the loaded cars along the butt and main entries, hauling the coal to the top of an incline. The tracks at the mouth of the mine are so arranged that the locomotive makes a flying switch, cutting loose from the loaded trip, allowing the latter to continue to the top of the incline, while the locomotive runs down to the empties, takes them in the mine and distributes them to the various points where they are taken by the miners into the rooms.

We understand that the Jeffrey Manufacturing Company has built quite a large number of these locomotives during the past year, having equipped in all some fourteen or fifteen different plants. This company has also under construction locomotives for a number of coal mines in Pennsylvania, West Virginia and ore mines in Arizona. These locomotives are built in all sizes from 15 horse-power up to 175, and for all gauges from 18 inches up to the standard 4 feet 8½ inch gauge.

Personals.

Messrs. E. E. Olcott, Percy L. Fearn and Robert Peele, have opened offices as consulting mining and metallurgical engineers at 18 Broadway, New York. Gold and silver mining are their specialties.

Mr. H. C. Zacharias, formerly resident engineer of the P. and R. C. and I. Co., and superintendent of the Silver Brook Coal Co., but now superintendent of The Peerless Coal and Coke Co., at Vivian, West Virginia, has been visiting his old home at Shamokin, Pa.

Mr. Thomas B. Rickford, an American mining engineer, was murdered on Feb. 29th near Jiminez, Mexico, by Evaristo Rodriguez, superintendent of the Aurelio mine. Mr. Rickford, it is said, was examining the property prior to reporting on it.

Mr. Chas. C. Jones, B. S., has resigned as general manager of the Coeburn Colliery Co. at Lotus, Va., and has removed to New Orleans, La., where he will be located for some months. Mr. Jones was one of the pioneers in the development of the Wise county coal field. His removal to New Orleans was due to the recent death of his father, Prof. Joseph Jones, M. D., of Tulane University, New Orleans.

Mining Machinery Ordered.

The Robinson Machine Co. of Monongahela, Pa., inform us that their shops are busier than they have been at any time for the past three years. Among the late orders received by this company are the following: One pair Robinson standard type single drum friction engines for the Pacific Improvement Co., San Francisco, Cal.; one standard type double tail-rope engine for C. Jutte & Co., Pittsburgh, Pa., (being second order within the year); one standard type double drum tail-rope engine for Frank Armstrong, Pittsburgh, Pa. (being second order from this firm); complete tipple equipment for the Rock Run Coal Co., Camden Pa.; one 25' ventilating fan, of the Guibal type, for the Johnson Coal Mining Co., Columbus, Ohio; one 20' fan for the Essen Coal Co., Pittsburgh, Pa.

Several features of the fan under construction for the Johnson Coal Mining Co. are worthy special mention, viz.: the fan and machinery is in no way attached to the building, but is supported by heavy cast-iron "A" frames bolted directly to the masonry, thus keeping the machinery in perfect alignment besides furnishing a rigid support for the fan and machinery. The building is of steel throughout, and is absolutely fire-proof. The Johnson Coal Mining Co. has spared no expense to make this the most indestructible and perfect mine ventilating fan yet erected by any firm.

A Handsome Souvenir.

The Jeffrey Manufacturing Co., of Columbus, Ohio, presented a handsome souvenir to the members of the American Institute of Mining Engineers who attended the recent Pittsburg meeting. The souvenir consisted of thirty-eight fine half tone plates of mining, elevating and conveying machinery constructed by the Jeffrey Co. The plates were beautifully bound in dark red covers of artistic design.

VALUABLE STEAM APPLIANCES.

Types of Valves, Which Automatically Control Steam Delivery.

In this age of economy and efficiency in the production of any staple commodity, it is absolutely necessary for managers of mining and manufacturing establishments to be well informed as to such appliances as will tend to make possible the most economical and efficient utilization of steam. The old idea that fuel at coal mines "costs nothing" is recognized by mine managers as being radically wrong. At metalliferous mines fuel is usually an expensive item. Again, the large and generally lengthy lines of steam pipe used at mines entails the adoption of special appliances to secure best results. Therefore, appliances calculated to ensure efficiency and economy in steam plants are of interest to our readers.

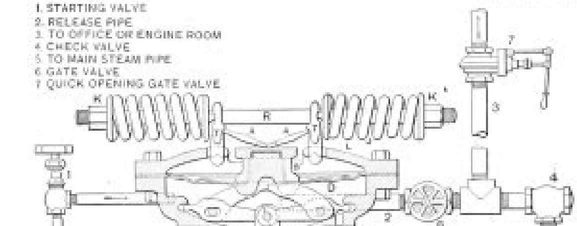


Fig. 1.—The Foster Automatic Safety Stop Valve.

Some time ago our attention was called to an automatic safety stop valve in use at the Lykens Valley Coal Company's mines near Lykens, Pa. This valve, shown in sectional view in Fig. 1, was designed by the Foster Engineering Company, of Newark, N. J., to meet a condition existing at one of the Lykens Valley Coal Company's mines, and which exists at almost every large mine in the country.

The condition was a very long line of large steam pipe, from the boiler plant on the surface to the point of utilization in the mine. These pipes are liable to injury, in which case the steam from the boilers is apt to escape, seriously interfering with the ventilation and doing great damage before notice can be sent to close off the stop-valve at the boilers. The same contingency is liable to occur in water mains. The breaking of a fitting, bursting of a pipe, or other accident, would result in more or less serious damage.

The operation of the valve is entirely automatic, and is as follows: Referring to Fig. 1, *A* is the pipe leading from the boiler; *B* is the pipe leading to the point of delivery. The normal position of the main steam valve, *H*, is closed. To open this main steam valve, close the gate valve 6 and open the angle valve 1. This allows steam from the initial pipe, *A*, to enter the diaphragm chamber, *D*, which, acting on the diaphragm against the power of the spring, opens the main valve, *H*. When the pipe, *B*, is fully charged, the angle valve

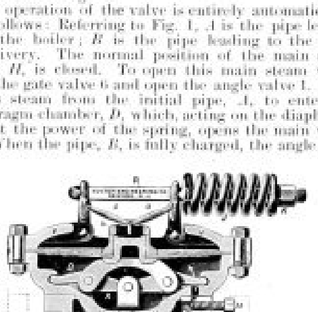

Fig. 2.—Foster Automatic Relief Valve.

1 is closed, and the gate valve 6 opened. The main steam valve, *H*, is then held open by the steam passing through the steam port, *E*, to the diaphragm chamber.

Pipe 5 is connected to the main steam line, *B*, at any desired point, or to a branch from the main line. In case of rupture of the pipe, *B*, or of any of its connections or fittings, the pressure in the diaphragm chamber is instantly relieved through the pipes 2 and 5, thereby allowing the spring to instantly close the main valve, *H*.

Pipe 3 is provided with an auxiliary lever gate valve, 7, which is properly located near the automatic stop valve. Cords or chains, running over pulleys, may lead from the end of the lever to any desired point or points. So that, in case of any accident requiring immediate stoppage of an engine, or pump, or to stop the flow of steam through the main line, it is only necessary to pull the cord or chain; this opens the valve 7, which relieves the pressure in the diaphragm chamber and instantly shuts off the steam. The check valve 4 is used to prevent back pressure from the main line *B*, from entering the diaphragm chamber and thereby making valve 7 inoperative. This device is attracting great attention from large steam users in all parts of the country. The United States Navy Department has recognized its great value by ordering two 5″ valves to be made throughout of government composition, for use on the battleship *Texas*.

Another application of a very similar principle forms the Foster Automatic Relief Valve for high and low pressure systems. Owing to the rapid introduction of high pressure boilers for mining work, which in many instances are to be used in connection with an older low pressure plant, some appliance is necessary to equalize the pressure from the two sets of boilers. The Relief Valve, located on a pipe connecting the high and low pressure systems, allows any excess of steam in the high pressure boilers to enter the low pressure system at any desired pressure. The action of this valve is as follows: The steam from the high pressure boilers acts on a diaphragm, similar to that in the Safety Stop Valve, which tends to open the valve against a spring, which can be adjusted to any point desired by the nuts *K*, Fig. 2. Fig. 2 shows a sectional view of an Automatic Relief Valve.

The Foster Pressure Regulator, see Fig. 4, applied as a pump governor ensures the automatic governance of the pump. When used as a pump governor it is applied to the steam pipe leading to the pump, and the speed and discharge is regulated by the nut *K*, Fig. 4.

This adjustment is so made that when the maximum discharge pressure is reached the pump will stop. This ensures immunity from danger of overflows if the water is pumped into a tank or reservoir. As a governor for mine pumps it ensures uniform speed for

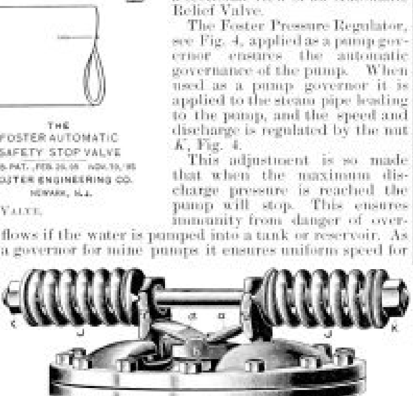

Fig. 3.—Large Size Foster Pressure Regulator, with Flanged Ends.

the pump. This is a great advantage, especially at mines where pumpmen are not on duty continuously.

The Mt. Lookout Coal Co., has in use at Mt. Lookout colliery one 3″ pump governor, and one 6″ reducing valve. The Forty Fort Coal Co., has in use at Forty Fort colliery one 4″ pump governor and two 2″ pump governors. Mr. J. L. Crawford, General Superintendent of the above two companies, speaks very highly of the appliances.

Fig. 4.—Foster Pressure Regulator.

In addition to the valves mentioned the Lykens Valley Coal Co., has in use one 8″ automatic safety stop valve, one 8″ reducing valve, one 4″ reducing valve and one 4″ pump governor.

The Susquehanna Coal Co., has in use at No. 1 shaft, Nanticoke, Pa., one 8″ relief valve capable of relieving pressure of from 100 to 125 pounds per square inch to a lower pressure of from 60 to 80 pounds per square inch. Full details of these specialties are given in the catalogues of the Foster Engineering Co., of Newark, N. J.

The Northwest Mining Association.

Below is the summary report of the meeting of the members of the Northwest Mining Association, held in Spokane, Wash., February 22nd, 1896: Meeting convened at 9.30 a. m., President G. B. Dennis in the chair, and about 100 officials of the association were present. After an address of welcome by Mayor H. N. Belt, the Secretary stated the objects of the meeting and the President outlined in an able address the plans, purposes and work done by the Association. He was followed by Judge W. P. Heyburn, of Osburn, Idaho, who spoke at considerable length on "Extra Lateral Rights" and presented the only true solution of this knotty problem yet offered to the miners of this section. In the afternoon John C. Davenport, of Nelson, B. C., addressed the convention on "Pioneer Mining." N. E. Lindsay, of Spokane, followed with the subject "How Can We Improve the Mining Industry Through This Organization." "Needed Legislation" was the subject of an address of A. F. Parker, of Grangeville, Idaho. William M. Pinkston, of Boundry City., Wash., spoke on "Good Roads." L. K. Armstrong followed with a brief address on "The Importance of Geological Surveys." S. G. Cosgrove, of Pomeroy, Wash., spoke at some length on general matters. A large number of telegrams and letters were read from absentees. General discussion followed, being participated in by A. P. Curry, C. H. Thompson and others, of Spokane; W. C. Butler, of Everett., Wash.; D. M. C. Gault, of Hillsboro, Oregon; Judge Heyburn, of Osburn, Idaho; H. C. Walters, of Libby, Mont.; F. A. Weber, of Lakeview, Idaho, and others. The meeting then adjourned after a brief session of detail work, and in the evening the citizens of Spokane tendered a banquet to the visitors which was participated in by about 125 persons.

The next annual meeting of the Association will occur October 3rd, next, and will be of three or four days' duration. The Association has Vice Presidents in all the districts of Montana, Idaho, Oregon, British Columbia and Washington, and the membership is increasing daily.

It is stated that the citizens of Butte, Mont., propose to invite the officials of the Association to convene in that city at an early date.

L. K. Armstrong, Secretary.

Personal.

Mr. Daniel Webster, for fifteen years associated with the Babcock & Wilcox Co., has resigned his position with that firm to take effect March 1st. Mr. Webster has for the last twelve years been the practical head of the manufacturing and construction department of the Babcock & Wilcox Co., and has made many strong friends among the large steam users and manufacturers throughout the United States, who will all be pleased to learn that his retirement from the Babcock & Wilcox Co. was for the purpose of accepting a better position with the manufacturers of the Cahall boiler, the Aultman & Taylor Machinery Co., Mansfield, O. Although the Cahall boiler has demonstrated its superiority as a steam generator, still there are many cases where lack of head room or prejudice prevents the adopting of anything but a horizontal water tube boiler. They have, therefore, decided to immediately engage in the manufacture of water tube boilers of the Babcock and Wilcox type, and Mr. Webster will have entire charge of this department. Aultman & Taylor expect to be ready to begin delivering the B. & W. type of water tube boiler by June 1st. H. E. Collins & Co., of the Bank of Commerce Building, Pittsburg, Pa., general sales agents for the Cahall boiler, will act in the same capacity for the B. & W. type.

Repair Time.

The approach of settled weather brings with it what is known to all mine owners as "Repair Time," and as the repairs about all buildings include painting, we are reminded that it is advisable in this regard as well as in every other, to get the most value for the investment. Therefore, we would suggest the use of an up-to-date paint, viz: that which will not only beautify the structure, but which will resist the action of the weather as well as the action of fire. Such a paint is made, as is well-known to most of our readers, by the Jamieson Fire-Resisting Paint Co. This company numbers among its patrons some of the leading mining companies; therefore it stands to reason that the users of these paints would not be experimenting with a new article.

For coating tin and other metallic surfaces, this company makes two kinds of special paints, viz: New York Graphite Paint, and Special Iron Paint.

A card to the Jamieson Fire-Resisting Paint Co., New York City, asking for particulars will receive prompt response.

Wanted—Second-Hand Machinery.

Advertisements of second-hand machinery for sale are of frequent occurrence, but a large display advertisement of second-hand engines boilers and pumps *wanted*, such as the Scranton Supply and Machinery Co. publishes in this issue, is rather rare. The Scranton Supply and Machinery Co. is a very reliable and enterprising concern, and when they advertise for anything they *want* it.

This department is intended for the use of those who wish to express their views, or ask, or answer, questions on any subject relating to mining. Correspondents need not hesitate to write for supposed want of ability. If the ideas are expressed, we will cheerfully make any correction in composition that may be required. Communications should not be too lengthy, and personal reflections should be carefully avoided.

All communications should be accompanied with the proper name and address of the writer—not necessarily for publication, but as a guarantee of good faith.

The Editor is not responsible for views expressed in this Department.

☞ Correspondents should be in as simple language, and as free of technical terms and formula as possible, consistent with clear relation.

Questions on subjects not directly connected with mining will not be published.

A Geometrical Problem.

Editor Colliery Engineer and Metal Miner :

SIR :—Please answer through your columns, the following question : A tree 120 feet high stands on the bank of a river 100 feet in width. At what distance from the ground should the tree be cut so that in falling the top will just reach the opposite bank of the river?

J. S. P.,
Feb. 28, 1896. Reynoldsville, Pa.

Correction.

Editor Colliery Engineer and Metal Miner :

SIR :—In my answer to Assistant Superintendent, Nelsonville, Ohio, in February issue of your valuable journal, the formula to determine the size of the steam cylinder should have been $\frac{(H \times P - B) \times S}{E} = A$, instead of $\frac{H \times P + B \times S}{E} = A$.

Yours respectfully, YES 0'.

Ventilation.

Editor Colliery Engineer and Metal Miner :

SIR :—Will some of your able readers kindly answer the following : I have a fan 15 feet in diameter, with blades 3 ft. 9 in. long and 4 ft. wide, incased in spiral expanding casing, the casing expanding from 0 to 37 inches. There are two central inlets each 7 ft. 6 in. in diameter, and the outlet is 4' 2'' × 6'. Now under ordinary conditions, with a water gauge of ¾ of an inch, and an angular velocity of 105 revolutions per minute, what quantity of air will be produced? What per cent. of the efficiency of the fan is due to the expanding casing? And at what speed will this fan cease to throw any air? I would like to have Mr. J. T. Beard of Ottumwa, Iowa, answer the above if he will kindly do so. Yours respectfully,

CARBON, Oskaloosa, Iowa.

A Fan Problem.

Editor Colliery Engineer and Metal Miner :

SIR :—Referring to the question put by your correspondent, James Hann, in the February issue of your journal, as to why there should be an increased quantity of air with the same water gauge, and the same tip speed: According to the understood theories of mechanical ventilation there can be only one explanation, and that is that there has been an enlargement of the air passages—that in fact, the new fan has been working on an enlarged equivalent orifice.

The equivalent orifice of the mine worked upon by the old fan $= \frac{.388 \times 43}{\sqrt{.4}} = 26.38$ square feet, whereas, the new fan is working on an orifice of $\frac{.388 \times 60}{\sqrt{.4}} = 36.81$ square feet.

The increased quantity on the same mine should have resulted in a higher water gauge, which with the larger quantity should have been $\frac{60^2 \times .4}{43^2} = .78$ inch.

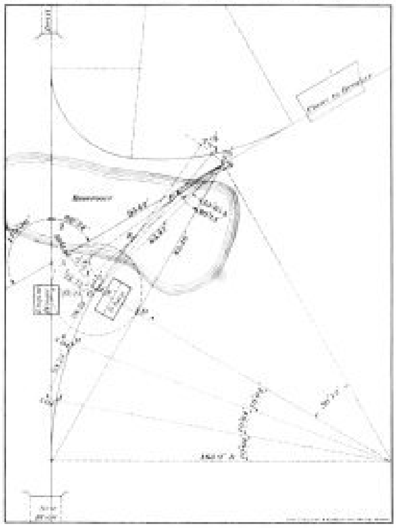
The manometrical efficiency of both old and new fan in this case, is, in the opinion of the writer, the lowest on record. (See a tabular statement of mechanical work performed by a number of fans at pages 160 to 163 in *The Practice and Science of Mining Engineering*. The circumferential speed of the fans referred to by Mr. Hann, running at 105 revolution per minute $= \frac{105 \times 12 \times 3.1416}{60} = 66$ feet per second, therefore, the theoretical water gauge is equal to $66^2 \times .000458 = 1.99$ inches ; hence, the manometrical efficiency is only $\frac{.4}{1.99} = .20$, which is so low that some explanation should be given of it.

Shafto House, Yours etc.,
Chester-le-Street, England. W. FAIRLEY.
Feb. 25, 1896.

Plan for Laying Out a Curve.

Editor Colliery Engineer and Metal Miner :

SIR :—As your valuable paper has been much help to me I contribute the enclosed sketch and show how I worked out a curve that may be of benefit to some of your many readers. I was called on to lay out a curve ; not having my plotting instruments with me I thought I would have to return to the office to work it out, but the superintendent was very anxious to get the stakes set at once, so that work could be commenced, therefore I set to work and staked it off as per the enclosed sketch that I made afterward. To tell the truth I was a little puzzled at first, but I found that I could get the intersection angle *I* 60° 24', and as I had to just miss the shop with the line, I could get the point *C* 25.75' or the intersection desired. To locate the curve, I divided the curve in 6 equal chords, so that the middle two would also intersect at the point *C*. Then I could locate my points of curves any place between 90 and 100 ft. from *A*, which gave me conditions that easily allowed the laying out of the curve as follows : The *I* angle being 60° 24', $180 - 60° 24' = 119° 36'$, $\frac{119° 36'}{2} = 59° 48'$, angle at *A*. The distance *A C* 25.75' represents the hypothenuse of a right angled triangle the base of which is the radius of a circle tangent to the two lines of intersection, that is, $A C - \text{Sin } 59° 48' \times 25.75' = 22.25$ ft. Then, $25.75 + 22.25 = 48'$, which is the central ordinate of the curve



chord desired, that will pass through *C* and fit to the intersected lines at an apex distance *A B* in the right angled triangles thus formed. $A B = \frac{A D}{\text{Sin } B}$. Now Sin $B = \frac{1}{2} I$ angle, or $\frac{60° 24'}{2} = 30° 12'$, then $\frac{48}{.503020} = 95.42' = A B$. In same triangle $D B = A B \times \text{Sin } A = 95.42 \times (\text{Sin } 59° 48')\ .864278 = 82.46'$ or ½ the total chord of the curve.

Then, $C B = \frac{D B}{\text{Cosine } b}$, angle $b = \frac{1}{2} B$ or $\frac{1}{4} I = \frac{60° 24'}{4} = 15° 6'$. We have, $\frac{82.46}{.965472} = 85.47$ ft. $= C B$. Now, having all the distances desired, I set instrument at *C*, sight to *B*, turn left 5° 2' and from *C* with radius of 85.47' set stake 1, turn left 5° 2' again and with same radius set stake 2. Then move instrument to *B*, sight to stake *C*, turn right 5° 2' radius 85.47'. Again, set stake 1' then 2', by same method. To check work, distance stake 1' to 2' is found to be 7.416' or ⅓ radius of the tangent circle around *C*. Then strings stretched from *C* to stake 2, from *B* to stake 1', intersect at point *E* on curve, and point *F* is found by the intersection of strings *C* to stake 1 and *B* to stake 2'. Then, by placing *C* and *B* to grade and locating at *C* 1' and 2' at same height as *C*, and at *B* locating 1 and 2 same height as *B* the grade of rail at *E* and *F* will also be located. Where a fill is to be made this method will be found to be very convenient. The other half of curve may be staked out as per article in October number of your paper. As indicated by the drawing, I am not sure that this method is new, but I have never found it in print. It being so convenient I submit it for what it may be worth and if it helps some other of your many readers I am well paid for the trouble. Yours, etc.,

S. W. DOUGLASS, Ashland, Pa.

Ventilation.

Editor Colliery Engineer and Metal Miner :

SIR :—Will you please insert the following in reply to "P. C.," Dominion No. 1, Nova Scotia :

1. Two shafts, 6 ft. by 6 ft., each 1,000 ft. deep, pass 45,000 cu. ft. of air per minute. How much must they be enlarged to reduce the power required one-half?

If the power is reduced by one-half, it will be as 2 : 1. Quantity varies as cube root of power ; therefore, $\sqrt[3]{2} : \sqrt[3]{1} :: 45,000 : 36,000$ cu. ft., the quantity that would pass with one-half the power, the shafts remaining as given. But the question calls for the same quantity, or 45,000 cu. ft. Now, if 36,000 cu. ft. passes in place 6 × 6, what must be the size of airway to pass 45,000 cu. ft., powers remaining the same?

$$\frac{45,000 \times (6 \times 6)}{36,000} = \frac{5 \times 36}{4} = 45 \text{ sq. ft.}$$

$$\sqrt{45} = 6.708 \times 4 = 26.832 \text{ ft. perimeter.}$$

$$\sqrt{36} = 6 \times 4 = 24 \text{ ft. perimeter.}$$

$$\frac{26.832}{24} = 1.118, \text{ relative perimeter.}$$

Divide the sum of square root and cube root of relative perimeters by 2 and divide the result into the area obtained by proportion above, for area of pressure remains the same. In this case,

$$\frac{\sqrt{1.118} + \sqrt[3]{1.118}}{2} \times 45 = 47.1375 \text{ sq. ft.}$$

$$\sqrt{47.1375} = 6.87 \text{ feet square.}$$

2. In a certain mine there are 10,500 cu. ft. of air per minute passing in an airway 5 ft. by 6 ft. and 2 miles long. Work was continued until the airway was 2½ miles in length, when a creep came on, which reduced the airway in area for 1 mile to 15 feet, or 5 ft. by 3 ft., and for a further distance of ½ mile to an area of 10 ft., or 4 ft. by 2½ ft. What quantity of air should then pass, the power remaining the same?

$$2 \text{ miles} = 2 \times 5,280 = 10,560 \text{ ft.}$$

$$2\tfrac{1}{2} \text{ miles} = 2\tfrac{1}{2} \times 5,280 = 13,200 \text{ ft.}$$

Pressure and power remaining the same, the quantity varies as the square root of the length of the airway, area being same in both cases.

Therefore, $\sqrt{13,200} : 10,500 :: \sqrt{10,560} : (\ )$
$= 114.9 : 10,500 :: 102.7 : 9,385$ cu. ft.

We would have 9,385 cu. ft. passing in the 2½ mile airway before the depression took place. Now, the question becomes : If 9,385 cu. ft. passes in an airway 13,200 ft. long, 5 × 6, what quantity will pass in an airway of the following dimensions : 5,280 ft., 5 × 3 ; 2,640 ft., 4 × 2½ ; 5,280 ft., 5 × 6, powers remaining the same?

Proceed to find the units of work in each airway and section of airway with 9,385 cu. ft. of air passing, using the formula

$$p = \frac{k s v^2}{a}.$$

13,200 ft. airway, $p = \frac{.0000001 \times 290,400 \times 313^2}{30} = 9.5$ lbs.

5,280 ft. " $p = \frac{.0000001 \times 84,480 \times 626^2}{15} = 22.1$ "

2,640 ft. " $p = \frac{.0000001 \times 34,320 \times 938^2}{10} = 30.3$ "

5,280 ft. " $p = \frac{.0000001 \times 116,160 \times 313^2}{30} = 3.8$ "

Units of work $= p \times q =$ 9.5 × 9,385 = 89,157 units.
22.1 × 9,385 = 207,408 "
30.3 × 9,385 = 284,365 "
3.8 × 9,385 = 35,663 "
527,436 "

Now, quantity varies as cube root of units or power. Therefore,

$$\sqrt[3]{527,436} : \sqrt[3]{89,157} :: 9,385 : 5,102 \text{ cu. ft.}$$

Yours, etc.,
A. MOLECULE,
Victoria Mines, C. B., N. S.

PRIZE CONTEST.

Prizes Given for the Best Answers to Questions Relating to Mining.

For the best answer to each of the following questions, the value of $1.00 in any of the books in our book catalogue, or six months' subscription to THE COLLIERY ENGINEER AND METAL MINER.

For the second best answer to each question, the value of 50 cents in any of the books in our book catalogue or three months subscription to THE COLLIERY ENGINEER AND METAL MINER.

Both prizes for answers to the same question will not be awarded to any one person.

Conditions.

First—Competitors must be subscribers to THE COLLIERY ENGINEER AND METAL MINER.

Second—The name and address in full of the contestant must be signed to each answer, and each answer must be on a separate paper.

Third—Answers must be written in ink on one side of the paper only.

Fourth—"Competition contest" must be written on the envelope in which the answers are sent to us.

Fifth—One person may compete in all the questions.

Sixth—Our decision as to the merits of the answers shall be final.

Seventh—Answers must be mailed us not later than one month after publication.

Eighth—The publication of the answers and names of persons to whom the prizes are awarded shall be considered sufficient notification. Successful competitors are requested to notify us as soon as possible as to what disposal they wish to make of their prizes.

Competition Questions for April.

QUES. 217. During the course of some experiments we have been making with a Mueseler lamp, with the view of perfecting our new safety lamp, we have found that when we make the top diameter of the conical funnel five-sixteenths of an inch, the lamp flame dies out when the entering air contains about 7 per cent. of marsh gas, and when we make the top diameter of the funnel five-eighths of an inch the lamp is not safe in an explosive mixture. We will therefore feel obliged if you will explain to us how it is that the lamp is safe with the small diameter and absolutely unsafe with the large one.

QUES. 218.—We are ventilating a mine with a furnace, and the quantity of fresh air entering per minute is 100,000 cubic feet. The furnace consumes 1.5 long tons of coals per hour. The composition of the coal is 78 per cent. fixed carbon, 10 per cent. volatile hydro-carbons and 12 per cent. ash. The volatile hydro-carbons may be taken at the average composition of $C_2 H_4$. Now, we wish to know what will be the volume measure per minute of the air and gases ascending from the furnace in the upcast shaft, when the temperature of the descending air is 60° F. and that of the ascending air 200° F.

QUES. 219.—We have a seam of bituminous coal 4.5 feet thick; it is lying nearly level; The bottom rock is hard and strong, but we have a following of 4 feet of slate that we cannot keep up. The shafts when sunk will be 800 feet deep, and we will therefore be obliged to you if you will explain with a sketch how we should work this seam so as to obtain the highest possible percentage of large coal, and yet be able to keep the roads and rooms in safe condition without the loss of much timber.

QUES. 220.—We have a ventilating fan exhausting from our mine 150,000 cubic feet of air per minute with a water gauge of .8 inch, and we wish to set up another and larger fan to increase the ventilation to 250,000 cubic feet. We will therefore be obliged to you if you will furnish us with the following values for the new fan, so that we may secure the best results:

First—The diameter of the fan.
Second—The breadth or length cylinderwise.
Third—The number of revolutions.
Fourth—The radial length of the blades.
Fifth—The area of the orifice of entry.
Sixth—The area of the throat.
Seventh—The area of the orifice of discharge.
Eighth—The effective horse power of the fan, taking *T* instead of *M* for the pressure per square foot.

QUES. 221.—In looking over a topographical map and the text of the notes of the survey, I observed three hills, and their apices were lettered *S*, *T* and *U*. The apices of *S* and *T* were shown to lie in a line that was bearing North 63° East from S, and the apex of *U* was shown to bear South 27° East from that of *T*. The mean angle of elevation of the southwest slope of *S*, measured from the foot of the slope at *A*, was 32° 45′, and the mean angle of elevation measured at *B* at the foot of the slope at the southeast side of *U* was 19° 56′. The vertical heights of the hills were: *S*, 784 feet; *T*, 472 feet, and *U*, 320 feet. The angle of elevation of the apex of *S*, measured from the level of the apex of *T*, was 6° 25′, and the angle of depression of the apex of *U*, measured from the level of the apex of *T*, was 4° 45′. I will be pleased to receive from you a sketch with the necessary explanation, showing the process by which you have found the distance in a straight line from *A*, at the foot of the southwest slope of *S*, to *B*, at the foot of the southeast slope of *U*.

QUES. 222.—In a mine shaft in course of being sunk an iron kettle full of water was hoisted from the bottom at a mean velocity of 6 feet per second. The kettle was cylindrical in shape and 3.5 feet in diameter and 3.5 feet deep, and by some unknown cause a round hole had been cut through the bottom, and it had a mean diameter of 3 inches. The result was that the kettle left the sump in the shaft bottom full of water and arrived at the top of the shaft empty, and by coincidence the discharge of water just ceased at the moment the kettle reached the surface. Now, I will be obliged if you will deduce for me, out of these facts, the depth to which the sinking has advanced.

Answers to Questions which Appeared in the February Issue, and for which Prizes Have Been Awarded.

QUES. 205.—As we are determined to leave no stone unturned until we secure all the necessary facts for constructing a new lamp on correct principles, will you tell us how much the illuminating power of the light of a safety lamp is reduced in its passage through the glass cylinder that surrounds it? Base your calculations on the following thicknesses: 1/16 inch, 1/8 inch, 1/4 inch.

ANS.—The lost and disposable light of the different glasses will be as follows:

Thickness of Glasses.	Loss of Light.	Disposable Light.
1/16 inch.	70 per cent.	30 per cent.
1/8 inch.	60 " "	40 " "
1/4 inch.	50 " "	50 " "

THOS. S. ASKEY,
Dysart, P. O., Cambria Co., Pa.
Second Prize, HUGH CAIRNS,
Elco, Washington Co. Pa.

QUES. 206.—We are constructing boilers for raising steam by the burning of bituminous coal in the State of Tennessee, and as we are going to manufacture fine white paper we wish to consume all the volatile matter and soot given off by the burning coal; will you, therefore tell us how this objectionable matter could be consumed, and thus increase our available energy instead of wasting it by allowing this combustible matter to escape? We do not want any plans or sections for the construction of a furnace, as we can do them ourselves when you supply us with the principle required for the burning of this waste carbon.

ANS.—For complete combustion and the prevention of smoke, no more than a sufficient supply of air must be admitted. Now the needful supply cannot all enter up through the grating and the fire, even with the help of a steam jet or forced draught, because the air loses much of its active oxygen in passing through the incandescent cinders. The admission, then, of the oxygen to burn the volatile matter of the coal must be over the fire, and provision must be made to maintain the right temperature of the mixed air and gases for the combustion of the carbon particles of the smoke. The provisions required for the complete combustion of the smoke may be noticed under three heads.

First—For the admission of the right supply of air, I use a stoke door hung by top hinges and made to turn in a box case, so that when the door is partly opened its sides are always close to the sides of the case, and thus the side entry of air is prevented, while provision has been made for the door to open inward under the control of a rack, and by this means only admit a thin sheet of air under the bottom edge of the door. The entering air is therefore projected in a sheet immediately onto the fire.

Second—Admit the correct supply of air; for too much air cools the gases and the carbon and prevents their combustion, and too little air directly prevents complete combustion, and, therefore, carbonic oxide CO is not burned into CO_2 with the consequent waste. Again, the necessary supply of air must not take place too early or too late, and to secure the best results I provide a peep hole for an attendant to observe the flame and admit the supply of air required from time to time.

Third—To secure the required temperature for the burning of the carbon particles and the other volatile matter, I line the sides and front of the fire box with fire brick, and make the bridge wall a fire brick trellis that is of sufficient area for the free passage of the burnt gases, and presents such a multiplied incandescent surface to the air and gases that complete combustion must ensue. The principles here explained can be applied to any style of boiler.

G. S. RICE,
Second Prize, 119 South Market Street,
WM. HIBBS, Scio, Ohio. Ottumwa, Ia.

QUES. 207.—Our bituminous coal is of excellent caking quality, but the demand for coke is small and the price is low; the vein is tender and we make 40 per cent. of slack. We have a good market for household coals and I have recommended the manager of the company to make the slack into briquettes, and he replied, "If you can furnish me with a successful plan for doing so, I will advise the company to raise your wages $50 a month." This being so, I will be obliged to you if you will assist me by supplying the following facts:

First—Which of the following materials will make, from a physical point of view, the best binder for the briquettes: Clay, hydraulic lime, Portland cement, asphaltum, pitch?

Second—Which binder gives the best appearance to the briquettes?

Third—Which binder is the best for its price and commercial advantages?

Fourth—What are the best forms and dimensions to give the briquettes?

Fifth—How are the briquettes made, and where are any briquette presses with their mixing appliances to be seen in the United States?

ANS.—Pitch makes the best binder, being sticky when heated and it will harden when dry and will also burn with the coal, but has the objection that it makes a great deal of smoke during combustion. It is now used almost entirely.

Clay would be the cheapest binder, but is objectionable from the fact that it represents just so much ash and dead weight in the briquettes.

The best shape for briquettes destined for domestic purposes is ovoidal and about the size of a goose egg; for steam purposes brick shapes of all sizes are employed.

In the manufacture of briquettes the coal is first ground to a uniform size and dried in a small furnace, one of which is described as having a rotating bottom and fitted with stirrers to mix the coal; the coal is then mixed with from 5 to 7 per cent. of partly melted pitch which is thoroughly incorporated by a pug-mill, disintegrator or screw which delivers it to the briquette machine; this machine is composed essentially of a mold plate and dies which compress the coal on several sides at once or sometimes a machine consisting of a long tube with a ram, is employed, the ram compressing and forcing out the paste which is cut up into sections of the proper length by a knife or wire, as in brick-making; the briquettes are then cooled.

CHAS. ED. BOURON,
Tracy City, Tenn.
Second Prize, HUGH CAMPBELL,
Gowrie Mines, Cape Breton, N. S.

QUES. 208.—Where is asphaltum mined on the continents of North or South America? What are the characteristics of its physical and geological environment; that is to say, is it found in veins or in solutions in oils? Has it any connection with salt lakes? Was its origin vital or chemical? And further, to what general use is it applied? And what is its chemical composition?

ANS.—Asphaltum is found in North America, as far north as the Ohio river, it is found in Breckinridge Co., Ky. Asphaltum bitumen is a smooth brittle substance which breaks with a polish. When pure it burns without leaving any ashes; the products of combustion emit a strong smell of pitch; it is found in a liquid state on the surface of the Dead Sea; it is found in many parts of Asia, Europe and South America. Our greatest source of asphaltum is from the Island of Trinidad, where there is a lake 4,000 feet long and 2,400 feet wide, containing 114 acres. Trinidad is part of the mainland, its flora warrants that, so I considered this South America. The lake is owned by the Island of Trinidad and is under a lease of 45 years to the Trinidad Asphaltum Co. This company pays $1.60 per ton royalty, and the profit to the government is $150,000 per year. The lake is steadily falling from year to year, but the supply will not give out in our generation. Test holes have been put down in the lake to a depth of 160 feet and did not find bottom. Assuming that it is no deeper and none added, the supply will last 300 years.

The consistency of the lake is about the same as cheese. This asphaltum comes from deep sources and no doubt had its origin from vegetable matter. Carbon and hydrogen enter into its composition.

In olden times asphaltum was used for embalming the dead. The solid asphaltum is employed in Persia and Arabia for ships instead of pitch. A composition of asphaltum, lamp black and turpentine makes a durable black paint. It is used for roofing purposes, covering bridges, etc. It is very durable in air and not penetrable by water. A composition of asphaltum and gravel is extensively used for paving streets.

A. W. EVANS,
Petros, Morgan Co., Tenn.
Second Prize, HERBERT A. WILCOX, Aspen, Colorado.

QUES. 209.—By closely watching four men at work, namely, *a*, *b*, *c* and *d*, we found that *a* and *b* could fill 65 tons of coal in 5 days; *a* and *c* could fill 84 tons in 7 days; *a* and *d* could fill 44 tons in 4 days; *b* and *c* could fill 135 tons in 9 days; *b* and *d* could fill 42 tons in 3 days; and that *c* and *d* could fill 78 tons in 6 days. Will you tell us, then, how many tons of coal each of the men, that is, *a*, *b*, *c* or *d*, separately can fill in one day?

ANS.—First find the weights the pairs would fill in one day, as

$$a \text{ and } b = \frac{65}{5} = 13 \text{ tons.}$$
$$a \text{ and } c = \frac{84}{7} = 12 \text{ tons.}$$
$$a \text{ and } d = \frac{44}{4} = 11 \text{ tons.}$$
$$b \text{ and } c = \frac{135}{9} = 15 \text{ tons.}$$
$$b \text{ and } d = \frac{42}{3} = 14 \text{ tons.}$$
$$c \text{ and } d = \frac{78}{6} = 13 \text{ tons.}$$

The tons filled in one day by each man can be found as follows:

$$a = \left[\frac{(a \text{ and } b) + (a \text{ and } c) - (b \text{ and } c)}{2}\right] \text{ or}$$
$$a = \frac{(13 + 12 - 15)}{2} = 5 \text{ tons.}$$
$$b = \left[\frac{(a \text{ and } b) + (b \text{ and } c) - (a \text{ and } c)}{2}\right] \text{ or}$$
$$b = \frac{(13 + 15 - 12)}{2} = 8 \text{ tons.}$$
$$c = \left[\frac{(a \text{ and } c) + (b \text{ and } c) - (a \text{ and } b)}{2}\right] \text{ or}$$
$$c = \frac{(12 + 15 - 13)}{2} = 7 \text{ tons.}$$
$$d = \left[\frac{(a \text{ and } d) + (b \text{ and } d) - (a \text{ and } b)}{2}\right] \text{ or}$$
$$d = \frac{(11 + 14 - 13)}{2} = 6 \text{ tons.}$$

QUES. 210.—A shaft for a coal mine has been sunk to a depth of 1,000 feet, and at a depth of 898 feet we tapped a feeder of water that shed 500 gallons per minute, and after an accident to the engine that caused the stoppage of the pumps, the water rose to a height in the shaft of 700 feet. The sectional area of the shaft is equal to 140 square feet, and I will be obliged if you will make a diagram to scale, showing by the ordinates the velocities of the inflowing water at eight equally distant points in the elevation, and while you are busy, please calculate for me the time required for the feeder to fill the shaft to a height of 700 feet.

ANS.—The head of the feeder must equal the height the water rises in the shaft, since water seeks its level. We use the well known formula:

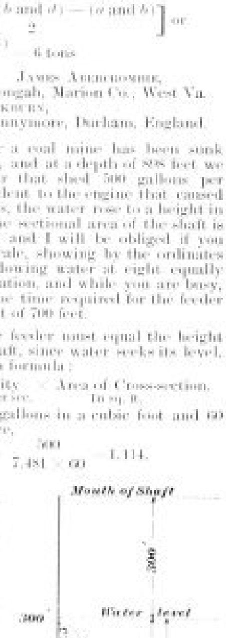
Discharge in cu. ft. per sec. = Velocity in ft. per sec. × Area of Cross-section in sq. ft.

There are 7.481 U. S. gallons in a cubic foot and 60 seconds in a minute, hence,

$$\text{Discharge in cubic feet} = \frac{500}{7.481 \times 60} = 1.114.$$

Velocity in ft. per sec. = $\sqrt{2gh} = \sqrt{2 \times 32.2 \times 598} = 196.2$. Area of Cross-section of feeder = $\frac{\text{Discharge}}{\text{Velocity}} = \frac{1.114}{196.2} = .0056763$ sq. ft.

If the water shot straight up, the time required for it to rise 598 feet above the feeder $= \frac{\text{Velocity}}{g} = \frac{196.2}{32.2} = 6.095$ seconds. But the time it fills 102 feet below the feeder is at the rate of the velocity at the discharge $= \frac{102}{196.2} = .52$ seconds. The time required to fill the entire shaft is proportional to the area of its cross-section $= \frac{140}{.0056763}(.52 + 6.095 = 6.615)$ seconds, which reduced to days =



$$\frac{140 \times 6.615}{.0056763 \times 60 \times 60 \times 24} = 1.9 \text{ days.}$$

Observe, the curve whose ordinates are represented by the velocities is a parabola.

Iron and Steel Roofing, Steel Buildings, Etc.

With this number of THE COLLIERY ENGINEER AND METAL MINER the Garry Iron and Steel Roofing Co., of Cleveland, O., begin the publication of an advertisement calling attention to their specialties of manufacture, iron and steel roofing, corrugated and plain metal siding, etc.

In addition to being manufacturers of such goods the Garry Co. also design and erect complete steel-framed structures for all purposes, in the mining trade soliciting the patronage of concerns who propose to make improvements in surface works, such as breaker structures, tipples, shaft-head frames, engine, boiler and fan houses, etc. They also make paints for such structures to meet the requirements of service.

This company issues a catalogue known as "No. 111," in which there is a great deal of useful information pertaining to roofing and architectural sheet metal work generally, which book they will gladly send to all mine operators and superintendents on application therefor.

THE COLLIERY ENGINEER

AND

METAL MINER.

WITH WHICH IS COMBINED THE MINING HERALD.

Established 1881. Incorporated 1890.

PUBLISHED MONTHLY AT SCRANTON, PA.

Entered at the Post-Office at Scranton, Pa., as second-class matter.

THOS. J. FOSTER, RUFUS J. FOSTER, MINING ENGINEER, } EDITORS.

THE COLLIERY ENGINEER COMPANY, PUBLISHERS.

TERMS.

Subscription, (Postage in the U. S., Canada, or Mexico, prepaid.) **$2.00 a Year.**

To Foreign Countries in the Universal Postal Union, $2.50.

THE COLLIERY ENGINEER AND METAL MINER and HOME STUDY, $3.00 per year.

Remit by P. O. Order, Express Money Order, Bank Check or Draft or Registered Letter.

P. O. Orders.—You can buy a Money Order at your Post-Office payable at the Scranton Post-Office.

Express Money Orders can be obtained at any office of the American Express Company, the United States Express Company, and the Wells, Fargo & Co.'s Express Company.

Registered Letters.—If a Money Order Post-Office, or an Express Office is not within your reach, your Postmaster will register the letter you wish to send us on payment of eight cents.

We Cannot Be Responsible for money sent in letters in any other way than by one of the four ways mentioned above.

EXPIRATION OF SUBSCRIPTION.

The date after your name on the wrapper of THE COLLIERY ENGINEER AND METAL MINER shows to what time your subscription has been paid.

RENEWALS, ETC.

If you do not want THE COLLIERY ENGINEER AND METAL MINER continued for another year after your subscription has run out, notify us by postal card to discontinue it. The courts have decided that subscribers to newspapers who do not order their paper discontinued at the expiration of the time for which it has been paid, are held liable for the payment of their subscriptions up to the date when they order the paper discontinued.

NOTICE OF DISCONTINUANCE.

THE COLLIERY ENGINEER AND METAL MINER is sent to subscribers until an explicit order for its discontinuance is received by us, and all payment of arrearages is made, as required by law. *Papers returned are no notice of discontinuance, as we cannot tell where they are from.*

CHANGES OF ADDRESS.

A subscriber wishing to have his address changed should be careful to give his *former* as well as his present address; otherwise we cannot find his name on our mailing list.

All communications should be addressed,

CORRECTION.

IN OUR editorial on "The Mineral Resources of Various Nations," in our March issue, we stated that "the output of *metallic copper* from the British mines in 1890 was 236,000 tons, and in 1894 it had fallen to 5,504 tons." This should have been stated as "*copper ore and copper precipitate*," as given in Prof. C. Le Neve Foster's Report to the British Government.

MINE FATALITIES.

AS the reports of the various inspectors of mines for 1895 are made public, our attention is again forcibly drawn to the enormous percentage of mine fatalities and serious injuries due to falls of roof or coal. It is not only in America that this is the case. The same relative percentages occur in European mining countries. Fully 60 % of all the deaths and serious injuries in coal mines are due to falls of roof or coal. "Whose fault is this?" "What is the remedy?" are two questions that are pertinent to every mine owner, mine official and miner.

The fault directly lies with the miner, and the miner at fault is almost invariably the victim. Neglect to properly support or pull down dangerous pieces of coal or rock, until another wagon is loaded, until another hole is drilled, or until some other piece of work that could be delayed with safety is accomplished, has resulted in more fatal accidents in coal mines than all explosions of gas, accidents from cars, explosions of powder and breaking of hoisting ropes combined. It is only when the record of fatalities for a year or a term of years is taken that the awful consequences of recklessness on the part of miners, in "deaths from falls of roof and coal," can be appreciated. As a rule such accidents only kill or maim one or two men at a time, and the public, made callous to *small* accidents, keeps no note of their frequency. An explosion of gas or coal dust in which a large number of men are killed at once excites the horror of whole nations, and the breaking of a hoisting rope by which from six to ten men may be killed does not pass unnoticed. But a three or four line item in a daily paper stating that "John Smith, a miner at Blank colliery, near Blanktown, was killed by a fall of coal this morning" is forgotten almost as soon as read.

That the miners themselves do not attach the importance to such matters that they should, is evidenced by the fact that most miners, who would not think of opening a safety lamp in a prohibited part of a mine, will not hesitate to work under a piece of coal or rock which they know to be loose, but which they *think* will "hold up" until another hole is drilled, another wagon loaded, or another rail laid. They will not hesitate to return to the working face immediately after firing a shot, notwithstanding the workings are full of smoke, and common sense and experience teaches them that every shot disturbs and loosens more or less coal and rock above their heads. As props are furnished free of expense to miners, and they know the danger of neglecting to set a prop or to pull down dangerous pieces, it is but just to directly blame the miner for the accident that either kills or maims him.

Now for the remedy. In touching on this portion of the subject it will be seen that the mine foreman or superintendent is *indirectly* responsible for many accidents due to falls of coal and rock.

Naturally it is impossible for a mine foreman to stand over every miner with a club and force him to look after his own safety. But there is another way. It is by the use of strict discipline and the enforcement of rational rules. If a mine foreman would instantly discharge every man he caught working under a dangerous piece of coal or rock, and continue doing so for a couple of months, he would soon give his employes salutary object lessons that would result in a marked diminution of accidents from this cause. While a mine foreman can not keep his eyes on the miners at all times, he does and can come on them at unexpected times. If when he does this he finds them neglecting their own safety, he should enforce the rule with greatest rigor and accept no excuse. A few discharges will be enough. His men will soon learn that the boss means business, and that if they disobey his orders by neglecting to set necessary props or pull down a loose piece of slate, they lose their jobs. This duty should be impressed on the foreman by the superintendent or owner, and the foreman should instruct his assistants, if he has any, to enforce the rule as rigidly as he does himself. To make the rule effective, there must be no appeal from the discharge given by the foreman. His discharge for a violation of the rule should be final. Such action may seem harsh, but in reality it is not. It is calculated to work for the good of the miner. The mine foreman or superintendent who does not apply some such rule as this is not doing his duty, and he is in a measure responsible for the accidents.

STATE GEOLOGICAL SURVEYS.

OUR remarks last month on the desirability of making State Geological Surveys of permanent value, and of keeping them up to date, by the employment of a permanent State Geologist, and a small corps of assistants, has met with considerable favor in Pennsylvania. However, there is some opposition to such a plan from influential men, who appreciate the value of such reports as would naturally be issued. This opposition is due to a misunderstanding regarding the operations of the Second Geological Survey. It is claimed that the Second Geological Survey discriminated in favor of the anthracite coal fields, and against the bituminous fields of Western Pennsylvania. This statement is based on the fact that more reports were issued bearing on the anthracite fields than on the bituminous fields, which cover a far greater area.

Let us calmly look into this charge and see *why* such was the case. In the first place, the large anthracite companies, and many of the individual operators had competent corps of mining engineers who had been for years, and were at the time of the Geological Survey, actually making geological surveys. The cross-sections, maps and notes of these surveys were generously placed at the disposal of the State. The result was the State employees had ready made for them accurate and comprehensive surveys which needed only connections and intelligent compilations to make them available for reports. While some of the bituminous mining companies were equally generous to the officers of the survey, they did not have the elaborate system of surveys in force that were peculiar to the anthracite regions, and therefore a certain amount of work put on a bituminous field by the State did not supply one-fourth as much information as the same amount of work put on an anthracite field.

Again, the peculiar geological features of the anthracite fields made necessary more detailed reports than would have been required by the bituminous fields, even if the bituminous mine owners had been able to give the officers of the survey the most comprehensive maps, etc. In fact it was the peculiar geological features of the Schuylkill and Lehigh regions that made necessary geological surveys on the part of the mining companies.

It can be stated as an absolute fact that the mine owners and mine officials of the anthracite regions furnished fully seventy-five per cent. of the information in the reports and atlases pertaining to those regions. This statement is not intended as a reflection on the officers of the survey. They were bright, intelligent men, and appreciated the value of the surveys, etc., so freely donated to them. In fact, most of the officers of the Geological Survey had previously helped make some of the surveys donated.

The work of a State Geologist and his assistants, in the future, would be more in the line of completing the reports of other sections of the State than in doing any work in the anthracite regions. The anthracite regions are well surveyed and the geological features are well known to all interested. As much cannot be said of all our bituminous fields. Besides, there are other mineral deposits in Pennsylvania besides coal, that need attention. We therefore repeat that a permanent State Geologist for Pennsylvania will place a permanent value on the work of the Second Geological Survey, and will make forever unnecessary a complete resurvey of the State. Other States of the Union, now having geological surveys in operation, will be greatly benefitted by providing for a continuance of their surveys on a rational scale after the general and more expensive work has been done.

MINE EQUIPMENT CATALOGUES.

WE DESIRE to impress upon mine managers and superintendents the importance to them of manufacturers' catalogues in all lines of mine equipment.

Every enterprising maker of mining goods, as of others, is constantly making changes and improvements suggested by his experience and observation; and well-prepared trade catalogues secured at intervals form an excellent means of keeping informed on what such manufacturers are doing. And besides the catalogue feature proper, not a few concerns put out publications for gratuitous distribution to men interested as users of their goods, which are of decided merit and convenience as books of reference.

It involves no great expense or trouble on the part of any mining company to make suitable receptacles for filing and recording such publications and once done and its frequent replenishment properly attended to, it forms a veritable encyclopaedia of mining appliances. This, in case of accident or emergency might prove invaluable.

Many manufacturers, with good reason, are chary about sending out expensive catalogues until asked for them, as too often they go into waste-baskets unopened and unread, though they contain matter really valuable to the recipients. But these same manufacturers will without exception be more than glad to send their publications to any interested parties who will ask for such.

The advertising pages of THE COLLIERY ENGINEER AND

METAL MINER are a directory of leading makers of mine equipment, but from the nature of the case the advertisements cannot go into such detail as well-prepared catalogues. The advertisements point the direction in which to look for the best catalogues, and, we may say, for the best machinery.

In this connection we will suggest to makers of mining goods that in future editions of catalogues &c., they adopt what has come to be known as "standard" sizes for such publications. We recently saw in a mining engineer's office just such a collection of catalogues as we have herein suggested for mine managers generally to keep up, and while very valuable for reference, the variety in sizes and style of bindings used was enough to distract most men to whom order and convenience is some objective. Too often a catalogue, the real value of which is recognized by the recipient, is allowed to go to waste simply because its shape or manner of binding makes its preservation almost an impossibility. Good paper and typography are appreciated by all, but we fear some of these latter-day "works of art" in trade catalogues are not, and the result falls heavily on the men who pay the printer's bills.

In closing we desire to again emphasize the need of better appreciation by mine managers of catalogues and other trade publications, and, on the part of manufacturers, more careful regard for the convenience and patience of mining men when sending out printed matter.

LIFE OF THE WYOMING ANTHRACITE COAL FIELDS.

THE series of articles on anthracite coal, prepared by Mr. Wm. Griffith, E. M., of this city, for *The Bond Record*, of New York City, are not only very interesting, but of great value, especially to those financially interested in anthracite mining or anthracite stocks. His first instalment, which appeared in the February number, was of an historical nature. His second installment, for the March issue of *The Bond Record* is primarily statistical, but at the same time is accompanied by text that bears on and makes clear the statistics. The most important portion of the article so far published, from an economical standpoint, is the tabulated estimate showing the approximate future supply of coal tonnage from lands owned or controlled by the various railroads having access to the Wyoming region.

In analyzing this table it is necessary to have an understanding of the term "Foot Acres" used by Mr. Griffith. This term means that there are so many acres of coal one foot thick. In other words, 100 acres of land containing a 4 ft. seam of coal, would mean 400 ft. acres. In his estimates Mr. Griffith did not include any coal under 4 ft. in thickness. An analysis of Mr. Griffith's comprehensive table furnishes the following summary:

RAILROADS.	Original Contents of Land Owned or Controlled in Foot-Acres.	Contents of Land Remaining Unmined Jan. 1, 1896, in Foot-Acres.	Unmined Tonnage On Jan. 1, 1896, at rate of 650 tons per Foot-Acre.	Tonnage 1895. (Estimated).	Duration of Supply Based on 1895 Shipments.
Delaware & Hudson Canal Co	330,445	178,188	115,822,200	4,517,845	26 years.
New York, Ontario & Western Railway	37,290	21,494	13,971,100	1,424,467	9 "
Erie Railroad	97,549	59,816	38,879,400	1,820,028	21 "
New York, Susquehanna & Western R.R.	83,095	41,370	26,890,500	1,492,244	18 "
Erie & Wyoming Valley Railroad	224,854	145,964	94,876,600	1,746,832	54 "
Delaware, Lacka. & Western Railroad	686,517	511,280	332,332,000	6,129,260	54 "
Lehigh Valley Railroad	372,562	276,000	179,400,000	5,116,495	35 "
Central Railroad of New Jersey	642,733	534,925	347,701,250	2,790,692	124 "
Pennsylvania Railroad	255,773	155,917	101,346,050	1,962,996	52 "
Individual lands as yet undeveloped and not controlled by any corporative interest	41,401	41,401	26,910,650		
Totals	2,746,396	1,966,355	1,278,130,750	24,031,679	52 years.

A Great Electrical Mining Plant.

When the Westinghouse Electric and Manufacturing Company installed an alternating current electrical power transmission plant at Telluride, Colorado, in 1891, the electrical world was very much interested in the operation, because it was the first plant of its kind that had ever been installed in this country. The apparatus had been ordered by the San Miguel Consolidated Gold Mining Company, a corporation owning a vast area of gold-mining territory in the Colorado mountains. Hitherto it had been commercially impracticable to operate these mines, because the excessive cost of fuel and power at an altitude of 3,000 feet above the sea level made it prohibitive. It was then that electric power was suggested, which promised to overcome the difficulty, especially since the company owned a waterfall in the San Miguel valley, which contained a sufficient amount of water power to operate all their mines, if it could be made available.

It was then that it was suggested to Mr. Nunn, the general manager of the company, to investigate the Tesla polyphase system of electrical power transmission. This was done with the result that a contract was entered into and the Westinghouse Electric and Manufacturing Company asked to install a 100 horse-power A. C. generator and a 100 horse-power motor, with the necessary switchboard appliances. The generator was connected with a Pelton water wheel and the current was carried for three miles up the mountains to the Gold King mine. The wonderful success of this undertaking was established from the first. The owners of the San Miguel company have become so thoroughly convinced of this fact that they recently contracted for an extensive increase in the electrical plant. The additional machines were ordered from the Westinghouse company some time ago, and they are now being installed.

These machines are two 800 horse-power, 500 volt quarter-phase generators running at 7,200 alternations. These generators will be direct connected to two Pelton water wheels, and two 30 horse-power multipolar generators will be operated as exciters. While this machinery will be installed in the central power house, the company will have a number of sub-stations at the different mines throughout their property. Among these stations will be distributed twelve 50 horse-power polyphase Tesla motors, fifteen 20 horse-power polyphase Tesla motors, twelve 100 K. W., 100-11,000 volts, 2-phase-3-phase step-up transformers; ten 50 K. W., 10,000-220 volts, ten 25 K. W., 10,000-220 volts, and sixteen 10 K. W., 10,000-220 volts, step-down transformers. The motors will be attached either by belt or direct connected to operate stamps, pans, hoists, crushers, elevators or pumps. It is expected that this installation will prove the most complete electrically equipped mining plant in the world. The Westinghouse company will also furnish all the necessary switchboard apparatus with the plant.

Death of Mr. Nat. W. Pratt.

It is with sincere regret that we announce the death of Mr. Nat. W. Pratt, president of the Babcock & Wilcox Co., which occurred on the 10th ult. at his residence in Brooklyn, N. Y.

Mr. Pratt was born in Baltimore in 1852. He was a descendant, on both his father's and mother's sides, of the early settlers of Plymouth county, Mass., both branches of the family having settled there in 1630. His mechanical tastes were inherited, his father, William Pratt, having been superintendent of the Burnside armories, in Providence, R. I., during the war of the Rebellion.

Mr. Pratt entered the employ of the firm of Babcock & Wilcox when quite a young man in 1870. His energy, engineering qualities and remarkable business qualifications soon won the confidence of his employers. In 1881 when the Babcock & Wilcox Co. was organized as a corporation, he was made treasurer and manager of the new company, retaining this position until the death of Mr. George H. Babcock, in 1893, when he was elected president.

Combining engineering knowledge and inventive genius with extraordinary business qualifications, to his efforts were largely due the wonderful success achieved by the Babcock & Wilcox boiler throughout the civilized world.

As an illustration of his versatility, we would simply mention that in 1884 he became consulting engineer to the Dynamite Gun Co. Under his designs and patents the first successful dynamite gun was built. It was with this gun, 8 inch calibre and 60 feet long, that the experiments in throwing aerial torpedoes were conducted at Fort Lafayette, N. Y.

Mr. Pratt leaves an aged father and mother and also a wife and three children. He was a member of the American Society of Mechanical Engineers, of the American Institute of Mining Engineers, of the American Naval Institute, and a member of the Engineers' Club of New York City. His early death in the prime of life is a loss not only to the Babcock & Wilcox Co., but to the mechanical world at large. By his extraordinary sagacity and sound business judgment the business that engrossed his life developed and grew from a very small beginning to the enormous and world wide business of the Babcock & Wilcox Co. This enormous business and the world wide reputation of the Babcock & Wilcox boiler form the best monument that he could leave behind him. Mr. Pratt was noted not only for his sound business judgment and remarkable energy but also for his generosity and kindness of heart. Even his business opponents admired him for his singular aggressiveness as applied to business, and he was universally loved and admired by all with whom he came in contact both in a social and a business way.

Maryland Coal Statistics.

We are in receipt of the reports of the Inspector of Mines for Alleghany and Garrett counties, Maryland, for the years ending Dec. 31, 1894, and Dec. 31, 1895.

The output of coal for the year 1894 was 3,101,982 tons. The number of men and boys employed in and about the mines was 4,147. During the year there were seven fatal accidents, three of which were caused by falls of roof coal, one by fall of rock, one by fall of earth, one by fall of breast coal, and one by cars. During the year there were 13 non-fatal accidents, the causes of which are not stated.

An analysis of these figures shows that there were 443,140 tons mined for each fatality and 238,614 tons mined for each non-fatal accident. There were 748 tons mined per each employe and 1.688 fatalities per each 1,000 employes.

During the year 1895 the output was 3,479,499.15 tons, an increase of 377,517.15 tons over the production of 1894. The number of men and boys employed was 3,921, a decrease of 226 as compared with the preceding year. During the year there were 9 fatal accidents, one only of which was due to fall of roof coal. Five deaths were due to accidents with cars, etc.; one from injuries received from a circular saw; one from "injuries received in mine," and one from a natural sudden death. The number of non-fatal accidents was 13, the same as in the preceding year. Six of these accidents were caused by falls of breast coal and two by falls of top coal. The other five were caused by cars.

There were 386,611 tons of coal mined per fatality, and 267,654 tons per each non-fatal accident. There were 887.4 tons mined per employe, and 2.295 fatalities per 1,000 employes.

Montana Mining Statistics.

Captain C. S. Shoemaker, State Mine Inspector of Montana, has completed his report for the year 1895, but owing to lack of available funds, the report will not be printed until next year. The following extracts from the report we clip from the *Western Mining World* of Butte, Montana:

"It is gratifying to note that as the mining industry increases throughout the state, modern improvements are introduced, work is made easier, greater facilities are readily forthcoming, the cost of extracting ores is reduced and the science of mining is becoming so systematized that properties carrying low grade ores can be worked profitably.

"More care for the safety of the miners is now being exercised, as noticed in the greater number of precautionary measures adopted; also in the careful instructions given to employes and in the rules adopted in many mines.

"The improvement in ventilation throughout the state is noticeable and managers generally are looking after the health of their underground employes, and furnishing them with fresh air so far as can be consistently done.

"There are hundreds of good silver mines in Montana already opened which would be worked at once, and hundreds of others which would be opened and worked could the owners be assured of a steady paying market. I find very many gold properties and small mines are being worked now. Old gold mines that have lain idle or been abandoned for years are now being developed and many of them with good results. Prospectors during the past year have made many new discoveries and their search for the yellow metal will continue. While Lewis and Clarke county is a good gold producer, Jefferson county is also rich in the same treasure. Gold has been discovered in every county in the state in both placer and gold formation.

"I would recommend that all mines working below the 200-foot level should have not less than two exits. I consider that a valuation cannot be set upon the lives of those who work at such depth. Two or more exits supply the necessary fresh air and also means or ways of escape.

"I find the law governing the handling or storing of powder is fairly well complied with. With one single exception I have found no cause for complaint so far as a material violation of the law is concerned.

"I would recommend the use of chair indicators in all hoists. Their great value and use can hardly be estimated until after their utility has been demonstrated. These chair indicators will show the engineer at what station the chairs are in or when the shaft is clear for the passage of cage.

"I herewith give a table of accidents which have occurred since my incumbency. It is of some importance, statistically considered:

Year.	Fatal.	Non-Fatal.
1893	29	4
1894	27	19
1895	41	18

"While the average fatal is 28 and non-fatal 17 for 1893-94, the year 1895 shows an increase of 13 fatal and one non-fatal over the two preceding years. This is accounted for by the increased number of mines in operation in 1895.

"During my incumbency the number of mines inspected and miners employed therein are shown by the following tables:

Year.	Total Mines Inspected	No. Men Employed.
1893	56	4,399
1894	71	6,061
1895	82	6,337

"Of this number of mines inspected, there were in 1893 in Silver Bow county 28, in other counties 22; in 1894, Silver Bow 39; others 32; in 1895, Silver Bow 48; others 34.

"The coal mines in operation during these years were as follows:

Year.	No. Mines.	No. Men Employed.
1893	5	1,067
1894	7	1,021
1895	6	2,411

"The grand total of coal, and gold, silver and copper mines was as follows:

Year.	No. Mines.	No. Men Employed.
1893	61	5,332
1894	78	7,082
1895	88	8,758

"I will add to the total number of men engaged in steady mining, 1,242, who are working small mines and representing the large number of prospectors who are classed as miners. This gives a grand total of 10,000 men. I consider this number sufficiently large, as my estimate is made from actual observation and general information gathered in the mining districts."

Removal.

The Boston Belting Co., whose home office is at 256-258-260 Devonshire Street, Boston, notify us that on April 1st, owing to increasing business demands, their New York office will be moved to the large and commodious store at 100 and 102 Reade Street. They will occupy the ground floor, basement and sub-basement, carrying a complete stock of their manufactures, and they expect to have one of the handsomest mechanical rubber goods stores in New York.

THE PROGRESS IN MINING.

Abstracts From the Proceedings of the Mining Societies

And Journals of Europe and America, Illustrating the More Modern Developments in all Branches of the Mining Industry.

MANUFACTURE, USE AND ABUSE OF DYNAMITE.—Mr. Harry A. Lee, Commissioner of Mines of the State of Colorado, has written the following able article on the above subject:

The Dangers of Dynamite Manufacture.—Under the most favorable conditions the manufacture of dynamite is a hazardous business, safety being entirely dependent upon the purity of materials used and the skill and care of the workmen employed. In the manufacture of explosives, as in all lines backed by American ideas and energy, the American product stands pre-eminent. Although the first plant was established in this country only a little over 20 years ago, the art has to-day reached that point of perfection, brought feats of engineering within the range of possibility and exerted an influence upon modern civilization, which entitles it to take rank with the application of steam power.

The aim of the various powder companies is to supply a product which can be transported and handled with safety, which will give uniform results in blasting, keep in good condition when properly stored, and, as far as possible, neutralize all poisonous fumes when exploded. The explosives used almost universally throughout Colorado are compounds having nitro-glycerine for a base, commonly called by the miner "30 per cent. powder" or "60 per cent. powder," according to percentage of nitro-glycerine in the mixture.

The strength of the American nitro powder is not, as is generally supposed, wholly dependent for force upon the amount of nitro-glycerine present in the mixture. The compound is composed of various elements which in manufacture not only absorb the desired amount of nitro-glycerine but are in themselves an explosive. In blasting, the exploder or cap, which is charged with fulminate of mercury, explodes the nitro-glycerine and the nitro-glycerine, in turn, the remainder of the mixture. A line of experiments, conducted by experts, shows that the force exerted by this combination exceeds that of the sum of the three exploded separately.

The American dynamite of to-day is not an accident, but is the result of a long line of careful experiments, conducted by eminent chemists, and demonstrated by practical tests. These tests, aided by great advances in the art of manufacturing, have demonstrated that the products can be handled with greater impunity than many other things common to transportation by common carriers. They have also demonstrated that the safety of the compound is dependent upon purity of materials used and care in mixing. During the past few years competition among various powder companies has been so keen and bitter that gradually but steadily the cost of dynamite to the consumer has been reduced. It is a dangerous contest and a rivalry in which, sooner or later, if continued, safety will be sacrificed. To be more explicit upon this point—skilled labor commands a certain price, likewise chemically pure nitro-glycerine, the two being the most expensive parts in the compound of dynamite; combined the product is a safe mixture. Unskilled labor and impure nitro-glycerine can be had for less money, but the product of this combination is a mixture subject to decomposition. Decomposition in such a compound is practically explosion. Decomposition may not set in for some time, and the great danger of the competition, in the manufacture and sale of dynamite, is that of forcing some of the competitors to use impure or cheaper materials and labor, in order to meet a lower price, and take chances upon decomposition not commencing before the stock thus manufactured is disposed of. This danger point may not as yet have been reached. The older powder companies have much invested and a reputation to maintain; the newer companies have much invested and a reputation to make. From the standpoint of safety, however, the bottom price is very little below the market price of to-day.

The Storage and Age of Powder.—Powder should be stored in a dry, cool and well-ventilated magazine built for that purpose. A brick or stone magazine is preferable to a frame, both on account of being affected less by sudden changes in temperature and freed from any danger of bullets from careless marksmen. When built of wood the frame, or studding, should be covered inside and out with boards and so set that the air can circulate all around, and the inner boards be but little affected by the heat of the hot sun.

Caps should not be stored with powder.

Regarding the age of powder—when powder has had proper care in manufacture and storage, decomposition will not set in. If there is no decomposition there is no chemical change, and under these circumstances powder 10 years old or older is just as good and safe to handle as powder 10 days old.

One of the main sources of accident is from thawing powder, and the only safe plan is the use of heat from hot water. The powder should not be dipped in the water, but placed in a water-tight vessel and the vessel set in hot water, or a regular powder warmer should be made. These vessels can be obtained from any of the mechanical firms or from the powder companies, at nominal cost. Do not place powder under or on a stove, or in the oven. Do not lay on boiler wall or on back plate of a boiler. Do not heat around a blacksmith forge, or over a burning candle. Do not lay on hot sand, or, in short, do not thaw powder with dry heat. Do not consider these precautions unnecessary, or reason that because you have done so many times there is no danger. An explosion is usually fatal, and numberless escapes in no manner reduce the explosive force.

Freezing Temperatures.—Powder freezes at from 40° to 44° F., explodes, when confined, at from 320° to 360° F. From a quick application of dry heat, powder is liable to explode at 120° F. A stick of powder heated to 120° F. can be held in the hand with little inconvenience, and this degree of heat is soon reached when placed under or about a stove.

That frozen dynamite is liable to explode from heat quickly applied has been demonstrated many times, and to ignorance, non-appreciation or carelessness of this fact, most accidents are due. If you have heated powder about a stove for years without harm, consider yourself fortunate and stop it. If the warning of those who make the powder has no effect, let the accidents constantly occurring from this cause convince you. If you cannot procure a powder-warmer, take a 5-lb. lard bucket, fill it with powder, and set in warm water. If you have no warm water, put some sharp rocks in the bottom of a larger vessel to keep smaller vessel off the bottom, surround the inner vessel with water and set two lighted "snuffs" about an inch long under the big can, throw an ore sack over the whole, and in a short time the powder is in good condition for use and no has risk been incurred. With slow heat thus applied, dynamite may be heated to temperature of boiling water with safety. Do not use frozen powder to load a hole. It is unfit for use. If it explodes at all it will do poor work. If it does not seemingly burn or explode, it may be smouldering or decomposing, and the dropping in of a spoon, a drill or the stroke of a pick or hammer may be sufficient to explode what is left.

Do Not Hurry Back to a Shot.—Constant care in preparing charge and loading will avoid "missed holes." Next to warming powder with quick, dry heat, "picking out a shot" is the cause of the most fatal accidents. If a hole "misses," do not be in a hurry to return, and especially if the hole was tamped close. More accidents are caused from supposed missed holes than from actual. A small, sharp rock may be tamped into a piece of fuse so that the fire will not pass that point for hours; this is often mistaken for a "missed hole." The hole is picked out, this particular rock removed and an explosion follows. To fully demonstrate this, put some V-shaped clamps on a piece of fuse and see how long it will take to burn by certain points. Long after the fuse is supposed to be out, loosen the clamps and see how quickly it will "spit" at other end. Some holes do miss fire and have to be picked out. In these great care should be exercised to clean down not nearer than 5 in. from cap, then reload with another charge, and, instead of using a small piece of powder, use plenty. A heavy charge on top may destroy the effectiveness of the lower charge, but it will explode it and get rid of a bad job. If the "collar" of the hole is simply blown off and the lower charge has not broken to bottom of hole, do not drop in a drill or spoon to see "how much hole is left"; leave it alone as long as possible. The lower powder may have frozen and all may not have been consumed.

Caps are charged with fulminate of mercury, one of the most violent explosives and one of the most unstable chemically, and may explode from the slightest jar or least amount of friction. The caps at all times should be stored well away from the powder and at no time in or round a miner's pocket.

Powder should under no circumstances be stored underground. Poor ventilation with damp air will produce decomposition and decomposition explosion. There is practically no danger in transporting powder in cases and especially when frozen. Even well-thawed powder will not explode from any of the jars occasioned by a wagon haul or pack train. A case dropped several hundred feet upon rock might explode, but separate sticks would simply break out of the wrapper and no explosion follow.

Powder will burn in the open air and not explode, providing the gases generated in the adjoining powder from the heat of combustion have room to escape. For example, place two boxes of powder side by side, open one and ignite, leave the other box closed. The burning box will not explode, but the heat will explode the closed box.

* * *

SAFETY LAMPS AND SHOT FIRING IN MINES. The following is taken from an article in the *Pottsville Republican*, that was contributed by a mine foreman.

The safety lamp not a safe gauge of gas.—Personally speaking, and we have only our individual opinion to express, even though our say so don't make it so, we have never yet seen a real safety lamp, one in which a miner could with any degree of safety repose confidence. In the hands of a thoroughly practical and reliable man the Davy is an excellent detector, but in the hands of a careless or inexperienced person it is an instrument of destruction, being so constructed that a current having a velocity of eight feet per second will force the flame through the gauze and ignite the explosive mixture, or, where the current has a velocity of four feet per second and the velocity of a miner running from a blast or to escape a threatened fall of coal of rock, is equal to eight feet, the same result follows. Again, how frequently do we find instances where the miner hangs a "safety lamp" at the top of a prop as a warning of the approach of gathering gases; while his mind is occupied with some other duties the lamp becomes filled with the burning seething gas and before he notices its condition the fine wires are burned away, and before he can reach and remove the lamp there comes a blinding flash, a deafening report and dozens, if not hundreds, of valuable lives are sacrificed, their souls hurled without a moment's notice from time into eternity, while loving wives and children are widowed and orphaned, thrown upon the mercies and of a cold and unfeeling world. The mine itself is turned into a seething hell, whose victims writhe in torment, and those who have not been killed outright meet death by the noxious fumes of the stealthy afterdamp or atmosphere from which the life-supporting oxygen has been burned away, to say naught of the pecuniary loss to the operators, for in many instances after an explosion we have a mine fire on our hands, entailing heavy loss. With these facts so plainly set before us, we must look for a remedy whereby the cause may be removed that the danger may cease to exist, for we must admit that the gauze of a lamp is too weak a barrier between life and eternity.

Adequate ventilation required.—An adequate system of ventilation must be our next recourse. On this subject mine officials vary materially in their opinions, not only in regard to the various types of fans in use, but also as to the system of distribution. To the everlasting credit of the officials of the P. & R. C. & I. Co. be it said that they have adopted a system of ventilation at their collieries which can be relied upon in almost every instance and under all circumstances. With largest and most improved type of fan, direct acting engines, airways of large area, few doors and many overcasts, the column ascensional wherever possible, with the conviction that we are as powerless to stop the flow of noxious gases from the strata as we are to prevent the fall of rain from the heavens, and, regardless of expense, they are determined to pass through their workings such a quantity of air as will dilute and render harmless that hideous enemy of the miner. Their reward has been that although they own and operate some of the most gaseous mines in the anthracite basins, their quota of fatalities from explosions of gas is decreasing steadily, and if the employes would carry out the instructions of their superiors, who, as a rule, are men of a high order of intelligence, loss of life from this source would be indeed a rare occurrence, thus proving that if more time had been devoted to ventilation in the past, the appalling chapter of fatalities need never have been recorded.

Accidents from falls and blasting.—The fatalities resulting from this source are of every day occurence, and as long as the workmen will take the foolhardy risks which they do there can be no remedy. Seventy-five per cent. of these accidents are due to criminal carelessness on the part of the victim, insufficient timbering, undue haste in returning to the working face before the smoke from a shot has passed away. Neglect in dressing off the loose wings of coal from the rib or sides, too much confidence in the strength of top slate or coal, delay in taking down doubtful material or in making necessary examinations, greed or haste to load a large number of cars or take out a large amount of yardage. The object is gained, but eventually the miner or laborer pays the penalty with his life.

Josh Billings once said "Powder in itself is harmless; it is the fire makes it dangerous." Who among our miners would think of walking into a powder mill with a lighted cigar in his mouth? None you, say. Yet it is surprising the number of them who will sit in a pillar heading of about twenty-four square feet area, with a keg containing twenty-five pounds of powder in their arm, a naked lamp on their head, and very often a burning pipe in the mouth, and pour the loose powder into a paper shell, or tin can. Comment is unnecessary.

When shots have been charged with fuse the most careful miner will at times bruise or injure the fuse, so that the blast will fail to explode. Under no circumstances return to the face under twenty-four hours' time, and warn others to keep away.

Where shots are charged with the needle and fired by patent squibs, the squib is provided with a match of sufficient length to allow of the escape of the miner; if "touch" or gas squibs are used, the match should be lighted with "touch" paper, but never by a lamp or other blaze, as a slight waver of the air may cause the flame to reach the powder, and the result is invariably death. Do not tamper with the squib, and after lighting it give it ample time to explode the charge, for by returning too soon the miner is generally forced to pay for his haste with his life, and his name is added to the lists of deaths from "premature explosions."

Accidents on the roads.—A good rule to guard against this class of accidents is to enter the mine, proceed at once to your own working place, devote your time and attention to your own particular business, and, on leaving, guard yourself against moving cars, take time in getting on or off cars or cages, obey to the letter the mine law and the orders of your foreman and his assistants, and you will materially aid in reducing the chapter of accidents and preserving your own health and safety.

* * *

COLLIERY EXPLOSIONS AND COAL DUST.—(From the *Colliery Guardian*, by James Ashworth, M. E.) Again we have to deplore a colliery explosion in a district which is unfortunately noted for the magnitude of such accidents, but if on this occasion we are fortunate enough to gain an intelligible insight into the cause, the propagation of such explosions, and the way in which the forces generated expend their energy, we shall have gained information which, when practically applied, will conduce to the prevention of such great disasters in the future, and also in some measure atone for the sacrifice of human life and property in past explosions.

Many of our scientists have, in the course of experiments not directly connected with colliery explosions, discovered and elucidated facts bearing on this subject, and accompanied these facts with such sound reasoning that if their discoveries could be tabulated and brought to our notice we should be able to accept them without indulging in the small doubt which is popularly represented by the proverbial grain of salt. To enumerate these scientists would be a difficult task, and any attempt to do so would inevitably result in the leaving out of many whose useful and unostentatious labors entitle them to inclusion, and therefore the non-reference to such in the following paragraphs must not be thought to imply that their labors have been useless. One scientist whose labors appear to the writer to be especially applicable to this subject is Professor P. Phillips Bedson, D.Sc. of the Durham College of Science, Newcastle-on-Tyne, who has shown us that certain gases are occluded in coal dust, and that these gases are not of the same composition in all cases. Thus we know that fresh coal dust contains gases of the denser hydrocarbons, and that the enclosed gases are retained with varying degrees of firmness, also that the lighter gases, such as marsh gas and hydrogen, are the most readily removed. We also know that this fresh coal dust, being extremely fine, allows of the ready diffusion of its lighter gases (*a*) into the air, while the denser gases (*b*) remain for a time, and thus form the chief combustible constituents of the fresh deposited dust on the roadways. He has further proved that these denser hydrocarbons also in time diffuse into the air and are replaced by condensed oxygen (*c*). Thus we find that we have at the outset a most dangerous mixture, consisting first of coal dust lightly floating along in the ordinary ventilating current of the mine, and supported by the buoyancy of the gas which may be said to surround it, and which is continually diffusing, until at length it finds a resting place on the top of the timbering or on the roughnesses of the sides of the roadways. We have no means of readily estimating the quantity of gas thus continually present with us, but when such dust passes through a safety lamp, say, one burning hydrogen gas as its testing flame, it is at once seen that the presence of this dust makes the flame luminous, and therefore vitiates any test which we may desire to make for very low percentages of fire-damp. This fact alone shows us that the floating coal dust is of a very inflammable nature, and it will be even more evident when we consider that we have on the timbering and roughnesses of the sides of the roadways three layers of coal dust containing gases diffusing and diffused, thus, at the bottom, condensed oxygen (*c*), above that the denser hydrocarbons (*b*), and at the top of all, the lighter gases (*a*), finally diffusing from the newest coal dust.

Having now discovered what explosive ingredients lie hidden in coal dust, we next need to ascertain what information is available as to the temperature at which the above mentioned gases are given off. Professor Bedson tells us that the greater portion are given off at the temperature of boiling water, and that this fact is most emphatically true with regard to the lighter gases. He has also called our attention to a recent demonstration by Professor Victor Meyer, viz., that explosive mixtures of oxygen and ethane (C_2H_6) ignite at lower temperatures than similar mixtures of oxygen and marsh gas. And, further, that the Austrian fire-damp commission was led to conclude from the experiments they made that the sensitiveness of dusts increases with the proportion of easily-inflammable hydrocarbons, especially with the amount of ethane liberated at 100° C., and with the dryness of the dust. With respect to this question of dryness, it is to be observed that the Prussian fire-damp commission found the exactly opposite result in the course of their experiments—viz., that the drier sorts of dust gave the shortest flame. As to which of the three classes of dust previously named is the most dangerous, Professor Bedson says that that which by long exposure has absorbed a considerable volume of oxygen (*c*) must necessarily be easily ignited, and may lead to violent and explosive combustion. There is another point to note here—viz., that if the smallest percentage of fire-damp is present with coal dust, the burning effects are much more intense and the dust is more easily ignited. The importance, therefore, of knowing what gases are occluded in various seams of coal is clearly demonstrated.

Having found that gas is readily given off from coal dust at 100° C., we now want to know what degree of heat is sufficient to ignite coal dust. Again, taking Professor Bedson as our authority, and some of the upper dust from an engine haulage road in Washington colliery, adjoining Usworth colliery, as given in Messrs. W. N. and J. B. Atkinson's book on "Explosions in Coal Mines," as our sample, and which on analysis was found to consist of—

Moisture	2.5
Volatile matter	24.5
Fixed carbon (by difference)	57.8
Ash	15.2
	100.0

and also contained 1.69 per cent. of sulphur, we find that its temperature of ignition lay between 190° and 200° C. (374° and 392° F.). Another list of Professor Bedson's analyses may also be added from the same book, as they not only throw further light on the question of moisture, but are obtained from dust collected only thirty-three days after the Usworth colliery explosion and from the field of that colliery explosion:

	Moisture and volatile matter. Per cent.	Moisture. Per cent.
1. Coal dust from the floor near the shaft end of the stone drift	28.79	3.06
2. Coal dust from the air pipes in the stone drift	24.81	3.21
3. Coal dust from the floor of the crosscut haulage road	30.16	2.25
4. Coked coal dust from the traveling way between the middle and low north	20.41	1.70

Specimen 2, from the flanges of the air pipes in the stone drift, had feeble coherence, and may have been slightly coked. Further and more detailed information with regard to the ignition heat of coal dust will be found in Professor Bedson's report, as a member of the committee of the North of England Institute of Mining and Mechanical Engineers, appointed to inquire into a mysterious explosion which occurred in the air receiver and delivery pipes in the pit of an air-compressing plant at Ryhope colliery, on the 1st of March, 1880. In five out of ten experiments with 10 oz. of coal dust, ignition took place, with the temperature of the bath varying from 291° to 320° F. In none of the cases did the time from which the dust was placed in the bath to the moment of ignition exceed one hour. It was observed in every case in which ignition of the dust took place that immediately after the thermometer immersed in the dust began to rise, a peculiar odor, like "gob stink," was noted, soon followed by a rapid rise of temperature and a commencement of the burning of the coal was noticed by the experimenter. The readings of the air thermometer showed satisfactorily that after the coal dust reached the temperature of 356° F. the oxidation was then greatly accelerated and the thermometer rapidly rose to 392° F., after which it was no longer able to keep pace with the rise in temperature in the coal, then proceeding with such rapidity that in a few minutes—two or three—the coal took fire.

It was shown that with an easily oxidizable material, such as coal dust, it is only necessary to accelerate the oxidation by heating the dust in contact with air to a temperature within the limits of those likely to be reached in compressing air to 58 pounds in order to bring about the ignition of the dust. Two experiments were made with coal dust under air pressure, and it was observed that when the temperature reached 293° F. ignition took place, and that the combustion was vivid, and that a higher temperature was reached than when experimenting with air under ordinary pressure.

Principal Garnett, in reference to this explosion, said that there was one point he thought worth mentioning, and that was the increasing intensity of the explosion as it went down the shaft. The phenomena observed afforded a good illustration of what was known as "detonation" as distinguished from explosion. The explosion in the receiver started a wave of compression, which produced a sufficiently high temperature to cause the generation of combustible matter in the pipes. This combustion increased the temperature and the pressure, and thus a wave of compression went on increasing in intensity until it produced an explosion to further raise the temperature, and was capable of producing the stupendous effects observed at a distance of 200 fathoms from the receiver.

It has now been shown what gases may be found occluded in coal dust and also at what heat such coal dust may be ignited, and it remains now to consider, as being within the scope of this article, what gases are produced by mixtures of coal dust and air in the galleries of a mine. No actual sample of the after-damp produced from an explosion where coal dust has formed an important factor has, so far as the writer knows, been taken and analyzed. Mr. Atkinson took a sample some days after the Usworth explosion, but as this afterdamp was complicated with a standing fire, it cannot be accepted as a genuine sample of after-damp. The sample on analysis proved to consist of carbon monoxide 2.48, carbon dioxide 4.54, light carburetted hydrogen 8.68, oxygen 7.23, and nitrogen 76.80. With reference to this analysis, Messrs. Atkinson observe that carbon monoxide does not show on a safety lamp until the volume exceeds 10 per cent. The text-book composition of after-damp gives its most deleterious gases as carbon dioxide and nitrogen, but it has long been known that this statement was not found to agree with the effects produced underground, and it is now certain that Dr. Haldane, of Oxford, who was sent by the Home Secretary to examine the bodies of the men and animals killed in the Tylorstown explosion, and to ascertain the cause of death, will be able to say positively that the most fatal gas produced was carbon monoxide.

That there are other gases which have an important place in the composition of after-damp is also certain; thus, for instance, it is well known that explorers suffer from a smarting of the eyes and of the back of the throat, more often described as dryness. The writer was at one time of opinion that this smarting was caused by ammonia, but the late Dr. Carnelly told him that ammonia was only formed in actual colliery explosions by being distilled from the coal, as in the manufacture of ordinary gas, and that the smarting was probably due to oxides of nitrogen. Afterward, in the course of a lecture on "Colliery Explosions," he said "explosions in mines may possibly give rise to the production of oxides of nitrogen, and this may to some extent account for irritation produced in the eyes and throat on entering the workings after an explosion, for it appears that though the oxygen and nitrogen of the air unite directly with great difficulty under ordinary circumstances, yet they do so when a flash of lightning occurs, or simultaneously with the combustion of certain bodies in the air. Thus, if I burn some magnesium in this glass globe, it combines with the oxygen of the air, producing a brilliant light, and forms magnesia, but at the same time a small portion of the oxygen and nitrogen of the air unite to form oxide of nitrogen, which may be recognized by its smell, or better by dipping in the vessel a piece of paper moistened with potassium iodide and starch, which is turned blue, proving the presence of oxide of nitrogen. In a similar manner it is probable that the same substance may be produced during the combustion of fire-damp in air. Death by explosions is due not so much to the actual explosion as to suffocation by the carbonic acid or after-damp, and also to the highly poisonous action of the carbonic oxide—for the return fire proceeds backward so slowly that between the time of the actual explosion and the return of the fire to any particular point the atmosphere there will contain considerable quantities of carbonic oxide, and sufficient time will have elapsed for it to produce its poisonous effects."

A consideration of the initiation of a modern colliery explosion, based on the facts, experiments and analyses here tabulated, will make it quite clear that the actual presence of explosive gas, apart from that diffusing from and occluded within the coal dust, is not necessary to carry the explosion forward and throughout the whole length of the haulage road, because each particle of coal dust is either diffusing explosive gas or is charged with condensed oxygen. Moreover, the diffusion which is only proceeding at a normal speed may have this speed greatly increased by raising the temperature to or above 100° C. It has been shown, by quotations from Dr. Bedson's experiments, that compression of the air may not only raise the temperature to 100° C., and thus increase the speed of the diffusion of the contained gases, but that it will actually ignite the coal dust with the heat developed by the sudden air compression. When, therefore, a hot wave of sudden compression is set in motion by a blown-out shot or other cause, the instantaneous nature of the destruction of human life and property is clearly demonstrated. The chief thing necessary, therefore, to create an explosion in a dusty mine is the sudden production of sufficient energy at the point of initiation to produce a heat wave of high air compression, say 58 or more pounds per square inch, and that even greater energy than this is always exerted, may be calculated from one or more incidents of all large explosions, and as proved in one instance by Mr. A. L. Steavenson, who estimated that the mechanical force exerted had been equal to or exceeded 200 pounds per square inch.

***

APPARATUS FOR EXPERIMENTING WITH FIRE-DAMP.—The following is taken from the *Colliery Guardian*:

A strong iron chamber for testing.—For the purpose of studying the action of various mixtures of air and fire-damp on the safety lamp flame, the mining engineers of Ostrau (Austria) have devised the apparatus forming the subject of the present paper, the main idea embodied in its construction being to establish the conditions actually existing in practice.

The main body of the apparatus consists of a case or conduit of strong iron plate fixed against a wall and supported by a couple of brackets clamped on to the latter. The case, which has a total length of about 4 m., is composed of two U-shaped pieces of plate, arranged laterally and connected by two flat plates forming the top and bottom, so that the transverse section measures internally about 40 × 40 cm. One end of the apparatus is left open, and into the other is inserted a jet for the admission of steam to induce a current of air through the case from the open end, the intensity of the draught being, of course, controllable by regulating the pressure of the steam issuing from the jet.

At about two-thirds of the distance from the open end of the case a circular opening is made in the bottom, and into the projecting collar from this is fitted a shouldered cylinder about 6 cm. or 8 cm. deep, forming a receptacle for the lamp. A small rectangular hole is cut at the side of the case for the purpose of observing the flame, and is closed by a pane of glass about 15 mm. thick. To deaden vibration and form an elastic cushion whereby the glass is enabled to stand the shock of explosions which would otherwise shatter it, a frame of caoutchouc is interposed between the glass and the iron plating. Two other square openings, fitted with covers are also situated near the lamp and are intended to act as safety valves in case the gaseous mixture becomes ignited. They are balanced by counterpoises, and the joints are made tight by a layer of caoutchouc; in this manner the apparatus is preserved from the risk of damage from the frequent explosions it has to withstand.

How the air and gas are mixed.—The air, after entering the open end of the case, passes through a plate of thin copper, perforated by twenty holes of exactly equal size; the dimensions of these apertures being accurately measured give the complete section of the current of air admitted into the apparatus. The fire-damp is introduced through a pipe fitted with a regulator cock. This pipe, terminating at a distance of about 1.50 m. from the the lamp, ends in a lyre-shaped box of copper surrounding the outer case, the two arms being pierced by a couple of holes on the inner side, and united by a copper pipe passing through the walls of the apparatus by way of a couple of perfectly tight joints and pierced by a great number of openings, through which the gas streams in. Before reaching the box the gas is made to pass through an arrangement to enable the section of current entering the testing apparatus to be accurately determined. This is effected by interposing between two joints a metallic plate pierced with holes of known diameter. In this manner the amounts of air and gas entering the apparatus are known exactly.

In order that the experiment may be conclusive, it is necessary that the gas and air shall be intimately mixed by the time they reach the lamp. For this purpose the mixture is made to pass a series of baffles of various kinds which have the effect of finally making it homogeneous. In the first place there is a copper plate pierced with a series of small holes to reduce the sectional space. This is followed by several sets of vertical rods, which mix the gases still more, and finally by three plates of wire gauze of very fine mesh placed close together and which complete the operation. The regularity of the mixture has been demonstrated by taking a number of samples, all of which showed the same percentage composition. Another function performed by the gauze plates is to prevent the lighting back of mixtures exploded by the lamp.

The volumes of the mixed gases.—The apparatus is, however, incomplete, without an arrangement for determining the quantity of gas and air under test, and for this purpose a couple of pressure-gauges are required, one to measure the pressure of the air and the other to indicate the pressure of the fire-damp, the former being in communication with the open air, and the latter connected at both ends with the pipe conveying the gas to the testing apparatus. Both work in the same manner, one measuring the pressure of the air in relation to that of the atmosphere and the other the pressure of the fire-damp entering the box, as compared with that existing in the mine, this latter being known precisely.

Working exactly alike, a description of one of these gauges will suffice for both, if the modifications in the second one be detailed. The gauge is formed of a column of copper, graduated in millimetres, of triangular section, but with one of the points of the triangle replaced by a rectangular strip. Two runners connected by a screw to regulate their distances from each other, move along the column. This screw engages in a fixed nut on the lower runner and moves freely in a collar on the upper one, so that—as will be readily understood—by turning the screw one way or the other the runners can be fixed at any desired distance apart. The movement is controlled and excessive separation prevented by a semi-circular spring. The upper runner has attached to it, at the side, the measuring bottle fitted with a vernier sliding over the graduated scale. This bottle terminates below in a caoutchouc U tube, which itself forms a continuation of the glass column of the pressure-indicator. Another caoutchouc tube connects the column with a mouthpiece leading into the testing apparatus.

The mode of working the apparatus is simple. Whilst the internal pressure exactly balances that on the outside, the water in the bottle is adjusted to the level of the zero of the gauge, and thus the super pressure is determined.

LEGAL DECISIONS ON MINING QUESTIONS.

(Reported for THE COLLIERY ENGINEER AND METAL MINER.)

Mining; The Right of Support.—Where the mineral estate in land is severed from the surface by a conveyance, the owner of the former is bound to leave enough of the mineral in place to support the surface, unless the owner of the latter has released his right of support. The release must be by express words or by necessary implication.

Robertson v. Youghiogheny River Coal Co. (Supreme Ct. Pennsylvania) 33 Atlantic Reporter, 706.

Engineer and Draughtsman; Partner or Employe.—A contract reciting that in consideration of a salary of a certain amount per annum paid by a firm to a party, and a further consideration of a certain share in the net profits of the business of the firm, the second party agreed to devote his time to their business as an engineer and draughtsman, is a contract of employment and not of partnership.

Porter v. Curtis (Supreme Ct. Ia.) 65 N. W. Reporter, 824.

Unsafe Place to Work in Mine.—In an action by an employe of a mining company for injuries due to the falling of the roof of a coal mine where he was working, evidence of the condition of the roof for a year prior to the injury, when connected with evidence of the existence of the same condition until the injury, is admissible to show notice. It is also proper to admit evidence showing that the part which fell could have been propped up.

Island Coal Co. v. Neal (Appellate Court, Ind.) 42 N. E. Reporter, 953.

Mining Claims.—In an action to determine the right to proceed in the United States land office for patent on certain mineral land, a party having offered in evidence the receiver's receipt for entry thereon, which by the laws of Montana is prima facie evidence of title to the land, the one sued may give in evidence decisions of the land office, made on a protest against the issuance of patent to the first party, cancelling the receipt for fraud in obtaining it.

Murray v. Polglase (Supreme Ct. Montana) 43 Pacific Reporter, 505.

What Constitutes a Mining Lease.—A contract reciting that the land-owner assigns to the other party all minerals on the land for a term of years, "to farm," and that such other party shall have the right of way over the lands on condition that he pay the land-owner a percentage of the profits made from mining the minerals, is a mining lease which is forfeited by failure on the part of the lessee to mine the minerals within a reasonable time.

Shenandoah Land & Anthracite Coal Co. v. Hise (Supreme Court App. Va.) 23 S. E. Reporter, 303.

When Lien Will Not Attach to Mining Property.—Where in an action to foreclose mechanic's lien it conclusively appears from the record that credit was given to the party in possession of the property under an option to purchase and not to the owner of the property, such liens will not, on the failure of the party in possession to whom credit was given to avail himself of his option be enforceable against the owner of the mining property.

Steel v. Argentine Min. Co. (Supreme Court, Idaho) 42 Pacific Rep. 585.

Conclusiveness of Surveys.—The official survey made of a Mexican land grant, after the grant has been confirmed by Congress, is conclusive as against any collateral attacks in the courts, and in an action to quiet title, by one claiming under the grant lands lying within the survey, against one claiming the same under a subsequent homestead entry, evidence by the latter that the survey was incorrect and that a correct survey would have excluded the lands in question, is inadmissible.

Colorado Fuel Co. v. Maxwell Land Grant Co. (Supreme Ct. Colo.) 43 Pacific Reporter, 556.

Pneumatic Drilling Tools—Patentable Invention.—Patentable invention was involved in bringing together, and adapting in size, proportion, and relation, the various parts necessary to form a cylindrical pneumatic drilling tool, which may be held in, and guided by the hand, while at work, even though like parts, operating by steam or air, in engines of various sorts, were previously known. Therefore the Bates patent, No. 364,081, for a pneumatic drilling tool, is infringed by a tool made in accordance with the Drawbaugh patent, No. 472,495.

Fisher v. American Pneumatic Tool Co. (U. S. Cir. Ct. App.) 71 Federal Reporter, 523.

Sufficiency of Proof of Mining Partnership.—Where it appeared, on an issue as to whether a party suing and another were partners in working a mine, that the lease thereof was in the name of the first party and a third person, because the latter would not have the name of the second party in it; that an alleged written partnership agreement was lost, and the testimony relative to it was vague and indefinite; and that it was not shown that the second party ever participated in the working of the mine, or shared the profits and losses; but that the first party assumed ownership and control, the Court of Appeals of Colorado held that there was no sufficient proof of partnership.

Hodgson v. Fowler, 43 Pacific Reporter, 462.

Hazardous Employment.—In an action to recover damages for the loss of a hand, it appeared that the party suing had been employed to drill holes, was directed by his foreman, without being instructed or questioned as to the nature of the attendant danger, to draw a charge of gunpowder and dynamite; that this party was experienced in gunpowder blasting, but did not know that the charge contained dynamite; that in his efforts to draw it, it was exploded. The court held that negligence was chargeable to the foreman, but not the party bringing the action; but that in such an action, the direction of the foreman was that of a fellow servant, and not that of the employer.

Vitto v. Farley (Com. Pl. N. Y. City) 36 N. Y. S. Reporter, 1105.

Coal Mining in Indiana: Weighing Product.—Act March 2, 1891, Laws of Indiana, requires coal mined under contracts providing for payment by specified quantity to be weighed before being screened and the full weight credited to the miner, provided that the payment for impurities loaded with or among the coal shall not thereby be compelled; section 7 provides the penalty. The Supreme Court of that state holds that, a conviction for failure to weigh before screening was improper, where the evidence for the prosecution showed that the coal mined was of such character that it was impossible to weigh the coal before screening, and credit the miner with the weight, without giving him credit for the impurities among the coal.

Martin v. State, 42 N. E. Reporter, 911.

Mining Partnership.—Where tenants in common in a mine form a partnership for the operation of the mine, without the mining property being brought into the partnership as a portion of the capital stock, the property does not for the purpose of payment of partnership debts become partnership property, as between a purchaser of one partner's interest in the mine and the remaining partners. In such a case the purchaser, as incoming partner, does not become liable for debts contracted by the partnership prior to the time at which he became a member. A member of a mining partnership is liable, as between the parties, for his proportionate share of the salary of an employe appointed by a majority of the members over his objection, such partner having reaped the benefit of the employment.

Patrick v. Weston (Supreme Ct. Colo.) 43 Pacific Reporter, 446.

Liability of Director of Mining Corporation.—The law of California declares it the duty of the mine superintendent to file weekly and monthly accounts and reports, verified under oath, showing receipts, disbursements, number of employes, and wages paid, reports to be kept in the office of the company, open to inspection of the stockholders. It further provides that in case of the failure of the directors to have the reports and accounts made and posted as provided, they shall be liable to an action by any stockholder, who, on proof of the failure, shall recover judgment for $1,000 liquidated damages. The Supreme Court of that state held that, the statute being remedial, and there being no ambiguity in it, recovery could be had of the directors for failure to have the accounts and reports of the superintendent verified by him, though they were full, true and correct, and there was no one within many miles of the mine who could administer oaths, and the directors acted in good faith, and had been advised by counsel that it was not necessary to have them verified. Under such statute, it is not necessary to prove damages. They will be implied from its violation.

Shanklin v. Gray, 43 Pacific Reporter, 399.

Pollution of Stream by Mining Company.—The Court of Chancery of New Jersey holds that, it is no defense to a bill by a riparian proprietor to restrain a mining company from polluting by discoloration, the stream, to show that the discoloration is the natural and necessary result of mining operations prosecuted in the ordinary way. Such result may amount to a nuisance, and its maintenance cannot be legalized by the legislature, even upon terms making compensation for the damage, and where the right is clear, and the facts undisputed, a court in equity is bound to give preventive relief; to refuse it is to allow such mining company to take the property of another upon terms of paying such compensation, from time to time, as a jury may allow. Where there is some danger of the occurrence of the discoloration in the future, the decree establishing the rights of the complainant should include a provision for a perpetual injunction.

Beach v. Sterling Iron & Zinc Co. 33 Atlantic Reporter, 286.

Spur Veins and Measure of Damages.—Where a party is adjudged the owner of a vein, having its apex within his location, dipping to the north, and extending under the location of another company, which lay north of this vein; and it appeared that there were certain ore bodies lying south of the vein and under it, with reference to vertical location, and that the ore had been taken by such company from such bodies, such ore bodies, since they could upon no theory have a separate existence, extending through said vein, and giving them an outcrop on the location of the company, should be regarded as having some connection with and belonging to the vein of the first party, and thus entitle him to whatever was in them.

The proper measure of damages in an action against the company for unlawfully taking such ore, when the company was not a wilful trespasser, is the value of the ore taken, less the cost and expense of breaking it and bringing it to the mouth of the mine; and where the ore has been taken out by a lessee of said company, it having received a royalty upon the ore, such royalty may be taken as its net profit.

Colorado Cent. Consol. Min. Co. v. Turck, 70 Federal Rep. 294.

What Constitutes a Mining Partnership.—A contract providing that the one party should have a certain undivided interest in all ores extracted from certain mines, and should bear a proportionate share of the expenses in extracting the same, the other parties to have the remaining interest in the ores, and to bear the balance of the expense, and also that the first party should furnish a mill for concentrating the ore, the expense of concentrating and rental of the mill to be divided among the parties, renders them partners in the extraction of the ores, and a subsequent verbal agreement that the first party should receive a certain price for each ton of ore concentrated, to be paid from the proceeds of the ore, he to pay the rental of the mill, repairs and improvements, does not prevent the parties from being partners.

After the formation of a mining partnership, an agreement that one of the parties shall ship the ore after concentration, receive the proceeds, and pay out the money under the direction of another partner, who was to manage the mine, does not affect their relations as partners.

Ashenfelter v. Williams (Court of App. Colo.) 43 Pacific Reporter, 664.

Negligence of Vice-Principal in Mining Operations.—The Supreme Court of Colorado, in considering the question of responsibility of a company for the acts of its representatives, said: There are decisions which hold the master liable for any acts done by the vice-principal, whether they were such as relate generally to the duties which the master owes to his servants, or whether the acts be merely on a level with those of a fellow-servant; but, the better rule, as we extract it from the best reasoned cases, is that for the acts of the vice-principal, done within the scope of his employment, and such as properly devolve upon the master in his general duty to his servants the master is liable; while for all such acts as relate to the common employment, and are on a level with the acts of the fellow employe,—except such acts as are done by the vice-principal against the reasonable objection of the injured servant,—the master is not responsible. In other words, the test of liability is the character of the act, rather than the relative rank of the servants.

Deep Mining & Drainage Co., v. Fitzgerald, 43 Pacific Reporter, 210.

Location of Mining Claims.—A party discovered a mineral lode, and posted on the spot a notice claiming the right to locate 1,500 feet on the lode and 300 feet on each side of it, naming it the "R. J. Lode" and also claiming the right to have 20 days in which to complete his boundary monuments. He afterwards went to the premises to mark the boundaries, but was prevented by sickness, but within 20 days he agreed with three other persons to give them half the claim if they would complete the location, which they did by setting up monuments at the corners and on the lines, and posting a location notice, describing it, in which the claim was called the "R. J. Gold, Silver and Nickel Quartz Mining Claim." The United States Circuit Court of Appeals held that the location made by the associates was a completion of the claim made by the first party, notwithstanding the addition of descriptive terms to the name of the claim in the notice posted by them. Also, that the first party had a right to transfer by parol an interest in his right to locate his claim to his associates, and his doing so and permitting them to complete the location was not an abandonment of such right.

Also, that the discoverer of a mineral vein should have a reasonable time after his discovery to complete his location, the length of time depending on the nature of the ground, the means of marking it, and the ability to ascertain the course or strike of the vein, and that in the case stated 20 days was not an unreasonable time, the vein being situated on a rough mountain side, the dip not exposed, and 1,000 feet of the vein covered.

Doe v. Waterloo Mining Co. 70 Federal Reporter, 455.

Safe Place for Employe to Work In.—Evidence that a rock fell from a place where a party had been blasting, striking one of his employes, at work below, and that a prudent examination would have detected the danger, shows a failure of the duty of the employer to provide his employes a place in which to work. The court said: A fair opportunity to avoid harm is sufficient to impose upon a person the peril of his conduct, if, when judged by common experience, he is blameful for his act. It may now be assumed that the stone which fell and produced the injury had been detached and loosened by a blast two or three days prior to the injury. Ordinary knowledge and experience teach us that the inspection and examination of the rock would have detected the insecurity and danger of the place where this man was set to work. The menacing position of the stone was easy of discovery. Under the rules, the employer was bound to give the reasonable inspection that a man of ordinary prudence would give. He was bound to see whatever a prudent, intelligent man would have foreseen. Negligence arises from imputed or presumed foresight. In fact, negligence may be said to be want of foresight. The circumstances that make men liable for their acts or omissions must be determined by experience; that is, whether the circumstances under which an act is committed are sufficient to sustain a charge of negligence must be determined by the common experience of mankind. The care which the law demands of the employer cannot be delegated to an employe, so as to exonerate the employer from responsibility to an employe who has sustained injury by reason of its nonperformance. Very different are the duties which the law imposes upon the employe; while he accepts the risks and hazard of the service in which he voluntarily engages, and must contribute the exercise of his faculties, he may assume that the employer has performed his duty and used all reasonable diligence to make the place where he labors safe and secure. He assumes only the risks which are ordinarily incident to the employment, from causes which are open and obvious, or which are announced to him in advance. He does not assume the risk of his employer's negligence, and the latter is negligent if he fails to discover insecurities and dangers which could be determined by the exercise of reasonable care.

Perry v. Rogers (Supreme Ct., 2nd Dept.) 36 N. Y. S. Reporter, 208.

TEMPERATURES AT GREAT DEPTHS.

At What Depth and Temperature Can Miners Work?

Mr. Agassiz says, for several years past he has, with the assistance of the engineer of the company, Mr. Preston C. F. West, been making rock temperature observations as they increased the depth at which the mining operations of the Calumet and Hecla Mining Company were carried on. They had now attained at their deepest point a vertical depth of 4,712 ft., and had taken temperatures of the rock at 105 ft.; at the depth of the level of Lake Superior, 655 ft.; at that of the level of the sea, 1,257 ft.; at that of the deepest part of Lake Superior, 1,633 ft.; and at four additional stations, each respectively 550, 550, 561 and 1,256 ft. below the preceding one, the deepest point at which temperatures have been taken being 4,580 ft. They proposed when they had reached their final depth, 4,900 ft., to take an additional rock temperature, and to then publish in full the details of their observations.

In the meantime they thought it might be interesting to give the results as they stood. The highest rock temperature obtained at the depth of 4,580 ft. was only 79 degs. Fahr., the rock temperature at the depth of 105 ft. was 59 degs. Fahr. Taking that as the depth unaffected by local temperature variations, they had a column of 4,475 ft. of rock with a difference of temperature of 20 degs. Fahr., or an average increase of 1 deg. Fahr. for 223.7 feet. "This," says Mr. Agassiz, "is very different from any recorded observations. Lord Kelvin, if I am not mistaken, giving as the increase for 1 deg. Fahr. 51 ft., while the observations based on the temperature observations of the St. Gothard Tunnel, gave for an increase of 1 deg. Fahr. 60 ft. The calculations based upon the latter observations gave an approximate thickness of the crust of the earth, in one case of about 20 miles, in the other of 26. Taking our observations, the crust would be over 80 miles, and the thickness of the crust at the critical temperature of water would be over 31 miles, instead of about 7 and 8.5 miles as by the other and older ratios. With the ratio observed here, the temperature at a depth of 19 miles would only be about 470 degs. Fahr., a very different temperature from that obtained by the older ratios of over 2,000 degs. Fahr.

"The holes in which we placed slow-registering Negretti and Zambra thermometers were drilled, slightly inclined upward, to a depth of 10 ft. from the face of the rock and plugged with wood and clay. In these holes the thermometers were left from one to three months. The average annual temperature of the air is 48 degs. Fahr., the temperature of the air at the bottom of the shaft was 72 degs. Fahr.

Mr. Edward Hull, in his work on "The Coal Fields of Great Britain," made an enquiry into the physical limit to deep coal mining, and he states that in Paris, at an artesian well sunk to 550 yards, the general result in chalk was found to be 1 deg. Fahr. increase for every 60 ft. beyond the normal; in Westphalia, a similar boring was carried to a depth of 768 yards, and the result was an increase of 1 deg. Fahr. for every 54 ft. Near Geneva an artesian boring gave 1 deg. Fahr. for every 55 ft. At Mondorf, says Mr. Hull, an artesian boring gave 1 deg. Fahr. for every 57 ft., and he gives details as follows:—

	Yards.	
Lias	59.15	about
Keuper	226.02	"
Muschelkalk	156.17	"
New red sandstone	342.00	"
Old schistose rocks	17.32	"
	801.26	

In the Tresavean mines in Cornwall, Mr. Hull goes on to say, the depth is about 2,112 ft. and the temperature was between 90 degs. and 100 degs.; this result would give an increase of 1 deg. for every 56½ ft. At the Monkwearmouth colliery, experiments showed an increase of about 1 deg. for every 60 ft. At the Dukinfield colliery, during the course of sinkings, the thermometer was inserted in a dry bore-hole and removed as far as possible from the influence of the air in the shaft, and left in its bed for a length of time, varying from half an hour to two hours. The sinkings went down at that time to 2,055 ft. There were also observations made in the open workings at 120 yards from the shaft, and at a depth of 2,151 ft. The first of these observations gave 51 degs. as the invariable temperature throughout the year at a depth of 17 ft. Between 231 yards and 270 yards it was nearly uniform at 58.0; and the increase from the surface, says Mr. Hull, would be at the rate of 1 deg. Fahr. for 88 ft. Between 270 and 309 yards the increase was at the rate of 1 deg. for 62.4 ft.; between 309 and 419 yards the increase was at the rate of 1 deg. for 60 ft.; between 419 and 613 yards the increase was at the rate of 1 deg. for 86.91 ft.; between 613 and 685 yards the increase was at the rate of 1 deg. for 65.6 ft. The result of the whole series of observations gives an increase of 1 deg. for every 83.2 ft.

Mr. Hull adopts 50.5 degs. Fahr. as the standard of departure—or, in other words, as the temperature of no variation at a depth of 50 ft. underground—and then adding 1 deg. for every 70 ft. beyond the first fifty, and taking into account the increased density of the air, he considers the theoretical increase of temperature at several depths would be found as follows:

Depth in feet.	Increase of temperature due to depth.	Increase of temperature due to density of air.	Resulting temperature.
1,500	21.42	5.0	76.92
2,000	27.85	6.5	84.85
2,500	35.5	8.5	94.00
3,000	42.14	9.83	102.47
3,500	49.28	11.66	111.44
4,000	56.42	13.16	120.08

Mr. Hull did not consider our miners could work at a higher temperature than that of 94 degs.—almost that of the tropics. But he thought it would be possible to reduce the heat even of a mine 4,000 ft. in depth to a degree not only tolerable, but admitting of healthy labor, and it was for that reason he fixed the limit of possible coal mining operations at 4,000 feet.—*American Journal of Science.*

FOUNDATIONS.

The Importance of Good Foundations for Machinery and How to Secure Them.

By Walter H. Mungall, B. Sc.

(From Transactions of British Society of Mining Students.)

The importance of a sound and unyielding foundation for machinery or other erections has long been realized, and at an early stage in the work of opening and fitting a new colliery, the engineer has to turn his attention to this subject. The first engine that is to be used in sinking a shaft requires to have a foundation previously provided for it. Boilers and chimneys; the permanent winding, pumping, and haulage engines; head-gear and screening plant all require foundations. In the present article, the subject will be dealt with only so far as it lies within the province of the mining engineer, and it is not intended to enter into any discussion of the theory of foundations.

A foundation in its simplest form consists of an excavation in the ground of such form and dimensions as will give a firm base for the superstructure. Such a foundation is all that is required for comparatively light structures, not subject to sudden and severe strains. But for most structures about a colliery such a foundation is quite inadequate, and the excavation is partially or completely filled with some material which will form a firm and solid base. In many cases, as for example in the case of a pulley frame, the area of the base of the structure is small in comparison with the weight upon it, and the pressure per unit area is consequently great, greater often than simple earth foundations can resist. To reduce the pressure per unit area it is customary to form the excavation of sufficient size, and subsequently to fill it with some solid material as masonry, brickwork, or concrete, through which the pressure is distributed to any desired extent. Before proceeding with the construction of foundations, the first thing to be ascertained, after an acquaintance with the nature of the ground, is the approximate weight to be supported, and the foundations must be so designed that the pressure per unit area will be well within the limits of safety. The direction of the pressure must also be taken into account, and the base of the foundation should be formed as nearly as possible at right angles to the direction of pressure upon it. As a general rule also, the line of the resultant pressure on a foundation should pass through the center of gravity of the foundation, or as near thereto as possible.

In some few cases a firm and sufficient foundation is readily obtainable on rock, in which case all that is necessary to prepare it for the superstructure resting on it, is to cut away all loose or decayed parts, and to hew or dress the surface of the rock to suit the form and pressure of the structure to be erected. When the surface of the rock is irregular, it may be necessary to fill hollows in it with masonry or concrete. It is customary in engineering practice to allow for stone structures a factor of safety of not less than eight, and for foundations on rock the pressure should not exceed, at any point, one-eighth of the pressure required to crush the rock. Experiments on the crushing pressure of rocks have from time to time been made by various engineers of eminence, the average results of some of which are given in the subjoined table:—

TABLE OF THE STRENGTH OF ROCKS.

	Crushing Stress, lbs. per sq. in.
Sandstone (strong)	5,000 to 9,000
" (weak)	2,000
" (ordinary)	3,000 to 5,000
Limestone, compact (strong)	8,000
" magnesian (strong)	7,000
" " (weak)	1,000
" granular	4,000 to 4,500
Chalk	200 to [illegible]
Whinstone (basalt)	9,000 to 17,000
Granite	6,000 to 11,000

Where the rock surface is not accessible for forming the foundation, the base of the structure has to be rested on the earth above the rock and the total pressure must be more or less distributed as the earth is softer or firmer. In firm earth, such as hard clay, clean sharp sand, or firm dry gravel, the greatest pressure in general engineering practice is from 2,500 to 3,500 pounds per square foot of bearing surface. For a superstructure that is in itself heavy, or that has to support a heavy load, or that is liable to severe strain, the foundation base must be made of such area that the pressure per square foot will not exceed the above limit. Usually the footings or lower courses of ordinary masonry or brickwork, as of an engine house, have an additional breadth or "spread" equal to one-and-a-half times the thickness of the body of the wall when built on compact gravel, or of twice that thickness when built on sand or stiff clay.

Before building on *soft* earth, additional precautions must be taken with regard to the foundations, and some other expedient must be adopted than those applicable to firm earth foundations. Of course there are degrees of softness, and no general rule can be laid down applicable to the variety of cases that may occur in practice. The simplest class of foundations on soft earth are those already referred to as applicable to firm earth, with this difference, that the base must be further increased to reduce the pressure per unit area. When softer earth, as peat moss, soft alluvial clay or silt, with, in some cases, a natural slope of one vertical to eight or ten horizontal, is met with, of considerable depth, other methods have to be adopted. These generally entail the use of timber or iron. Timber platforms are usually constructed by forming a grating of crossed beams of elm or oak which in turn is covered by planking on which the superstructure rests. The beams employed are usually from 10 to 12 inches square, and laid about three feet apart, the spaces between being filled with concrete.

The method usually adopted, however, for securing a good foundation in very soft ground is by piling. Piles are usually of square or round timber from 6 to 9 inches diameter for piles from 6 to 12 feet long, and larger in proportion to the length, the ratio of diameter to length being in general about one to twenty. In setting the piles they are placed as close together as practicable. When piles are driven to form a rectangular or circular foundation, the outer circuit of piles should always be driven first, the work being finished at the center. The piles may be surmounted by a platform as above described, or simply by a layer of concrete. The most suitable timber for making piles is elm. In general practice the limits of pressure on pile foundations may be taken at 1,000 pounds per square inch of head area when the piles are driven till they reach firm ground, or 200 pounds per square inch of head area when the frictional resistance between the timber and the earth is the only support. In all cases where timber is thus employed in foundations, care should be taken to keep it entirely removed from the influence of the atmosphere, and to keep it wet, otherwise it will soon decay.

Engine foundations, as a rule, require to be raised sufficiently high above the surrounding ground to give clearance for the fly wheel, drum, or gearing, or for other purposes, as also to form a sufficient weight to which to fix the engine. Engine foundations may be constructed of timber, brickwork, masonry, or concrete. For permanent work timber foundations are not to be recommended, as they are liable to early decay, but for temporary winding or pumping engines at a sinking shaft they form a convenient, simple, and cheap foundation. They are easily built and easily removed, and the material may subsequently be used for similar or other purposes.

One form of engine foundation, now almost obsolete, was built of ashlar masonry, the stones being of large size, each measuring about ten cubic feet, the usual dimensions being 4 feet by 2 feet by 15 inches thick. Stones of larger size are more expensive, and were consequently seldom, if ever, used. Undoubtedly this makes a very good foundation, but it is costly and is now generally superseded by brickwork or concrete.

Brickwork built with Portland cement mortar is in very general favor, and forms an excellent foundation. The bricks should be tightly built, the joints not exceeding a quarter of an inch in thickness, and the whole structure well bonded together so as to form, as nearly as possible, one solid block. The cost of this kind of engine foundation is considerably less than one of ashlar masonry.

For engine foundations, and, indeed, for all sorts of foundations about a colliery, there is much to recommend the use of concrete. It forms the best foundation, and is less costly than either ashlar masonry or brickwork. Concrete is essentially a species of rubble building, the stones of which are cemented together by a mortar, usually of Portland cement and sand or fine gravel. About a colliery where, as a rule, a plentiful supply of sandstone is readily obtainable, especially during sinking operations, it may with advantage be used in the manufacture of concrete. A quantity of stone is broken to about the size of ordinary road metal, or from 1½ to 2½ inches diameter. This is mixed with certain proportions of clean sand and of Portland cement, the proportions of the various ingredients varying with the purposes for which the concrete is to be employed. For ordinary foundations the proportions are generally about four parts, by measure, of broken stones, one part of sand, and one part of cement. These, after being thoroughly mixed, have sufficient water added to make the whole a plastic mass, which is forthwith transferred to the excavation or other receptacle previously provided for it. At the same time, a number of large stones may with advantage be thrown in, care being taken that they are thoroughly bedded in the concrete, which should also fill all interstices between them. When using sandstone for making concrete, it is not generally necessary to add sand, as in breaking the stone a quantity of sand is produced, unless the stone be very hard. By a little experience one can readily estimate whether there is a sufficient quantity of sand among the broken stones, and it becomes unnecessary to measure them out separately. Broken bricks, blast furnace slag, limestone and other materials are frequently used for making concrete. It should be noted that the concrete occupies only about two-thirds of the volume of the ingredients when unmixed.

When concrete foundations have to be raised above the level of the surface, a casing, usually formed of planks, has to be erected, of the form and height of the monolith, into which casing the plastic concrete is placed. After it has sufficiently set to permit of the casing being taken away, this should be done.

In conclusion it may be useful to compare the cost of building engine foundations of the three classes referred to. For a set of coupled winding engines, each foundation will contain about 40 cubic yards, or say 80 cubic yards in the two, and the total cost will be approximated as follows:—

80 cubic yards Ashlar masonry at 75s.	£300 0 0
80 " brickwork in cement at 16s.	64 0 0
80 " concrete (5 to 1) at 9s.	36 0 0

NOTE.—These figures for cost, will be interesting to American readers, as showing the proportionate cost of the three types of foundations. Naturally the British figures will not directly apply in America.

Contractors' Methods.

"Contractors' Methods, Employed on the Great Chicago Drainage Canal, 2nd edition," is the title of an interesting illustrated pamphlet just issued by the Lidgerwood M'f'g Co., of New York, Chicago and Boston. The book illustrates and describes the various appliances used on the canal, by means of which the stupendous work is being rapidly accomplished. A copy of this pamphlet should be in every engineer and contractor's library. It will be sent free on request by the Lidgerwood Co.

EXPLOSIVES

FOR FIERY AND DUSTY MINES.

The Report of the Flameless Explosives Committee of the North of England Institute of Mining and Mechanical Engineers.

The results of the labors of this committee are of great importance, and we, therefore, hasten to present to our readers an epitome of the facts established by their experiments.

The report begins with a statement that the experiments were conducted in mixtures of coal dust, air, and mine gas confined in a plated tube built like a cylindrical boiler, that was 3.5 feet in diameter and 45 feet long. At the rear end of the tube a cannon or steel mortar was fixed for firing, and it was in the bore 1.5 inches in diameter and 20 inches long. Three trays or frames were fixed in the tube, and each of them was 6 feet in length and of a breadth equal to the width of the tube at their level; the rear end of the first tray or the edge next the mouth of the cannon or shot hole was 15 inches, and its front end was 19 inches above the bottom of the tube, and the ends of the other trays in succession were at elevations of 11 and 13 and 7 and 13 inches. Some of the coal dust was scattered in the air of the tube, and the rest was laid on these trays. The rear end of the first tray was 10 inches from the mouth of the shot hole, and the rear ends of the second and third trays were at distances of 12 inches from the front ends of the first and second trays. The tube was fitted with escape valves and windows and an exhausting fan for removing foul air, and pipes and cylinders for injecting measured volumes of mine gas from the adjacent Hebburn colliery, and it contained 78.8 per cent. of combustible gas, that consisted of 61 per cent. of marsh gas. The material used for stemming or tamping was puddled clay. The coal dust was weighed before it was cast into the air of the tube or placed on the dust trays.

The following is a summary of the time occupied in making one of these experiments:

	Seconds.
Running the mine-gas into the tube	60
Mixing mine-gas and air with the fan	60
Putting in the coal dust	20
Mixing the mine-gas air and coal dust	15
Interval before firing the shot	3
Total time	158

It is almost needless to say that these experiments were conducted with intelligence and care, and are, therefore, reliable, and perhaps what is of prime importance about them is the conclusions that the committee have arrived at, and here are some of them:

"In the experiments with coal dust in suspension, it was difficult to ascertain the amount of dust which was actually in suspension in the air at the moment when a shot was fired.

"Only a small proportion of the coal dust placed in the tube appears to pass into actual suspension, and the heavier particles fall before the shot is fired. These experiments, therefore, are of a double nature, the greater weight of dust being *in situ*, and the lighter and more inflammable portions being in suspension.

"The experiments with coal dust in suspension appear to approach to the conditions generally prevailing in mines, in which the greater weight of dust is lying on the bottom, sides, roof, timber, etc., and a smaller weight of fine dust is floating in the air.

"The committee felt justified in adopting this method of obtaining the suspension of the coal dust, as it approximated to the actual conditions of the mine, and more especially as in the first experiments with unstemmed shots four of the safety explosives failed to withstand the test."

"On referring to the experiments made in gaseous mixtures of air and pit gas it will be seen that none of the explosives, when stemmed, caused an ignition of the gaseous mixture. It was therefore decided to make experiments with stemmed shots and mixtures of air and pit gas, with the addition of coal dust, the object being to ascertain whether the addition of coal dust to an explosive gaseous mixture would render it more susceptible of ignition.

"The Austrian firedamp commission found, after making a large number of experiments, that a small admixture of firedamp greatly increased the sensitiveness of coal dust to ignition. This danger requires especial consideration, although the above conclusion (based upon experiments with dynamite) was not wholly sustained by the experiments of this committee made with safety explosives."

EXPLOSIVES (UNSTEMMED) FIRED INTO MIXTURES OF PIT GAS AND COAL DUST IN SUSPENSION.

"*Roburite and Carbonite.*—Only roburite and carbonite were tested in this series of experiments. It was deemed unnecessary to test the other safety explosives when unstemmed, as each of them had ignited mixtures of pit gas or pit gas and coal dust at one time or another during the course of the several series of experiments. Roburite and carbonite, however, had in no single instance ignited such mixtures, either when the shots were stemmed or when unstemmed.

"In this series of experiments roburite ignited a mixture containing 8.03 per cent. of pit gas and 1 pound of coal dust, but carbonite did not ignite any of the pit gas and coal dust mixtures."

EXPLOSIVES (UNSTEMMED) FIRED INTO COAL DUST IN SITU.

"*Bellite.*—Three experiments were made with bellite; sparks were observed in two experiments, and nothing seen in the other experiment.

"*Ammonite.*—Three experiments were made with ammonite, a quantity of sparks being observed in each. In one experiment a flash was seen for a length of 7 feet, and in another experiment for a length of 53 feet from the cannon.

"*Roburite.*—Three experiments were made with roburite. Sparks were observed, without flame, in each experiment.

"*Carbonite.*—Three experiments were made with carbonite, neither flame nor sparks being seen.

"*Ardeer Powder.*—Three experiments were made with ardeer powder, without sparks or flame being observed.

"*Westfalit.*—Seven experiments were made with westfalit. In two experiments the charge was incompletely detonated, sparks were observed in five experiments, and flame in two experiments. In one experiment nothing was seen, and the charge was found to have been incompletely detonated.

EXPLOSIVES (STEMMED) FIRED INTO COAL-DUST IN SITU.

"Each shot was stemmed with 3 inches of damp puddled clay. The coal dust was not ignited in any of the experiments.

"*Bellite.*—There were seven experiments with bellite, including two experiments when the charge was incompletely detonated, and neither flame nor sparks were seen.

"*Securite.*—Three experiments were made with securite, and as the charge in each case was incompletely detonated, the stock in hand was condemned and the experiments were discontinued.

"*Ammonite.*—There were twelve experiments made with ammonite, including one experiment in which the charge was incompletely detonated; a flash at a distance of 45 feet was recorded in two experiments, and at 13 feet in one experiment, and in the other experiments neither flame nor sparks were observed.

"*Roburite.*—There were thirteen experiments with roburite, including three experiments in which the charge had been incompletely detonated; neither flame nor sparks were observed in any of the experiments.

"*Carbonite.*—Five experiments were made with carbonite, without flame or sparks being seen in any of the experiments.

"*Ardeer Powder.*—Five experiments were made with ardeer powder, and neither flame nor sparks were observed."

SUMMARY OF EXPERIMENTS WITH THE FOLLOWING EXPLOSIVES.

"*Roburite.*—The experiments made with roburite numbered fifty-three in all, and in no instance was the coal dust ignited. The quantity of coal dust, the method of placing the coal dust, and the duration of the running of the fan were varied from time to time during these experiments. Coal dust from Hebburn, Seaham, and Silksworth collieries was used. There was little or no appearance of flame, but sparks were observed in most of the experiments. In one experiment, included in these results, there was incomplete detonation of the charge.

"*Carbonite.*—One experiment only was made with carbonite, resulting in ignition of the coal dust. Two pounds of Hebburn coal dust were placed upon No. 1 frame, and the fan was revolved for about 10 seconds. There was evidence of considerable violence reaching to the end of the tube, resulting from this ignition of dust; Nos. 1, 2, 3 and 4 plugs were forced from their position, and the cannon recoil was considerable. There was no appreciable interval of time between the firing of the shot and the ignition of the coal dust; rolling red flames were observed for a length of 45 feet from the cannon, and sparks were seen, without flame, at 53 feet from the cannon.

"*Ardeer Powder.*—There were thirty-three experiments made with ardeer powder and in no instance was the coal-dust ignited. Variations in the quantity and in the method of placing the dust, and the period of the running of the fan were made from time to time. In one experiment, a second shot was fired into the tube about one minute after the firing of the first shot, without igniting the coal dust. No flames or sparks were observed during these experiments.

"*Westfalit.*—Fifteen experiments were made with westfalit, and in no case did it ignite the coal-dust. A quantity of coal-dust varying from 3 pounds to ½ pound was used in the experiments, and the method of placing the dust and the time of running of the fan were also varied. The experiments were made with coal dust from the Hebburn and Silksworth collieries."

The committee further remark: "The results of the inquiry point very conclusively to the unreliability of all of the safety explosives; contrary to the general opinion at the time when these experiments were commenced, it is proved that no explosive is flameless, and that all are capable of igniting gaseous or coal dust mixtures.

"Very interesting results have been obtained during the course of this inquiry. Firstly, the sensitiveness to ignition of coal gas, as compared with pit gas, has been clearly demonstrated. Secondly, the presence of flames in an explosive gaseous mixture has been proved (the flames sometimes being first observed at points several feet remote from the cannon), without ignition of the gaseous mixture ensuing. The retarded ignitions of explosive mixtures of coal gas and the point of first ignition of gas mixtures occurring many feet distant from the cannon are interesting features in the inquiry.

"Knowledge of this extensive subject—explosives—has only been obtained at the cost of much labor and expenditure from properly conducted experiments, and there still remains much to be done. Interesting results might be obtained by firing shots through a space containing atmospheric air into a chamber containing gas or coal dust mixtures. Many varieties of coal dust have not yet been tested, and little is known about the propagation of coal dust ignitions. By means of a constant current of air and coal dust, many interesting experiments might be made, and much useful knowledge gained.

CONCLUSIONS OF THE COMMITTEE.

The lengthy series of experiments, which have occupied the attention of the committee since March, 1892, appear to establish the following conclusions:—

1.—The high explosives (ammonite, ardeer powder, bellite, carbonite, roburite, securite, and westfalit) on detonation produce evident flame.

2.—The high explosives are liable to ignite either inflammable mixtures of air and fire-damp, or air and coal dust; or air, fire-damp, and coal dust, and therefore cannot be relied upon as ensuring absolute safety when used in places where such mixtures are present.

3.—The high explosives are less liable than blasting powder to ignite inflammable mixtures of air and fire-damp, air and coal dust, and air, fire-damp and coal dust.

4.—The experiments have shown that ignitions of mixtures of air and coal dust, with or without the presence of fire-damp, can be obtained when there is present a much smaller quantity of coal dust than has been previously supposed to be necessary.

5.—It is essential that similar examinations of the working places and precautions which are in force in mines where blasting powder is used, should be rigidly observed where a high explosive is employed.

6.—In selecting a high explosive for use in a mine, it should not be forgotten that the risk of explosion is only lessened and not abolished by its use.

7.—In view of the changes from time to time made in the proportions and constituents of high explosives, it is desirable that the name of the explosive should be printed on the wrapper of each cartridge, and that the date of manufacture and the proportion of the ingredients used in the manufacture of the explosive should be printed on the case of each packet of cartridges.

8.—As these explosives alter in character if improperly kept, it is necessary that every care should be taken in the storage to ensure their being maintained in good condition.

The North of England Institute of Mining and Mechanical Engineers deserves the praise of all the miners, mine engineers, and coal operators throughout the world, for they have done a good work, the benefits of which will not only be felt in the saving of life and property, but in directing the minds of those interested along the correct lines of further progress.

An Ignition of Coal Dust.

We have gathered the following facts concerning an ignition of coaldust that occurred in the No. 7 Eureka coal mine, Clearfield county, Western Pennsylvania, on January 19, 1896, at 4:40 p. m., when four men were burned, and two of the poor fellows severely.

There can be no doubt of the cause of this ignition, as the following narration of the particulars will show: It appears that a frozen dynamite shot was first fired in a hole at the bottom of a top bench of coal lying immediately on a parting band of stone, the object of the shot being to break down the stone after the bottom bench of coal had been taken out. This frozen shot, however, failed to do its work, for instead of shattering the stone

it pulverized the coal into dust at the back end of the hole, and from what followed we learn that this dust afterward supplied the fuel for the ignition under notice.

The first shot mentioned was drilled in the coal on left side of heading and close to the left side rib and in the coal directly over a 20-inch band of stone, and 6 feet deep, charged with 1¼ lbs. of dynamite, and was intended to break the stone down; but owing to the dynamite being at or near a frozen temperature, it was of insufficient power for the work intended and did not even break the front of coal, which resulted in a dull sounding shot and a confining of the gases given off from dynamite in the back of the hole, together with the pulverized coal from the effect of the shot.

The accompanying sketch shows the point at which the ignition occurred. When the second shot went off, the effects of the heat of ignition, and the mechanical effects of the sweep of the swiftly rushing air were remarkable, for coked dust was forced into crevices in the sides and cracks in the timbers, and the course dust lying on shelves of the coal walls and that lying on the top timbers was all charred, while the dust on the floor was swept up against the sides of the road. The flame swiftly moved 210 feet back against a ventilating current of 20,000 cubic feet of air per minute, and strange to say, it left untouched a can containing three pounds of powder, that was situated only 45 feet from the initial point of ignition by the shot.

Fatal Mine Explosion.

Four men were killed and four fatally injured in an explosion in the Rosslind mines at Winnepeg, Manitoba, March 20.

BLASTING IN FIERY MINES.

Methods of Reducing the Danger in Austrian Mines.

By Franz Brzezowski.

(Translated from *Oesterreichische Zeitschrift für Berg und Hüttenwesen*, by *The Colliery Guardian*).

In view of the dangers constantly attending blasting operations in mines where fire-damp is present, attention has long been directed to the development of implements to replace explosives, as well as to such modifications of usual blasting methods as shall minimize the risk in question. Latterly the accident at Karwin has given a fresh impetus to the endeavors in progress in this direction, and led to results calculated to lessen the facility of explosion of the fiery gas. Such explosion is generally influenced either by the fuse or by the blasting charge itself. As regards the former, there are now several reliable systems of central-fire cartridges in existence, such as the electrical fuses (high tension, or quantity—the latter for choice, as offering less danger of igniting the gas by sparking); Tirmann's percussion detonator, which, out of 400,000 shots, only gave 0.2 per cent. of miss-fires; the improved Lauer friction fuse; and the Jaroljmek water-cartridge.

Much more difficult is the solution of the second problem—the ignition of gas by the explosive; although much has also been done here towards the attainment of the desired end. The main factors by which the safety of a blasting charge is influenced are: (1) The suitability of the explosive to the work it has to perform; (2) the diameter of the borehole; (3) the wrapping of the charge; (4) the strength of the detonator; (5) the mode of tamping; (6) the composition of the charge. In treating the above in order, it is, in the first place, manifest that when all the heat evolved on the ignition of an explosive is used up as mechanical disruptive energy, there will be less danger of an explosion of of fire-damp than in the converse event; wherefore, badly arranged borings should not be charged, but ought to be abandoned. In the second instance, a cartridge freely suspended in fiery air is more dangerous than a blown-out shot, the amount of surface exposed being greater, and for the same reason the danger from blown-out shots varies as the diameter of the borehole. The method of packing the charge, and particularly the kind of paper employed to cover the cartridge, seriously affects the safety of the shot under all conditions. On this account the Mahrisch-Ostrau special committee employed in their experiments a uniform wrapper of cellulose parchment paper in order that the results obtained should be capable of comparison. Paper soaked in ceresin has shown itself especially dangerous; asbestos paper or paper impregnated with water glass, on the other hand, behaves well.

Von Lauer's experiments go to prove that the disruptive power and therefore the danger of an explosive is modified by the strength of detonator employed, and it has been found with the Trauzl method the volume of gas evolved from 15 grains of explosive varied with the detonator as follows:

	Detonator cap.			
	1 grm.	2 grms.	3 grms.	
Wetter-dynamit	350	356	—	cubic metres.
Westfalit	550	546	648	"
Progressit	354	566	590	"
Fellfractor	—	560	—	"

The decrease of security resulting from the use of large detonators may be gathered from the fact that a blown-out shot of 500 grammes of westfalit fired by a 1-gramme detonator did not explode a 7 per cent. mixture of firedamp, whilst 300 grammes ignited by a 3-grammes cap under similar conditions did. It is, therefore, evident that the term "safety," as applied to these explosives, is only relative.

The effect of stemming is to decrease the danger of exploding firedamp by converting the evolved heat into energy, and in this respect water, sand, and moss tampings have proved particularly efficacious, but it was not until the recently published researches of Siersch on the photographic pictures given by various blasting materials when exploded, that the relative value of these methods could be accurately compared. At the invitation of the author, photographs were taken of the flash from 100 grammes of dynamite No. 1, fired as a blown-out shot in a mortar 30 mm. in diameter, 14 cm. from the mouth of the borehole, both open and stemmed; and in order to ensure the correctness of the observation the tests were repeated ten times, when the result that the moss was found to make such an effectual stemming that its employment, in conjunction with the Tirmann percussion fuse, has been made compulsory in the mines of the Archduke Friedrich at Karwin.

Concerning the constitution of the explosives suitable for fiery pits, "safety explosives," with the exception of "wetter"-dynamite (a mixture of dynamite and crystal soda), mostly consist of ammonium nitrate (up to 96 per cent.), mixed with aromatic hydrocarbon compounds (benzol, naphthalin, anilin) or their nitro-compounds, resins or fats, and can only be fired by powerful detonators, their safety depending on the smallness of the flame produced. These substances are completely harmless in themselves, being proof against shock, or flame, and can be handled with red-hot iron tongs or exposed to the flame of the oxyhydrogen blow-pipe without exploding, merely fusing and burning with a small flame, and ceasing to burn when removed from the fire. These properties are valuable for mining purposes, as none of these preparations give deflagrating shots. "Wetter"-dynamite will deflagrate if the detonator is insufficiently powerful, but the others under consideration simply refuse to explode, under similar conditions, and they have the further advantage over dynamite of not freezing except at very low temperatures—seldom, therefore, requiring to be thawed out. In fact, they can only be fired by means of very powerful caps, and the closer they are compressed the stronger will the cap have to be. When of a density of 1.6 to 1.7, a 2-gramme cap or dynamite fuse is insufficient. The most convenient density is 0.8. The dispersive power increases, and the security decreases with the proportion of hydrocarbon compounds, and with the strength of detonator employed. Ammonium oxalate or the salts of chlorine, bromine and iodine diminish the efficiency, but heighten the safety of these explosives. On the other hand, amongst the disadvantages may be noted their low density—which necessitates wider boreholes—and especially their hygroscopic power, which, however, may be counteracted by careful packing.

The only reliable method hitherto discovered for determining the comparative safety of these explosives, is by the photographic examination of the flame produced when they are fired. This, however, enables the following points, *inter alia*, to be solved, viz: The constancy of the flame under identical conditions, and how far the flame alone affords a sufficient indication of the degree of safety; that the danger of a particular charge increases with the diameter of the borehole. It will also assist in determining the limit of safety—as regards weight of charge—of a blown-out shot, *i. e.*, the maximum charge that can be used without producing an escape of flame from the borehole.

The value of "safety explosives" may be judged from the following experiments with "progressit," a preparation which for security is found to be surpassed by none: 150 grammes of progressit could not be exploded by a 2-gramme cap when lying free in a mixture containing 2 per cent. of gas and 3 kilos. of coal dust, whereas 300 grammes of No. 1 dynamite exploded with violence; 150 grammes of progressit lying free in presence of 10 per cent. of gas and 3 kilos. of coal dust were exploded by a 1-gramme cap, but failed to ignite the mixture in any of the ten tests applied, and in only two out of four cases did a 2-gramme cap explode the mixture; 400 grammes of progressit lying free in a mixture containing 7 per cent. of gas and 3 kilos. of coal dust and fired with a 2-gramme cap did not produce ignition.

The means at present at disposal for combating the danger of exploding firedamp in blasting are briefly: The central-fire cartridge; moss stemming; good quality paper for covering the cartridges; safety explosives (up to the minimum charge of each); removal of suspended coal dust by spraying; and finally, the entrusting of the operations to a skilled workman.

A Disastrous Explosion.

An explosion of gas at the Berwind-White Coal Mining Co.'s mine at Dubois, Pa., on the 23d ult., resulted in the death of thirteen men. The mine is a new one which the company has been opening up for some time. On the morning of the accident eighteen men entered the mine. Four of them went into the south heading, the remainder into the north heading. At ten o'clock a. m. the four men in the south heading felt a severe shock, and being joined by the mine foreman they started for the north heading to investigate the cause of the shock and render help if necessary. The men on the surface were notified of the explosion by the shock and the rush of air up the shaft. Help was immediately summoned from the neighboring Bell, Lewis and Yates mine, and by noon the work of rescue was well under way. The first attempt of a relief party to enter the mine was a failure, owing to large quantities of "after-damp." However, this failure did not deter the rescuers, and a second attempt was made, and the mine foreman and four other survivors, who had started into the south heading, were brought out alive, but suffering from the effects of the gas they had inhaled. Successive descents into the mine were made, and the bodies of the dead were brought to the surface. The interior of the mine on the north side is very badly wrecked, timbers smashed and rails twisted. The victims all met their death from the explosion. The cause of the explosion is, as yet, unknown, as all witnesses were killed. An inquiry and investigation will, however, be made, and it is to be hoped that the cause of the disaster will be discovered. It was the first serious explosion in the Dubois region.

Graphite Paint

There is on exhibition in the office of the Colliery Engineer and Metal Miner a piece of iron cut from a chimney formerly very rusty from exposure, but later protected by an application of the graphite paint made by the Detroit Graphite Manufacturing Company, which should be of interest to mine operators. This stack, as shown by the part impossible to reach at the time of the painting referred to, was very rusty when painted, and was considered, it is stated, to have at that time about outlived its usefulness.

After painting as above referred to, it served three years without further attention or repair, and was then only taken down to be replaced by a larger one necessary from the addition of more boilers to the power plant.

This paint has also proved itself of value in preventing corrosion and pitting of boilers from the effects of bad feed-water. In an experiment made in which a few tubes and a part of the inside surface of the shell of a return tubular boiler were painted, the balance of the exposed surface being left as ordinarily run, the paint was found to have had a wonderfully beneficial effect.

The address of the makers of this paint, whose advertisement appears for the first time in this issue, is 542 River Street, Detroit, Michigan.

Feed-Water Heating and Purifying Apparatus.

The above caption is the title of a pamphlet issued by Wm. Baragwanath & Son, 46 W. Division Street, Chicago, a copy of which should be in the hands of every mine operator and superintendent. In no industry are more serious problems encountered in keeping boilers in good condition than in mining, and in none is there greater importance of economy in the use of fuel, as trade conditions now exist.

This pamphlet, while put out in the interest of "Baragwanath" appliances, contains much matter worthy the careful attention of every steam user, showing as it does what economies can be effected by the use of improved and approved plant over that of less modern construction. Messrs. Baragwanath & Son make a full line of feed-water heaters, line steam purifiers, power boiler feed pumps, boiler cleaners and condensers. Their "Water Jacket Condenser" is shown in their advertisement.

Modern Methods of Mining and Handling Coal and Ore.

"Modern Methods of Mining and Handling Coal, Minerals, Etc." is the title of the Link-Belt Machinery Co.'s latest catalogue. It illustrates with fine engravings and descriptive texts, their electrical mining machinery, their elevating and conveying appliances, tipples, screens, etc., etc. It is a fine piece of typography, and should receive attention from the managers of all coal and ore mines. The apparatus and machinery described is all of the latest and most approved type, and every progressive mining man should familiarize himself with it. The catalogue is sent free on application to the Link-Belt Machinery Co., 39th St. and Stewart Ave., Chicago, Ill.

Steam Specialties.

No industry affords a larger and more profitable market for steam specialties than the mining business, and probably no makers of such goods are more favorably known to users than the International Specialty Co. of Detroit, Mich. The reputation of this firm has been built up on the Penberthy injector, but they make a general line of steam "brass goods" for nearly all purposes. The particular specialty they head their advertisement with in The Colliery Engineer and Metal Miner, is their "International" injector. We suggest that users of such goods provide themselves with this firm's catalogue, and keep it for reference whenever goods of this class are needed.

Air Compressors, Steam Pumps.

The Hall Steam Pump Co., of Pittsburg, Pa., begin with this issue of the Colliery Engineer and Metal Miner an advertisement of the machinery built by them. This company in addition to a full line of steam pumping machinery, is prepared to undertake the construction of air compressors of any desired capacity, the latter having been a specialty with them for some years past. On these two lines of machinery, both extensively used in the mining industry, the Hall Co., hopes for a share of the patronage of our readers.

Air Compressors.

Mr. Robert Laidlaw, president of the Laidlaw-Dunn-Gordon Co., of Cincinnati, Ohio, informs us that his company is doing quite a large business in air compressors, and especially in compressors for mining work. They have just furnished a large compressor to the Brown Mining Co., of Cardiff, Tenn.; and a pair of 20''x20''x36'' compressors with Corliss valve steam ends to W. J. Rainey, of Cleveland, Ohio, for use at his Mt. Braddock, Pa., coke plant.

Wages Advanced.

The following notice has been posted on the mine tipples of all the mines in the Clearfield, Beech Creek, Cambria and Gallitzin coal region: "On and after April 1 the employes of this company will be paid 45 cents per 2,240 pounds for mining. Day labor will be paid the same rates as when this price for mining formerly prevailed." The above notice means an advance to the miners of 5 cents per ton, or 12½ per cent. over the wages that have prevailed in the above named regions for the past two years.

Two Dead in a Mine.

Fire broke out in the Adrian No. 1 mine at Delaney, Jefferson county, Pa., March 23. Superintendent W. Robinson and five men entered to locate the fire and were overcome, but were rescued unconscious. A rescuing party was organized and Charles Lawrence, a track layer, and I. Jones, machinist, were found dead. Mr. Robinson and the other men will recover. The mine is owned by the Rochester and Pittsburg Coal and Iron Company.

Remarkable Escape of Eight Men.

Eight men narrowly escaped death at the main shaft of the Chicago and Minonk Coal and Tile Works at Minonk, Ill., on the morning of the 12th ult., through the breaking of a hoisting rope. The cage in which they were fell 555 feet. One man's legs were broken, and the other seven were badly bruised. How they escaped instant death is a mystery.

Mine Explosion Kills Two Men.

An explosion of fire damp occurred in the Ohio and Pennsylvania Coal mines at Port Royal, Pa., March 23, killing Alexander McDonald, the fire boss, aged 35, and William Davis, aged 15. The mine is about 200 feet deep, and the explosion shook the earth around the mouth of the mine. It was caused by the fire boss carrying a lamp into an unused part.

A Disastrous Explosion in a German Mine.

A cablegram from Berlin under date of the 4th ult., states that an explosion, followed by fire, occurred at Cleophas mine at Kattowitz, Prussian Gallicia, on that day, which resulted in the death of 60 miners.

BITUMINOUS STATISTICS FOR 1895.

In our last month's issue we published a summary of the statistics from the advance sheets of the reports of the inspectors of mines for the anthracite districts of Pennsylvania. The accompanying tables for the bituminous districts complete the coal statistics for the whole state for the year 1895. They were compiled from the advance reports of the inspectors by our special representative, Mr. Baird Halberstadt, mining engineer, Pottsville, Pa.

Table Showing Total Production, Shipments, the Increase in Production in 1895 Over That of 1894, The Total Production of Coke in 1895 and the Increase in Production Over That of 1894, Number of Employes, Fatal and Non-Fatal Accidents, Kegs of Powder Used, Number of Horses and Mules, Number of Steam Boilers, Tons of Coal Mined per Life Lost and per Non-Fatal Injury in the Bituminous Collieries of Pennsylvania in 1895.

Opening a New Coal Tract.

Contractor Edward Askew, of Mt. Carmel, with a force of men, recently began opening up the Germantown coal tract, northwest of Ashland, for the Lehigh Valley Coal Company, and the work will be pushed ahead as rapidly as possible. The scene of operations is at the base of the Locust mountain, north of Nineteenth street in this borough. Lewis A. Riley & Co., opened up a slope there some time ago, but did not prosecute the work very far, as about the time they had the work begun, the negotiations that finally resulted in the transfer of the coal tract to the Lehigh Valley Coal Company began. The deal was completed a few weeks ago as was fully told in this paper, at the time, as was also the fact that this tract would be developed, and the other incidental points connected with the work. The new breaker that will be erected by the Lehigh Valley Coal Company will be situated on the flat near where operations have been begun. The site is admirably situated, and no better location for a breaker could be desired. There is ample room for culm, and good location for all the side tracking necessary. The breaker will be a model one in every respect, and will be fully equipped with all the latest coal cleaning appliances. It is expected to give employment to from 700 to 1,000 men and boys, and will be the means of greatly increasing Ashland's population. Before very much of this work can be done it will be necessary to get the branch of the Lehigh Valley railroad tracks built into the tract, and preparations are being made to push this work ahead. The engineers have begun work and have run the preliminary lines from North Ashland, where the main line connections will be made, to the site of the new breaker. It will take a week or two to complete the lines, to do which the work of survey will be pushed ahead with all speed, as it will be necessary to open up before the material can be taken to the grounds.—*Evening Telegram, Ashland.*

New Engineering Offices.

On March 1st Messrs. A. B. Cochran & Son, civil and mining engineers, of Pottsville, removed from their former offices in the Evans building to the new fireproof Smith building recently completed. The Messrs. Cochran occupy the entire second and third floors of the building, consisting of two suites of four rooms each. On the second floor front are the private offices of the firm, a toilet and map room. A fire-proof map vault will be built on the rear of this room. A very handsome map case of polished oak for blue prints and tracings has been erected in the map room. On the third floor are three draughting rooms and a second toilet room. A light well affords ample light to the interior rooms. The building is heated by steam, and all the rooms are fitted with combined electric and gas chandeliers. The arrangement of the rooms is excellent, and no handsomer or more commodious engineering rooms can be found anywhere in the anthracite region. The Messrs. Cochran employ nine engineers and draughtsmen.

Packing.

We are in receipt of a communication from the Garlock Packing Co., of Palmyra, N. Y., and Rome, Ga., that reports a large increase in their business during the past few months. This increase necessitated running their factories over time, and as the demand for their product continues to increase, they have begun the erection of a large addition to their Palmyra, N. Y., plant. This enterprising company has branch offices in New York, Boston, Chicago, Philadelphia, Pittsburg, St. Louis and Omaha.

The Girard estate asked for proposals for the construction of a large reservoir upon its lands, on Locust mountain, near Raven's Run, Schuylkill Co. Bids have been received by Major Thompson, the engineer, from Messrs. M. P. Quinn, Lewis Grant, Thos. H. Rickert, Chas. F. King and P. McManus.

EASY LESSONS ON MINING.

This Department contains articles to assist ambitious Miners to educate themselves, and obtain Certificates of Competency as Mine Foremen, or to become Mine Superintendents.

The articles are written to be understood by the unlearned and the learned alike. Plain language is used, no obscure terms are employed, and each subject treated, is made as clear and easy to understand as possible.

Further: The Questions asked at the different Examinations for Mine Foremen and Mine Inspectors, are printed and answered.

☞ The Series of Articles "Geology of Coal," "Chemistry of Mining," "Mining Methods" and "Mining Machinery" was commenced in the issue of March, 1894. Back numbers can be obtained at twenty-five cents per single copy, $1.00 for six copies, and $2.00 for twelve copies.

GEOLOGY OF COAL.

Ruptures in the Earth's Crust—The Effects of Eruptive Dykes.

58. **Ruptures in the Earth's Crust.**—Great fissures are sometimes met with in mining that are known to be of depths reaching from the surface of the earth to its heated and plastic interior.

These great cracks are filled with a hard flinty stone that has been injected in a state of fusion, and they are now known by such names as whin dykes, igneous dykes, lava dykes and elvan courses. They are correctly called dykes, because they are partitions that completely cut off the contact of the same ruptured beds on one side of them from those on the other.

These dykes seldom dislocate the levels of the fractured rocks, and yet they are always found passing through or running along the flanks of highly convulsed regions, where the strata have not only been upheaved, but broken and disjointed with great faults.

Many of these extraordinary lava dykes were injected during the periods of the deposition of the Carboniferous and Permian series of rocks, for we find their tops passing through the lower or older series, and overlaid with the newer or later series of the same formations. To sustain the interest that is required for making a close acquaintance with the part these intruding igneous rocks have played, in placing within the reach of man minerals and metallic ores, that could not otherwise have been accessible, we introduce Figure 94 and this will give the right cue to understand the character of these vertical sheets of igneous rock that lodge within the great planes of fracture, and are now known as dykes. In the figure a dyke is shown partly in plan

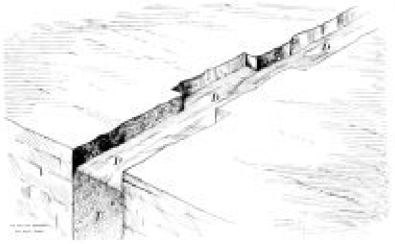

Fig. 94.

and partly in vertical section, and it is intended to represent the filling in of the fracture just after the injection of the fused rock, and at *D*, *D*, *D*, we are supposed to see the surface of the lava stream, while at *T* we see the upper portion of a vertical section that is passing down into the earth's crust.

The figure, however, only conveys to the mind a very finite idea of the longitudinal extent of these far reaching cracks that course, in some cases, for *hundreds* of miles through a vast region, and they are found all over the world where there are good, productive, metalliferous fields.

We cannot for one moment think of the enormous strain to which the shell or crust of the earth has been subject when it cracked right through to its molten kernel to produce these lava dykes, and not at the same time see that other contemporaneous cracks would be produced, accompanied with considerable sliding and disjointing of the strata, and thus providing spaces through which would upflow, for very long periods of time, boiling streams of water. We can see then that the forces that have broken the earth's crust, and filled many of the deep, penetrating and yawning cracks with molten rock, have been most generous to man in placing within his reach vast supplies of metalliferous and native metals, and yet as a general rule the ores are not often found in the lava dykes, but in the veins in their vicinity, for we now know that the boiling streams to which we have just referred were the carriers of the metals and other minerals into the fissures that are now known as metalliferous lodes. We see then that the earth's nether fires increased the solvent power of the water, and hence it acted selectively in percolating through the interstices of the rocks, and cumulatively made large deposits from infinitely small sources. The periods during which many of the lava dykes were formed are well known, and indeed they cannot be mistaken, for the tops of many of them are found to terminate in rocks of the Carboniferous and Permian ages, as has been noticed. The Permian period was one of great volcanic action but the period of the lower coal measures was more extensively so, for then, not only did the lava fill the gaping dykes, but it overflowed extensive areas of the sea floor, and wide spreading areas of dry land as lava sheets or "whin sills," and in some cases the molten stony fluid has been ejected with force sufficient to lift the overlying strata and insert itself between the bedding planes of coal measure strata as shown by Fig. 95, where a vertical section of a dyke is shown at *D*, and the intruding shelves are shown at *I* and *I* where they are seen to have crushed and broken a bed of shale *S*, *S*, but immediately after the upflow of the dyke, and during a succeeding period of repose, a later stratum is seen to have been deposited at *L*, *L*. Now what the miner must be careful to notice is this, the eruptive dykes are the constant accompaniment of veins whether productive or not, for the rocks may be so compact, dense and close that the ejected hot water cannot percolate through them, and therefore veins in them are always barren. On the other hand, loose conglomerates, breccias and open, gritty sandstones are often the seats of true segregations, and all the world over we find that under like

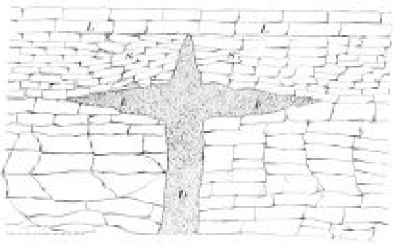

Fig. 95.

conditions the same results occur; for example, gash or true veins in limestones or shales frequently contain the ores of lead and silver, and when they do the ores are always richer in silver when the vein cuts through shales than when it cuts through limestones. We can, however, only rely on these occurrences for specific shales and specific limestones, for many shales and many limestones are not ore producing, because the conditions of location have not been favorable for the segregation of ore; for example, if during the filling of the vein the temperature of water injected into, and ejected out of, the vein has not been that best adapted, or if certain bodies are absent from the waters, that would act as powerful solvents when present, then the poverty of the vein is accounted for. Our subject, however, is dykes, and we are in this lesson more concerned about their effects on coal and coal-bearing strata, but before dismissing the question of the relation of dykes to metalliferous veins, let us notice a great fact that will collaterally concern us in relation to the great coal fields of the world.

59. **The Effects of Eruptive Dykes.**—In the United States the ore-bearing regions of value are always found in the neighborhood of great eruptive dykes, and such are those of Georgetown and Leadville, Colorado. We see, then, that the collection and concentration of metallic ores has been done largely by the agency of hot springs, and that we owe to the fires of the earth, directly and indirectly, not only the selection and collection of the ores, but the making of the great cracks in

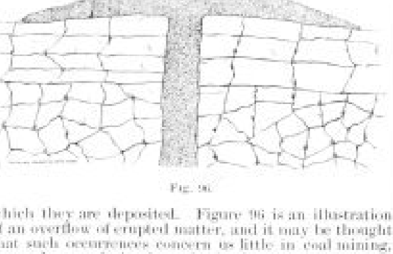

Fig. 96.

which they are deposited. Figure 96 is an illustration of an overflow of erupted matter, and it may be thought that such occurrences concern us little in coal mining, but such a conclusion is a mistake, because in some coal fields these dykes not only cut through the coal measures and completely separate one portion of the field from the other, but they have injured the coal by coking it, and have made barriers that are costly to drift through. Again, in the vicinity of the dykes the most serious interruptions in the coal seams occur, with all the consequent difficulty and expense in mining, and yet we now know that where the strata is not crumpled up, or cut through with faults and dykes, coal is never found, for it has only been preserved by gradual submergence in water where it was covered up with some protecting strata and then upraised by the same forces that depressed it, and produced the dykes and great faults, behind which it is sheltered from destruction. We see, then, that beyond all question, the eruptive dykes, if not a cause, are at any rate one of the results of a cause that has collected our valuable minerals in veins, and has preserved our coal seams, submerged them, covered them, upraised them, and sheltered them, and made them accessible for mining. The great canyons of

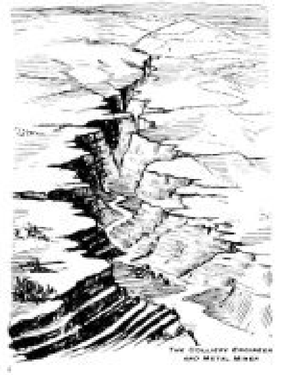

Fig. 97.

Colorado are like great fissures and really resemble them, but are now admitted to be the work of erosion by water. Figure 97 is a view of a canyon cut in marble, and it is a portion of the Colorado river and is here only introduced to furnish to the reader an idea of one of these huge cracks. The dykes are in many cases as wide as the Colorado river, although some are only six feet thick, and in length they far outrival the river, as some of them are of unknown lengths, although their course has been followed for hundreds of miles.

Recapitulation Questions.

QUES. 1. What are the names common to igneous dykes?

ANS. The igneous dykes are called whin dykes, elvan courses, lava dykes, porphyritic dykes, and dykes.

QUES. 2. Do dykes always dislocate the rocks they pass through?

ANS. Dykes seldom dislocate the rocks they pass through.

QUES. 3. In what regions are dykes chiefly found?

ANS. Dykes are always found in regions that have been subjected to great convulsive action where the disturbing forces have crumpled up the stratified and unstratified rocks and disjointed them with great faults.

QUES. 4. Can we in any way correlate the ages of these dykes, or name the periods in which they were formed?

ANS. The relative ages of the dykes or the periods during which they were formed can be fixed with great certainty, for during the Carboniferous and Permian periods the tops of some of these dykes are found to have penetrated up through the lower series of the rocks, while their tops are covered with the upper members of the series, thus proving conclusively that the cracks were made and the molten matter injected during the periods of the deposition of the rocks in which they are found.

QUES. 5. Have these dykes done any good service to mankind?

ANS. We cannot doubt the conclusion that these dykes have done good service to man, for even now their presence is a sure indication of a convulsed region where productive veins may be found; and where the dykes were formed they acted as the main channels for the ejection of hot water and steam into the collateral cracks that became the productive veins.

QUES. 6. Has the outflow of igneous rock from dykes ever exceeded the outflow from the funnels of volcanoes?

ANS. The outflow of igneous rock from dykes has far exceeded the outflow from volcanoes, for the lava sheets, that have intruded between the stratified rocks and overflown the sea floor and the dry land surface, furnish examples of rock masses far in excess of the masses due to the outpourings of volcanoes.

QUES. 7. Were jointed or close and unfractured rocks the most likely receptacles for the injected ores during the period of thermal activity in a region?

ANS. Soft, jointed, and porous rocks, such as conglomerates, breccias and gritty sandstones, were highly favorable receptacles for some kinds of metals that were so combined as to be soluble in the hot waters circulating through the interstices of these porous rocks.

QUES. 8. Are the ore-bearing regions of the United States the seats of porphyritic dykes and trap or lava sheets?

ANS. The ore-bearing regions of Georgetown and Leadville, Colorado, are the seats of porphyritic dykes and immense sheets of trap rock, and the same igneous rocks are found in all the productive ore-bearing regions of the United States.

QUES. 9. What effects have the intrusions of igneous dykes had on the coal seams, where the dykes were formed after the coal measure strata?

ANS. Where the igneous dykes have cut through the coal seams, the coal is burned into ash at the junction, and farther from the dyke the bituminous coals are coked, and also in the regions of such dykes, the coal seams are dislocated with great faults.

QUES. 10. Have faults been favorable or unfavorable to the preservation of the coal seams?

ANS. Faults have been favorable to the preservation of the coal seams, and we find, therefore, that the coal measure strata that have remained unaffected by the agencies of destruction and waste, have been preserved in the troughs or depressions between two or more great rock waves, or have been saved by the shelter afforded in the depressed sides of great faults.

(To be Continued.)

CHEMISTRY OF MINING.

Different Forms of Safety Lamp Glasses—The Dimensions of Lamp Glasses—The Surfaces of Glasses. Effects of Hot Glass on Light—Recapitulation of Facts.

96. **Different Forms of Safety Lamp Glasses.**—Many singular shapes have been given to the glasses of safety lamps, but none of them have survived the tests of actual use, consequently the old cylindrical glass is still the first favorite. When Mr. Silas Lever offered a reward for the best safety lamp for use in mines, the patent offices of all the great mining countries of the world were flooded with applications for the protection of the novel inventions of a mighty host of otherwise clever men, and yet this great multitude have since settled down in silence without even so much as having secured an undisputed claim to one new departure in lamp construction, and the result is, the safety lamp is not improved, nor will it ever be, by simply trying to reform the lamp as it is. What we require, then, is not so much the power of mechanical resource as the power of self-reliance to cast off the present mode of construction and contrive a new one from the teachings of knowledge, calculation and experience. We are not trying in this lesson to determine what should be the finality of construction for any of the parts of a safety lamp, but to show the lines along which we must travel to secure the best facts for the best results.

So far as the shapes of the glasses are concerned, crank shaped, frustum shaped and spherical shaped have

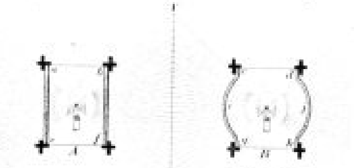

FIG. 134.

all been tried as successful rivals of the cylindrical shape, and yet the latter endures for reasons that will now engage our attention. Fig. 134 illustrates a test of a bulging glass *B*, against a cylindrical glass *A*, for diffusion; and it will be seen that the figure of the bulging glass does not give it any advantage over *A*, because the refraction due to the spherical form is so small that it may be disregarded, for when the glass is relatively thin, and the inside is parallel to the outside, it is no better, but worse, as a transmitter and diffuser of light; for be it observed that where the area of the surface of the glass is increased, the light meets with an increased resistance that is due to the passage of the same bundle of rays through a greater mass of glass. These facts are manifest when we observe that the angle of diffusion is the same for the spherical as for the cylindrical glass, for the center of the flame in *A* is at the same distance as the center of the flame in *B* from the vertical line *V T*, and as the top and bottom diameters of the two glasses are equal, that is, *a b* is equal to *c d* and *e f* is equal to *g h*, the angles of diffusion are also equal. That is to say, the chords of the angles of diffusion in the two cases are equal to *V T*. From all this we learn two things, and the first is: Before we can design a glass for a safety lamp on correct principles, we must be sure that the form and dimensions harmonize with the requirements of the laws of light. Second, when law is disregarded, fancy glasses are fruitful sources of disappointment.

97. **The Dimensions of Lamp Glasses.**—It is no easy matter to determine the form and dimensions of a lamp glass, for in no appliance are the ruling principles more seductive and misleading when *separately* considered; and with the view of pointing out how false conclusions may be arrived at, Fig. 135 is introduced. Here we have gas jets burning in the globes *G* and *g*, and if we take the jets to be of equal potential, or illuminating power, the light emitted from the glass globe *g* ought to be more powerful than that given

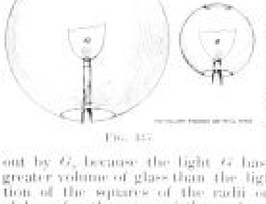

FIG. 135.

out by *G*, because the light *G* has to pass through a greater volume of glass than the light *g*, in the proportion of the squares of the radii or diameters of the globes; for the areas of the surfaces of globes vary as the squares of their diameters, when the thicknesses of the glass shells are equal. Then, if the diameter of the globe *G* is 6 inches and that of *g* is 3 inches, we find the resistance the light meets with in passing through *G* is 4 times that to be overcome in passing through *g*, for $\frac{6^2}{3^2} = 4$. We must, however, see, that the power or potential of the light will be inversely as the resistance, therefore the illuminating power of two equal gas jets, after the light has been passed through the shells of unequal spheres, will be for the large shell $\frac{d^2}{D^2} = p$, *p* being the effective potential of the light. Now, as the word potential may here perplex and not assist some of the readers, let us discover and explain its *factors* or *makers*. To find the potential of a light two factors must be known, and they are the *volume* and the *tension*, or intensity, of the light. For example, suppose the globe *G* in the figure to be a volume of flame, or matter in a state of incandescence, and the small globe *g* to be the same, then to make the potentials of the two lights equal, that is, their power to fill equal spaces with equal light, the tension or intensity of the light *g* would have to be 8 times that of *G*, because the volume of *G* is 8 times that of *g*, or $\frac{6^3}{3^3} = 8$; or let the large volume equal *V*, and the small one equal *v*, and the high tension equal *T* and the low tension equal *t*, then in this case the equal potentials would arise in this way, $V t = v T$, or $8 \times 1 = 1 \times 8$. We see, then, that the potential of a light is the product of its volume into its intensity. All have noticed that a very small candle illuminates a much smaller space than a

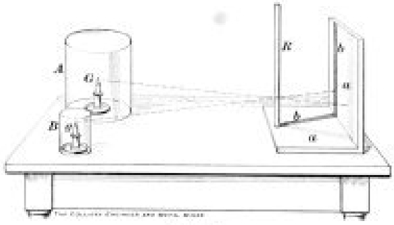

FIG. 136.

large one; that is to say, a small light fills a less space than a large one when their intensities are equal, and the intensities of the candle lights are supposed to be equal, for if the volume of the large light is eight times that of the small one, then the large one will fill with light a space eight times as large.

Again, suppose the large volume of light to come from a mass of red-hot iron, and the small volume of light to come from the flame of a kerosene lamp, and let the intensity of the light from the hot iron be equal to 1 and the intensity of the light of the lamp be 3,000 and the volume of the hot iron be 30 and that of the lamp flame be 1, then the light from the red-hot iron will only have an illuminating potential of the one-hundredth that of the lamp flame, for $\frac{30 \times 1}{1 \times 3{,}000} = \frac{1}{100}$. We now see the importance of the meaning and relative value of the terms volume, tension and potential. Next let us consider the relative resistances that lights are subject to in transmission through glasses of the same thickness but different areas of shell surface, and to assist in the investigation Fig. 136 is introduced.

98. **The Surfaces of Glasses.**—Would any one who had not tried the experiment suppose that the magnitude of the glass shell that encloses a light-giving flame would affect the potential of the light so much? In the figure, two candles of equal potential are set within the glass cylinders *G* and *g* to test the effect of increased resistance to the light passing through the large cylinder *G*. It will be seen that *G* is double the diameter of *g*, but there is another qualification in the dimensions of these cylinders that requires close attention, and that is their lengths, and be it observed that if *g* had been the same in length as *G* the photometric measurement of the lights would not have shown the shadow *b* to be so deep in tone in contrast with *a*, for the increased length of the narrow glass *g* would result in the cylinder being heated and as hot glass offers a greater resistance to the transmission of light than a cold one, the reason for the conclusion that a long glass would introduce a new resistance is at once seen, for the position of the flame in *g* is such that the heated gases ascend at once out of it, while the cold air in descending cools the otherwise exposed glass around the flame. We see then that the glass shells *A* and *B* are unequal while the lights *G* and *g* are equal and we now discover that, so far as the diameters of the cylinders are concerned, if their *temperatures* are equal, the effective potentials of the lights will vary inversely as the squares of the diameters of the cylinders. Hence the shadow of the rod *R*, cast on the back screen at *a a*, is scarcely visible beside the deep dark shadow cast by *g* on the back screen at *b b*. Here then if the temperatures of the glasses are equal the resistances to the passage of the lights will vary *directly* as the squares of the diameters of the cylinders, and therefore the resistances and potentials are the inverse of each other; for, let *r* stand for the resistance and *p* for potential, and *D* for the large and *d* for the small diameters, then $\frac{D^2}{d^2} = r$ for the large cylinder, and $\frac{d^2}{D^2} = p$ for the large cylinder, or for the small cylinder $\frac{d^2}{D^2} = r$, and $\frac{D^2}{d^2} = p$.

98. **Effects of Hot Glass on Light.**—If two kerosene lamps of equal illuminating potential are taken, some very interesting experiments can be tried. The reader will have found by observation that the biggest flame in a lamp does not supply the most satisfying light, for two reasons, first the combustion is not so complete in the large as in the small flame, and second the larger flame raises the glass chimney to a higher temperature and thus introduces a higher resistance to the passage of the light, and but for the elongation of the larger flame, that increases the volume of the light, the smaller light would far exceed in potential the larger one. These facts can be shown by the contrasted shadows as in Fig. 137. Here the cool glass that encloses the light *A* casts a shadow of deeper tone as *a a*, on the back screen,

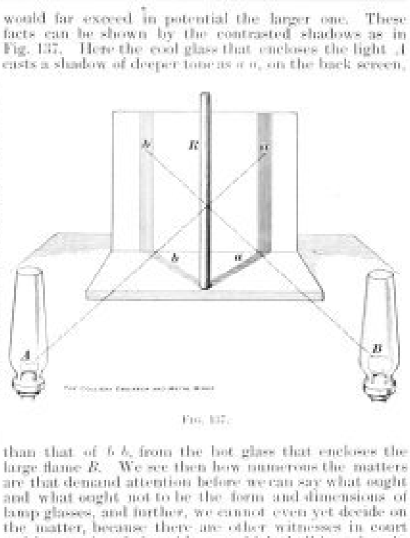

FIG. 137.

than that of *b b*, from the hot glass that encloses the large flame *B*. We see then how numerous the matters are that demand attention before we can say what ought and what ought not to be the form and dimensions of lamp glasses, and further, we cannot even yet decide on the matter, because there are other witnesses in court waiting to give their evidence, which shall be taken in the next lesson; and before we further proceed, let us observe that the early inventors of the safety-lamp were more concerned about a "convenient size of the lamp glass" than about how the different dimensions of the glasses would affect the transmission and diffusion of light, and strange to say the glass cylinders of the modern lamps are after all only copies of the early Clanny lamp, as illustrated by Fig. 138, at *G* and it will be seen by the directions of the descending and ascending arrows within the glass that so far as cooling was concerned the provision had been made, yet as the supply of fresh air was through the meshes at the lower end of the gauze tube, this air could not descend without receiving some heat by radiation.

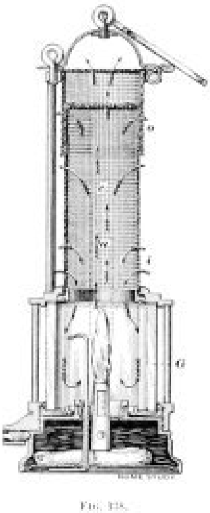

FIG. 138.

The Clanny lamp, however, is the parent of all the succeeding lamps that have been fitted with a glass cylinder and it remains until now very little improved.

99. **Recapitulation of Facts.**—QUES. 1. Would a bulging or spherical shaped glass give better results in diffusing the light of a safety-lamp than a cylindrical one?

ANS. A bulging or spherical glass in a safety-lamp does not increase the angle of diffusion when the top and bottom diameters and the lengths are the same as those of a cylindrical glass.

QUES. 2. Is the effective potential of the light from a bulging glass equal to that from a cylindrical one?

ANS. As the increased area of the surface of the shell of a bulging glass is greater than that of a cylindrical one whose top and bottom diameters and length are the same as those of the bulging one, the spherical glass introduces a greater resistances to the passage of the light and therefore reduces the effective potential.

QUES. 3. What principles should guide you in determining the correct form and dimensions of the glass of a safety-lamp?

ANS. To secure the greatest efficiency in illuminating power, the form and dimensions of the glass should harmonize with the requirements of the laws of light.

QUES. 4. What are the factors or makers of the potential of light?

ANS. The power or potential of light is the product of its two factors, namely the volume of the light, and the intensity of the light; for the volume of a light may be as small as the head of a pin on the one hand, and as large as a two inch globe on the other, and if their intensities are equal the large volume will illuminate a large space while the small one will illuminate a relatively small one, because their *filling* powers are proportionate to their volumes when the intensities of the lights are equal. To make the potentials of the two lights equal, the intensity of the small volume must as far exceed that of the large one, as the large volume is greater than the small one, or to make the matter clear let *I* equal the high intensity, and *i* the low one, and *V* the large volume and *v* the small one, then $v I = V i$.

QUES. 5. How does heat affect the transmission of light through glass?

ANS. When glass shells are set over illuminating flames the hot glass medium introduces a greater resistance than a relatively cold one and therefore the potential of the light from a cold glass is greater than that from a hot one.

QUES. 6. Give from nature an example of a large volume of light with a low intensity?

ANS. The volume of the light of the full moon is sufficient to illuminate half the surface of the earth, while its intensity is so low that if a pencil of its rays are admitted into a dark room through a hole about the size of a candle flame, the light giving power of this restricted beam is so small that it does not give sufficient light to enable one man to see another.

QUES. 7. Give from nature an example of a light that is at once great in volume and high in intensity?

ANS. The light in nature that is great in volume and high in intensity is the sun.

MINING MACHINERY.

Pump Movements and Resistances—The Sizes of Pump Valves—The "Tail" or Suction-Pipes of Pumps—Recapitulation of Facts.

109. Pump Movements and Resistances.—Mining students know the fact, intimately, that the resistances due to the motions of fluids vary as the squares of their velocities through orifices, and this being the case, we can understand how a high resistance is produced by a high velocity of the fluid at the port of entry, and how by this means the working efficiency of a pump is sometimes reduced.

The constriction or contraction at the entrance into the piston chamber of a pump may be caused, as it often is, by the valve orifice being too small. Mistakes of this kind are frequently met with, and they often arise from misconceptions of common causes; for example, what is called a one-inch faucet would be used to discharge water from a one-inch pipe, but on inspection it is found that the water-way or hole through the tap or shut-off plug only has a mean diameter of half an inch, or an area one-fourth that of the section of the pipe; and strange as it may appear, the water-way of the plug is large enough, because it can discharge at a velocity nearly equal to that at which the water can flow through the *length* of the pipe. It is therefore concluded that as a small water-way at the point of discharge is nearly as efficient as one having an area equal to that of the section of the pipe, the area of the water-way of the suction valve, or the area of the transverse section of the suction pipe of a pump, need not be more than a third or a fourth of that of the piston. The pump and the faucet are not, however, alike either in the discharge or the outflow, for we can lengthen to any extent the head of flow, which means that we can increase the length of the motive column to obtain pressures of more atmospheres than one, but we cannot obtain more than a vacuum under the piston of a pump, and if the suction pipe is any length at all, we never can get a pressure equal to that of the atmosphere to inject the entering water. Theoretically the pressure of injection varies as follows: Let a vertical column of water have a length of 34 feet to balance the pressure of the atmosphere, and let us represent this 34 by H, and let us use h to represent the height in feet the pump piston is situated above the level of the water to be pumped, then if the pressure of the atmosphere is equal to 2,125 pounds per square foot at the base of the column, the theoretical pressure of injection will be $\frac{(H-h)\,2{,}125}{H} = p$, and to give the matter a realistic character let us suppose that the pump piston is 16 feet above the intake water, then $\frac{(34-16)\times 2{,}125}{34} = 1{,}125$, equal the pressure per square foot producing injection. The number 2,125 pounds per square foot that balances the pressure of the atmosphere is found as follows: A cubic foot of water weighs 62.5 pounds, that is, mine water, for *pure* water weighs a little less; then 34 cubic feet set one over the other must weigh, as a column, $62.5 \times 34 = 2{,}125$ pounds. Again, let us notice that the pressure of the atmosphere in a deep mine is greater than at the surface, and therefore it sometimes requires at the bottom of a shaft a column of 37 feet to balance the atmospheric pressure, and as the barometer fluctuates in height at the surface of the sea, we sometimes find it so low that a column of 31 feet of water will balance it. Again, at high elevations in mountain regions the pressure may be as low as the equivalent of a column of 20 feet of water, and from the statement of these facts we learn that H varies so much in value that 2,118, or in the case before us, 2,125, cannot be taken as any other than average atmospheric pressures at the level of the sea. Let us next notice that the theoretical value of $\frac{(H-h)\,2{,}125}{H} = p$ is never true in practice, nor can it be, for water cannot move without meeting with resistance. It is nearer the truth of actual practice, then, to say $\frac{(H-h)\,2{,}125}{(H+h)} = p$, and therefore when h is equal to 16 we have $\frac{(34-16)\times 2{,}125}{(34+16)} = \frac{18 \times 2{,}125}{50} = 762$ pounds, the pressure of injection at the bottom end of the suction pipe, or "tail" of a pump. Again, let us observe that the *square* of the velocity in feet per second of water rushing into a vacuum, when propelled in doing so by the pressure of the atmosphere, is 2,180; then the velocity of the water, in feet per second, rushing into the piston chamber, when h is equal to 16, will be $\sqrt{\frac{(34-16)\times 2{,}180}{(34+16)}} = 28$, the velocity of the water in feet per second entering the pump. This conclusion is based on the law in mechanics that the pressures in relation to fluid movements vary as the squares of their velocities, therefore, in the case of water moving into a depression, the square 2,180 varies as $\frac{(H-h)}{(H+h)}$ varies. We are now in a position to resume the investigation of the effects of the constrictions of the water-ways through valves as affecting the efficient action of pumps; and let us lead off with the supposition that the available water-way through the orifice of a suction valve is only one-fourth of the area of the pump piston as shown by Fig. 143, where P is the pump piston and $b\ p$ is the available orifice of the valve, and the arrows are here given to indicate the acceleration of the fluid movement due to the small area through the valve.

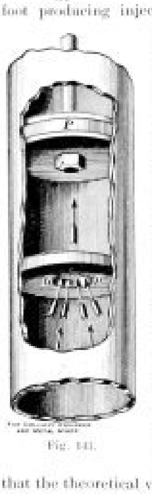

Fig. 141.

110. The Sizes of Pump Valves.—Now if the area of the water way through the valve at $b\ p$ is one-fourth of the area of the piston, we can see that the speed of the piston must be reduced to one-fourth, or otherwise the engine must advance the pump piston beyond the reach of the inflowing water because the inflow cannot take place at a higher velocity than the available pressure can maintain, then let us take h again at 16, then $\sqrt{\frac{(34-16)\times 2180}{(34+16)}} = 28$, but whether the area of the orifice be large or small, if the effective pressure remains unaltered, the velocity will be in all cases the same, therefore at equal velocities only one-fourth of the volume of the water will flow through the small orifice that would upflow and fill the pump cylinder if the channel was unobstructed, or in other words, to make the matter plain, if the orifice through the valve is one-fourth the area of the piston and if the piston is moving with a velocity of $28 \times 60 = 1680$ feet per minute, then the pump cylinder will only be one-fourth full every time the piston reaches the top of its stroke because $\frac{28}{4} = 7$; that is, only one-fourth of the water required to fill the cylinder could enter at a velocity of 7 feet per second. It might be inferred from these conclusions that if the engine or the pump piston was run at one-fourth of the speed of 1680 feet per minute that even with the small water way through the valve no loss of mechanical effect would then occur, but such is not the case, because the depression for quarter speed would have to be the same as for full speed, or the force to move the piston would be the same in both cases because both speeds require a vacuum under the piston. We see then that from every point of view it is important to have the water-way through the suction valve sufficiently large to keep the velocity of the fluid as nearly as possible equal to the speed of the piston of the pump. Fig. 144 deals with the suction pipe $V\ T$.

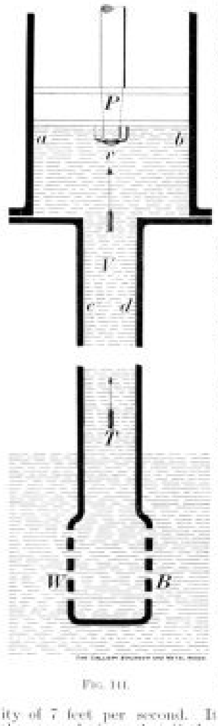

Fig. 144.

111. The "Tail" or Suction Pipes of Pumps.—Perhaps the best object lessons men get are those taught them by mistakes or gross errors that are highly magnified, and the figure before us is of the type of a "gross error magnified." The instinct of a man of any mechanical intuition would shudder at the thought of a tail pipe of a pump being only one-third of the diameter, inside measure, of the pump piston, or the area of $c\ d$ one-ninth that of $a\ b$, or that when the pump is in action, the velocity of the water in the tail pipe at V is nine times greater than the water under the piston at v, for the velocities are inversely as the squares of the diameters, or inversely as the areas; again, just fancy the velocity through the holes in the strainer $W\ B$, and especially if the joint area of the holes is less than the the area of T, and here is enough to magnify the gross error of making the tail pipes of a pump too small. Now taking h at 16 again,

$$\sqrt{\frac{(34-16)\times 2180}{(34+16)}} = 28 \text{ nearly,}$$

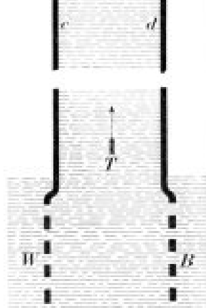

Fig. 145.

but the velocities of the water in the cylinder and tail pipe are inversely as their areas or if v is 1, V is 9, then $\frac{28}{9} = 3+$ and if the joint area of the strainer holes is one-fourth that of $a\ b$, then to entirely fill the cylinder at every stroke the speed of the piston would have to be reduced from 1648 per minute to $\frac{1648}{16} = 103$. It might be thought that a little reduction in the size of the tail pipe would have little effect on the efficiency of the action of the pump, but we must first understand what we mean by efficiency. Well, we mean the pump that will lift the volume of water required per minute with the smallest possible expenditure of energy. Just so, then let us apply this claim to Fig. 145, and let $c\ d$ be two-thirds the diameter $a\ b$, then the velocity of the piston being $v = 4$, that in the tail pipe at V will be 9, but if the joint area of the holes in the strainer or wind-bore $W\ B$ is ¼ of the area of the pump piston P, then, if the velocity of the piston is 4, that of the water entering the holes in the wind-bore will be 25 or 6.25 times the velocity of the piston, or this constriction would reduce the effective piston speed to 4.48 feet per second, because $\frac{28}{6.25} = 4.48$. On every hand then we are checkmated where the joint area of the holes in the wind-bore is too small, or where the area of the tail pipe is too small, or where the waterway through the suction valve is too small. Let us next consider then the results of introducing another "magnified gross error." Fig. 146 is an example wherein the tail pipe is too large, for if the diameter of the piston P or $a\ b$ is 2 and that of the tail pipe T or $c\ d$ is 3, then the velocity of the water advancing up the tail pipe will be 4/9ths that of the piston and, leaving out of the question the joint area of the holes in the wind-bore, we cannot but be satisfied that by this scheme any abnormal resistance is removed from the ports of entry into the pump cylinder, but to introduce such a tail pipe would be in keeping with the conclusion that if the frictional resistance due to the axle of a small wheel was greater than that due to a large one, it would be wise to fix 20-foot wheels on a buggy; now such a wheel would have to be very much heavier than a four-foot wheel, and therefore it would most likely increase the resistance more by its weight than it would reduce it by its decreased angular velocity; besides the large wheel would cause a needless shake and it would be subject momentarily to a break down. So with a large tail pipe we would be confronted with new troubles, for all water contains air in solution that is set free in a vacuum, and we would soon have a collection of air that would render the pump with the overdone tail pipe perfectly wasteful, even more so than in some cases where the tail pipe is too small; and therefore, to provide for the dislodgment of air and yet not to accelerate too much the velocity of the water in the tail pipe, it has been found by practice and experience that the best results are obtained when the diameters of the tail pipe and piston are to each other as 9 is to 10, or when the diameter of the tail pipe is .9 of the diameter of the pump piston.

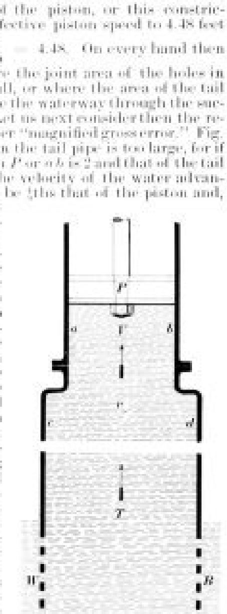

Fig. 146.

112. Recapitulation of Facts.—QUES. 1. Express for me the laws of pressure and resistance in relation to the motion of fluids.

ANS. The pressures required to set fluids in motion from a state of rest vary as the squares of the velocities of the fluid streams, or the reverse is equally true, and that is, the velocities vary as the square roots of the pressures.

Again, the resistances vary as the squares of the velocities, but the velocities vary as the square roots of the resistances inversely; for example, let v equal the velocity, and p equal the pressure, and r equal the resistance, and we can show that: The pressures vary as the squares of the velocities, as $v^2 = p$.

The velocities vary as the square roots of the pressures, as $\sqrt{p} = v$.

The resistances vary as the squares of the velocities, as $v^2 = r$.

The velocities vary as the square roots of the resistances inversely, as $\sqrt{\frac{1}{r}} = v$.

QUES. 2. If a vertical column of water, 34 feet high, balances the pressure of the atmosphere, what is that pressure in pounds per square foot?

ANS. The pressure will be equal to the weight of a vertical column of water 34 feet high, as $62.5 \times 34 = 2125$ pounds per square foot of section.

QUES. 3. If 62.5 pounds were lifted 34 feet high, how many foot pounds of work would be done, and if 62.5 pounds were to fall 34 feet, how many foot pounds of energy would be stored in the mass, and what would be its acquired velocity?

ANS. The foot pounds of work done in raising 62.5 pounds to an elevation of 34 feet would be, $62.5 \times 34 = 2125$ foot pounds. The energy stored in a mass of 62.5 pounds, after falling 34 feet, would be 2125 foot pounds and the final velocity of the mass would be $\sqrt{34 \times 2g} = v$, or $\sqrt{34 \times 64.32} = 46.76$, the velocity required in feet per second.

QUES. 4. What is the meaning of the expression $\frac{(H-h)}{H} 2125 = p$?

ANS. The letters represent the following values: $H = 34$, the length of the vertical column that balances the pressure of the atmosphere; h equals the height of the pump piston above the level of the water that is pumped, and therefore it reduces the effective pressure urging the upflow of the water, hence h is negative to H; p is the effective pressure, and 2125 is the pressure of the atmosphere in pounds per square foot, and therefore $\frac{(H-h)}{H} 2125 = p$ means that p is the effective portion of the 2125 pounds pressure that remains after h has been allowed for.

QUES. 5. What is the meaning of the expression $\frac{(H-h)}{(H+h)} 2125 = p$?

ANS. As the letters have already been explained, we need not again refer to their meaning and their use. The expression $\frac{(H-h)}{H} 2125 = p$ is purely theoretical, and makes no deduction from the calculated pressure for the resistances common to all pumps, put as the sum of the resistances in a well-constructed pump is correctly allowed for by the equation $(H-h)\ 2125 = (H+h)\ p$, it is used where the working efficiency of a pump is required, as $\frac{(H-h)\ 2125}{H+h} = p$.

QUES. 6. Why are small water-ways through the suction valves of pumps objectionable?

ANS. A small water-way through a valve reduces the velocity of inflow into the pump cylinder, and, therefore, when p is small the pump has to be run at a low velocity, and therefore does a reduced quantity of work per minute. A small water-way also sets up an increased resistance, and wastes a high percentage of the motive power.

QUES. 7. What is the best object lesson we can have in the right dimensions we should give to the water-ways of valves, and the suction or tail-pipes of pumps?

ANS. The best object lesson to learn how to determine the right dimensions of suction valves, and the areas of tail-pipes for pumps, is found in the case of a "grossly magnified error," such as making the area of the suction valve excessively small, or the diameter of the tail-pipe excessively small, and noting the results. Again, the correct sizes can be found by correcting one excess, by its opposite in excess, that is, by making the water-way of a valve too large, and the diameter of the tail-pipe too large, and then finding where the best results are found between the extremes of the grossly magnified errors.

(To be Continued.)

MINING METHODS.

What is Coal Dust?

93. **What Is Coal Dust?**—We mean by the word dust, a crowd of minute particles of solid matter that are easily suspended in air in motion; and as this definition applies to all solid matter in a state of very fine division, we have clay dust, road dust, stone dust, brick dust, mill dust, grain dust, cotton dust, woollen dust, powder dust, coke dust, coal dust, and many other varieties.

The definition just given, however, is only that of the popular conception, and it is quite sufficient to enable one man to understand another when its presence is announced, or a cause is indicated that will produce it, but as its presence in the air of mines is a cause of danger, we require to know a great deal more about it.

We ought, for instance, to know the sizes, weights and relative surface areas of the particles, and the laws that regulate their suspension and velocities of descent; and unless we know these particulars we are incompetent to discover the right means of keeping under proper control the dangers that arise in the presence of dust. The only classification at present recognized is "The dusts of different coal mines," "Heavy dust and flocculent dust," and unless we can assign the reason why the dust of one mine differentiates from that of another the classification is worthless; and as the terms heavy dust and flocculent dust are only relative ones, they have no applicate value, and therefore we are compelled to originate a classification that will enable us to determine when dust is and when it is not dangerous, and also how to treat it to keep it within the bounds of safety.

However minute the particles in a dust cloud may be, we ought to know their sizes, weights and velocities of suspension, and as the means are at hand that will enable us to find these values, it is our intention to begin in this lesson to explain the standards of measure and their unit values and the scales for weighing, and the unit values of the weights to be used in dust-gauging. The measures and weights of the particles can be deduced, and also the velocities required for suspension, by the application of the laws of the velocities of falling bodies, and the relationship of the areas of the surfaces to the weights of the particles.

When a body falls in a vacuum it accelerates or quickens its speed at the rate of 32.16 feet every second, but this law is very much modified when a body falls in air, indeed the increase per second *decreases* every second, until the acceleration vanishes altogether, and if the body falls from a great elevation, the positive acceleration actually becomes negative, or the body begins at

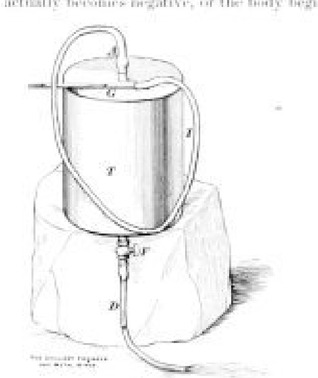

FIG. 133.

last to have an increasing retardation per second, as the result of the density of the air increasing. The velocity at which a body falling in air will cease to accelerate is of easy determination when the weight of the body and the area of its end surface is known.

We are all familiar with the fact that a spherical shot thrown by a smooth bore gun meets with a greater resistance from the air, on account of the large area of its "end," than a cylindrical shot from a rifle cannon with a small "end" area. If a cube or sphere of iron and an iron bolt are let to fall down a deep shaft at the same moment of time, the bolt will reach the bottom before the sphere, and if the shaft is *very* deep, the differences in the times will be considerable, and to make the matter clearly understandable, let us calculate a case. Suppose then we let fall a cube of coal equal to a cubic foot in contents, and let us find at what velocity it will cease to accelerate while falling. Then, let the specific gravity of the coal be 1.3 and the weight of a cubic foot will be $62.5 \times 1.3 = 81.25$ pounds. The resistance due to the air in which this cube is falling can be found as follows: 1,800,000 = the square of the velocity of air rushing into a vacuum from atmospheric pressure, 2,120 = the pounds pressure per square foot of the atmosphere, 81.25 = the weight in pounds of the cube of coal that falls.

The law of the resistances of air produced by bodies falling in it is: A body ceases to accelerate when falling in air, when the resistance per square foot of end area, is equal to the weight of the body; and as the resistances vary as the squares of the velocity it follows that $\sqrt{\frac{1{,}800{,}000 \times 81.25}{2{,}120}} = \sqrt{68{,}986} = 262.66$.

That is to say the resistances vary as the squares; or if 2,120 pounds require a square of velocity of 1,800,000, 81.25 pounds will only require 68,986; or in other words, when our falling cube of coal reaches a velocity of 262.66 feet per second, it cannot further accelerate, and if the density of the air did not increase, the body would continue to fall at that uniform velocity forever. In our next lesson we will proceed to show how the weights and sizes and suspension velocities of the particles in a dust cloud can be found, and to aid the description, suitable figures will be introduced, but in the meantime, the reader is advised to give special attention to this lesson, as all future ones will be based upon it. Let us then clearly understand that the velocity at which a falling body ceases to accelerate, is what we have noticed as "the velocity of suspension." Having, however, found the velocity of suspension for a cube of one cubic foot of coal, we can now dispense with the number 1,800,000 and adopt that of 69,000 for our unit, because the squares of the velocities of suspension vary as the weights per square foot of end surface; for example, suppose we split our cube into two slices, each one square foot in plan, and 6 inches thick, and let one of these slices fall flat, it is clear that the square of the velocity of suspension would be $\frac{69{,}000}{2} = 34{,}500$, because, we now have halved the weight per square foot of each end surface. It would be impossible, however, for the slab of coal to keep horizontal, and if it fell endwise it would actually have the same velocity of suspension as the entire cube, because for half the weight, it now has only half the end area; but if we split the slice into four parts, each one of them would be a cube one-eighth of a cubic foot in its contents, and yet it would have an end area equal to one-fourth of a square foot; if, therefore, we multiply $\frac{1}{8}$ and $\frac{1}{4}$ each of them by 4, we have $\frac{\frac{1}{8} \times 4}{\frac{1}{4} \times 4} = \frac{\frac{1}{2}}{1} = \frac{1}{2}$, then, $\frac{69{,}000 \times 1}{2} = 34{,}500$ the square of the velocity of suspension as before. We have indicated at any rate, the route along which we are going to travel, and to allow breathing time for study, we will illustrate the construction and use of an instrument of importance in the dust investigation. This apparatus is capable of considerable modification, but the one before us is the best we could select for simple explanation, and it is illustrated by Fig. 133. The use of this instrument is to measure the weight of the dust in a cubic foot of the air of a mine by passing it through a cotton wool filter. The filter consists of a glass tube G, which is filled loosely with fine fibrous cotton wool, to which the very small particles of dust adhere when they are carried into the tube with the stream of air. The air is set in motion and measured by a water displacement which proceeds as follows: At the beginning of the measurement the tank T is full of water, and this can be run off through the faucet F and out through the hose pipe D. Now let us suppose it is required that the weight of coal dust in a cubic foot of air should be known, and let us suppose that the tank T is full, and that its capacity is three cubic feet. If now the faucet F is opened, the water will flow out through the hose D and make a depression, and now the air will press through the filter G, and then after being clarified will flow through the pipe I and enter the top of the tank at A and so on until the tank is empty of water. Now the dust that has been filtered out of the air will be safely lodged among the fibres of the cotton wool, and, therefore, the tube is now disconnected from the pipe I, and carefully weighed, and if it is found to be fifteen grains heavier than it was before the filtration began, we know that every cubic foot of air contained 5 grains of fine coal dust in suspension before it was tested.

(To be Continued.)

Mine Harness.

One of the very necessary supplies at mines is mine harness, and as the various parts of a set are constantly wearing out or breaking, owing to the very severe service, the necessity of durable portions subject to strain is urgent. Hames, in particular must be made of such materials and in such shape as to meet hard strains and rough usage. The hame illustrated herewith, shows a

PITTSBURG HARNESS SUPPLY CO. HAME.

well shaped, properly protected and reinforced article fitted with strong and well arranged fittings.

Another specialty manufactured by the Pittsburg Harness Supply Co. is a double throat hair faced mine collar which has met with much favor among such large consumers as the Monongah Mining Co., W. J. Rainey, Cumberland Coal Co., and many others. This collar is shown in the annexed cut.

PITTSBURG HARNESS SUPPLY CO. COLLAR.

The Pittsburg Harness Supply Co. is the largest harness house in Western Pennsylvania, and, while having an important part of its business devoted to mine work as a specialty, also manufactures and carries a complete stock of buggy, coach and coupe harness, as well as a full line of harness supplies of all descriptions. Such harness supplies as are necessary for repairs at mines are shipped to purchasers on shortest notice. The facilities of this company are such that orders for supplies are filled in the shortest possible time, the large domestic and export trade done by the company making it necessary for them to carry the largest stock in the city of Pittsburg. In fact, few houses in the country carry larger stocks. Their illustrated catalogue will be cheerfully mailed to any mine manager requesting it. Their place of business is No. 50 Seventh street, Pittsburg, Pa.

MISCELLANEOUS.

THE SOURCE OF MALARIA.

The investigation on the source of malaria has had the writer's attention for over two years, and in that time a large amount of clinical testimony has been collected from all known malarial districts in North America; the final report, however, will hardly be ready for publication for some months, but from the work already completed certain facts have been obtained which will be embodied in this short notice.

The introduction of artesian wells, first by the railroad companies who desired a larger supply of water than had hitherto been available, and the accidental use of that water by the people in the immediate vicinity, soon produced a marked diminution of malarial trouble in those localities. The artesian supplies were, on the whole, so satisfactory to the railroads that their introduction became very rapid, and in a few years most of the South Atlantic lines depended upon this source of water supply. The evidence that in the exclusive use of the deep-seated waters there was entire immunity from malarial trouble was apparently so incontestable that I determined upon a critical examination of all waters known to produce malaria and those that in malarial districts were proof against it; this examination is not only chemical, but biological and pathological.

In the present state of our knowledge we do not expect to be able to draw a sharp line between waters that produce malaria and those proof against it by purely chemical analysis; nor, on the other hand, can we hope to identify by biological examination the protozoa producing that trouble; but we may by the former succeed in isolating certain toxic products peculiar to those waters only, and by the latter a certain line of testimony that, in conjunction with the chemical investigation, will yield very valuable results. The work thus far has proved satisfactory beyond expectation, and, from the work already done, and the character and amount of evidence before me, I am justified in stating that the long-current belief that the source of malaria is in the air is in error.

The germ, which is of soil origin, is strictly a protozoa, and reaches its highest development in low, moist ground, with a favorable temperature. Surrounded by the proper soil conditions, this protozoa passes from one stage of life into another with considerable rapidity; so that in the present state of our experimental knowledge it is impossible to identify it, nor is it probable that by culture we shall be able to produce the accepted Laveran germ outside of the human system.

As a rule, the potable water from the malarial districts is derived from driven wells not over twenty-two feet deep, in soil with clay or some other impervious substrata, which water is generally cool and palatable, often sparkling clear, but more frequently a little turbid. This water is filled with an incalculable number of these germs in all stages of development, and if used as a potable water they naturally find their way into the system through the alimentary channels. This protozoa passes through so many forms or stages of life that in some stages it is light enough to float and be transported by the moist air of low grounds, but in this state it is comparatively harmless except under most extraordinary conditions; it is not until the surface water is used that the mischief begins, when, by reason of higher development, it has become much more virulent than that floating in the air. A very short period of incubation is sufficient to develop a severe case of malarial fever in the newcomer who uses the surface water.

From personal observation I know that the exclusive use of pure, deep-seated water affords entire immunity against malaria in sections of country where no man dared live using the surface water. Nor must it be understood that the exclusive use of pure water simply fortifies and strengthens the system against the attack of the germ. The water is the primary cause of infection, which acts as the direct carrier of the germ into the system through the intestinal tract.

The impression that malaria is caused by purely atmospheric influences has become so fixed in our minds that, unless we come in actual contact with the evidence produced in the use of pure water as against that heretofore used, the physician will, in all probability, be very slow to allow himself to be convinced that the word malarial (*mal*, bad; *aria*, air) is a misnomer, and that malaqua (*mal*, bad; *aqua*, water) is the word that should be used to convey the pernicious effects known under the name of malarial fever.—*From The Medical Journal.*

A NATURAL BEAR TRAP.

In the Yellowstone National Park there is a locality to which was given the appropriate name of Death Gulch. It was discovered in July, 1888, by W. H. Weed, of the geological survey, and the writer. It is situated in the extreme northeastern portion of the park, on Cache creek, several miles above its confluence with Lamar river, or the east fork of the Yellowstone, as it is often called. It is easily reached by a horseback ride of about five miles from Soda Butte, the mail station on the route between the Mammoth Hot Springs and the little mining town of Cooke City, Mon.

In the center of the former hot spring area of Cache creek the creek makes a broad pool which "boils" furiously from the action of escaping gas, and is, in fact, a natural soda water fountain. Small particles of sulphur are also floating in the water, and are being deposited about the edge of the pool. Just above the pool the creek has cut through a bank of sulphur and gravel, and a few yards beyond is the debouchure of a small lateral gully or gulch coming down from the mountain side. Following this gulch we come within a quarter of a mile to the end, or, rather, beginning, which is a "scoop" or basin about 200 feet above the creek. The sides of the gulch, except at the head, are very steep, and in the bottom flows a tiny stream of cold, clear water, sour with sulphuric acid.

We were making our way up this gulch and had just entered the terminal portion when our attention was directed to a huge silver-tip grizzly bear within twenty feet of us. He was in such a natural position that we supposed him to be asleep, but a closer inspection showed him to be dead. The body was perfectly fresh, and could hardly have been dead two hours. We examined the body very carefully for bullet holes or other marks of injury, but beyond a few drops of blood under the nose there was not the slightest trace of violence. But during this examination we were conscious of the near presence of other decomposing matter, and a short examination revealed the presence of the more or less decomposed bodies of four more bears, an elk, several squirrels, rock hares, besides numerous dead butterflies and other insects. One of the bears was a good-sized cinnamon bear, and was in an advanced stage of decomposition. The other skeletons were almost denuded of flesh, although the claws and much of the hair remained.

At first we were unable to account for this strange accumulation of dead bodies of animals until a choking sensation of the lungs suggested the presence of noxious gases, and the death of the animals by asphyxiation. The hollows were tested with lighted tapers for the presence of carbonic acid gas, with only slight results, but as a strong wind was blowing down the gulch at the time, the gases would have been rapidly diffused. A strong sulphurous odor was present. On a subsequent visit, however, there was no wind, and the presence of carbonic acid gas was more manifest.

It is likely from the nature of the surroundings that there is never a very great accumulation of this deadly gas, for it would naturally tend to flow down the ravine, and be rapidly dissipated. If the head of the gulch was a more marked basin the accumulation of gas would undoubtedly have been very marked, and the consequent fatalities more numerous. The first animal doubtless wandered in and was overcome, and thus served as a bait to lure the others in turn to their destruction. Certain it was, the body of the bear that was fresh on our first visit was a widely advertised bait on a second visit some weeks later.

As Mr. Weed has suggested, this gulch has doubtless served as a death-trap for a very long period of time, but these bodies and skeletons must be the remains only of the most recent victims, for the ravine is so narrow, and the fall so great, that the channel must be cleared out every few years, if not annually.

Since the discovery in 1888, Death Gulch has been visited by people in this vicinity, and it stands without a peer as a natural bear trap.—*From the St. Louis Republic.*

UNIQUE MAIL ROUTES.

Probably the most unique method of transporting mails known to the United States Post Office Department is that in daily use between Telluride and Smuggler. The mining town of Telluride is located at the head of a picturesque gulch. The mountains rise in majesty to cloud-piercing heights about the town, and from every precipitous draw between the giant peaks foaming cascades, waterfalls and roaring streams come down from the snow-laden summits to swell the torrent of the San Miguel, which rushes through the town. Four miles above Telluride is Marshall Basin, situated among the snowy peaks and far above timber line, and in this basin is the little mining settlement of Smuggler, where the employes of the great Smuggler-Union and Tom Boy mines make their homes. Although the inhabitants have a post office of their own the postal authorities do not guarantee a regular service because of the difficulty of keeping a trail open in the winter time. The dangerous snowslides constantly threaten destruction to the hardy miners who scramble through the snow up the steep trails to the settlement in Marshall Basin. Until in recent years all supplies for the camp in Marshall Basin were transported thither by pack animals. Timber for the mines, coal for the boilers, and iron rails were dragged over the trails or packed securely about swaying pack saddles and carried to an elevation of 12,000 feet by the burro. When winter closed down and the burro trains could no longer be driven on schedule time the miners would take turns in going down on snowshoes to get the mails and a few necessary supplies that could be carried upon their backs.

But the practical application of the endless chain by the inventor of the Hudson tram has greatly facilitated the transportation of supplies from Telluride up to Marshall Basin. Great iron buckets, each carrying down the mountain a half ton of ore, furnish by their weight the active power which drives the endless chain from which they are suspended. In these buckets, upon their return, the necessary supplies for the camp are placed. One of the buckets is painted a bright red color and the letters "U. S. Mail" in black designate the use to which it is put. The daily mail for Smuggler post office is now delivered as regularly across the four miles of precipice, snow-buried gulches, and giant mountain ruggedness and with as much safety as between two settlements in the prairies of western Kansas or Nebraska.

Just over the range of peaks from Marshall Basin is the post office of Mt. Sneffels, near the famous Virginius mines, seven miles above Ouray, a mining town which is as picturesquely located as Telluride. A good wagon trail leads from Ouray up the mountain side to Virginius mine, but in the winter time the trail fills with snow, an occasional slide destroys the continuity of the route so that sledding cannot be done, and the mails are carried by men with snowshoes. There are a number of snowshoe routes in the mountains of Colorado, but none more hazardous than this one. The men who carry the mails over snowshoe routes seldom meet with accident. They have learned to understand the peculiarity of snowslides, and when a high wind is blowing or other meteorological conditions make traveling along the trails dangerous, they postpone their trips until settled weather returns. Sometimes the mails are two weeks in arrears when the mail carriers dare to venture forth.

A free delivery system is in vogue in the mining districts, though the postal authorities have nothing to do with it. From every mountain post office trails diverge up every draw and gulch. A miner setting out for his cabin, perched somewhere far up on a mountain, will take with him all the mail belonging to his neighbors, though they may live miles from his place. At each turning-off point, a small box will be found nailed securely to the trunk of a stout old pine tree, and upon this box is scrawled the names of all the miners who must pass that tree in going to their respective cabins. Into this box the last man from town deposits all the mail belonging to miners living up that particular gulch. From that gulch a miner will occasionally descend for the mail, and as he returns up his trail, he deposits in turn the several pieces of mail in other boxes placed at convenient points. In this manner one man can save many a weary step to other miners who live out the long winters in the very heart of the Rocky Mountains. Mails are collected in a similar manner, and often small errands are likewise done. Money deposited in mail boxes for the purchase of stamps, tobacco, and other notions light in weight, is always properly respected and the mission fulfilled, no matter how much the snow-shoe pedestrian may be under the influence of good fellowship as he returns from town.—*From New York Sun.*

CHINESE TELEGRAPHY.

All the principal cities of China are now connected with one another and with Pekin, the capital, by telegraph. Recent visitors to China say, however, that telegraphing there is a laborious and an expensive process, and that the lines are a charge upon the State treasury instead of a source of revenue.

The despatches are, of course, sent in Chinese, for not one in many thousands of the natives knows any language except his own. But the Chinese have no alphabet. Their literary characters, partly ideographic, partly phonetic, number many thousands. It is simply impossible to invent telegraphic signals that would cover the written language. Here was an obstacle in the way of using the telegraph at all.

The difficulty was obviated by inventing a telegraphic signal for each of the cardinal numbers, and so numbers or figures might be telegraphed to any extent. Then a code dictionary was prepared, in which each number from 1 up to several thousands stood for a particular Chinese letter or ideograph. It is, in fact, a cipher system. The sender of the message need not bother himself about its meaning. He may telegraph all day without the slightest idea of the information he is sending, for he transmits only numerals.

It is very different with his friend, the receiver. He has the code dictionary at his elbow, and after each message is received he must translate it, writing each literary character in place of the numeral that stands for it. Only about an eighth of the words in the written language appear in the code, but there are enough of them for all practical purposes.

But the Chinese system has its great disadvantages. Men of ordinary education have not sufficient acquaintance with the written language to be competent telegraph receivers, and the literati are not seeking employment in telegraph offices any more than our college professors are. So the Government recruits its employes with much difficulty. Besides, the patrons of the telegraph are comparatively few in number. There are almost no Chinese who have business relations all over the country, as is the case with many thousands of our business men. The public is not invited to buy stock in the Chinese telegraph lines, and if it was, nobody at present would buy with a view to dividends. The receipts do not equal the expenses, and the Government makes up the deficit.

There is another great disadvantage of the Chinese telegraph system. All over the world the movements of railroad trains are regulated by telegraph. The orders received by the station agent are filed in plain view of the employees, and if need be the switchman may take temporary charge and carry out the instructions from the central office. Railroads have been introduced into China to a very small extent, and there is talk of greatly extending the service. But how about running the trains?

A writer in *Le Mouvement Colonial* of Paris says that if railroads are introduced to any extent in China the personnel must be exclusively European and American, or recruited from the literary class. He says the Chinese Government will not take foreigners into its service, and that the educated men of China, who alone among the people have sufficient knowledge of the written language to be intrusted with the actual running of trains, would refuse most emphatically to be either train hands or station agents.

This is one of the many small stumbling blocks in the way of China's progress, but it is quite effective in its way.—*From the "Statesman's Year Book."*

HAWAII'S BURNING MOUNT.

After an interval of thirteen months of quiescence the volcano Kilauea is again in action. On the evening of Jan. 3, at about 11 o'clock, the inhabitants of Hilo, the largest town on the great island of Hawaii, noticed a peculiar rosy glow in the sky toward the southward. The tidings flew rapidly and all the population of the lovely village was aroused and thronged the streets to gaze upon the beautiful sight. It was known at once that Kilauea had once more broken forth in eruption and the news was hailed with joy. This statement seems a trifle startling when one considers the havoc which volcanoes in general are apt to play with the outward world; but it must be remembered that Kilauea is unique among volcanoes, and that, lively as may be its eruptions, its great sea of molten lava has never been known to overflow its mighty banks. The volcano is, in fact, the great show which the Hawaiian people have for their continental visitors.

Although it is a journey of a day and a half from Hilo to Honolulu the news soon reached there, and a party was at once made up to visit the volcano, and when the Kinau, the regular Hilo boat, finally drew away from her moorings and steamed out of the harbor, she took with her one of the merriest parties which has sailed out of Honolulu for many a long day. The day was glorious; the sea and sky, as always, deeply, beautifully blue. The southward course was taken, the tourists passing upon their trip the extreme southwestern point of Molokai, the green shores of Lanai, and the rock coast of Kahoolawe. Here the prow of the Kinau was turned northeastward, into the channel which separates the islands of Maui and Hawaii. Passing Upolu Point, she swung about until her prow pointed to the southeast and skirted the great island of Hawaii, until the lovely Hilo Bay opened before us.

As night fell the rosy glow of the sky, far away above Kilauea, became intensely vivid, and the tourists, charming as was the voyage, were all impatience to reach the scene of nature's great display.

It was but a short time after the arrival of the boat before the entire party was in motion, the majority in carriages, but some on horseback. Quite a number of these last were ladies, who, anticipating this feature of the trip, had brought their riding habits with them. A few of these were native Hawaiian women, whose custom it is to ride astride, and their flowing habits, reaching nearly to the ground upon each side of the horse, and streaming out in the rear when they rode swiftly, were a picturesque feature of the cavalcade. The road is bordered upon both sides with luxurious plant growth—palms, great tree ferns, and other tropical foliage; but beyond this and partially hidden from the road are the coffee plantations; for this is the region where the coffee plant grows, and now that the crown lands are open for settlement, this region is soon expected to rival in importance the great sugar-producing areas in other portions of the islands.

The journey to Kilauea from Hilo is not far from forty miles, and although the road is excellent, it was nearly sundown when we reached the Volcano House, where we found ample accommodations. The sensation of sitting down to a comfortable meal, and, above all, of going to bed in a house situated close to the crater of a volcano, is decidedly curious, and one which can be realized nowhere in the world but here. We did not, however, retire at once to bed, weary as we were from our journey, for it is after nightfall that the fearful sublimity of Kilauea is seen at its best. It is not safe, however, to venture far away from the Volcano House, even in the daytime, without a guide, for what may seem, perhaps, as solid ground, covered with a tangle of flowering vines, may be a pitfall, where the indiscreet wanderer may receive an unlucky tumble.

The volcano, as has been said, never overflows the upper rim of the immense crater upon the floor of the tremendous depression upon the summit of the mountain, which scientists have called the caldera. The outer rim of the caldera is several hundred feet above its floor, and it is a hard but not dangerous scramble down the declivity. The floor is composed of cooled lava, and is evidently only a crust covering the immense lake of molten fire which boils and seethes beneath. Here and there, as the traveller crosses this floor, are fissures through which are visible the fires below, and a stick thrust into one is quickly charred.

It is a walk of a mile or two over this lava floor before one reaches the great lava lake, Halemaumau, or the House of Everlasting Burning. Great cliffs surround the pit, up which one must scramble. Once at the summit, he gazes down into the awful chasm, for hundreds of feet, into the seething mass of boiling lava below. For more than a year prior to the 3rd of January the great lake had been quiescent. The great mass of lava had sunk away, down the vast shaft, until scarcely a vestige of it was to be seen. But upon that date it began to rise in the shaft, boiling and tumbling as it came. Within twenty-four hours it had risen to the top of the shaft and had begun to overflow upon the floor of Halemaumau. In a few hours a lake, 250 feet in length by 200 in width, had formed within the pit, and this hourly increases its area until it reaches its normal size, when the volcano is in full action, which is about 1,500 by 1,000 feet.

It is impossible to describe, adequately, the tremendous sight. Standing upon the crest of the cooled lava which surrounds the pit, we gazed down 400 feet into the cavernous depths, upon this enormous lake of fire, its surface covered with boiling fountains of lava. In places the lake is covered with a thick, black crust, through which the fires glow with an unearthly gleam. Now and then, from the centre of one of the fountains, a jet of molten lava, mingled with steam, is thrown up, but not with tremendous violence. Its force spent, it falls back upon the crust, where the glowing mass remains for a time until it gradually fades from a brilliant red to a rosy glow, and at last to the dull black of the crust. This crust is not continuous, but is formed in detached sheets, which, from time to time, are upheaved by some great commotion below and, turning, pitch downward and disappear below the glowing red surface of the lake. A period of great activity then ensues, the floating cakes of encrusted lava being tossed violently about, like cakes of ice upon a stormy sea, pitching and plunging until the whole surface of the lake is a glowing mass of fire, from which the onlooker draws back and shelters his face from the intense heat. By and by the lake, little by little, becomes more quiet, the intense agitation ceases, and again the sheets of black crust appear upon the surface.

When these ebullitions occur the air is filled with a curious substance, to which is given the name of "Pele's Hair." In the mythology of the ancient Hawaiians, the goddess Pele made her home in the House of Everlasting Burning, and to her the priests were wont to offer incantations and sacrifices to appease her wrath. Pele's hair comprises masses of minute threads of lava, drawn out, it is popularly believed, by the action of the wind upon the sprays of boiling lava. Scientists, however, find another explanation of the phenomenon in the sudden liberation of the watery vapors which are mingled with the molten lava, beneath the surface of the lake. Whatever may be the scientific cause of this curious formation, it remains that great bunches of Pele's hair, resembling finely shredded asbestos, are always found clinging to the rough lava rocks to the leeward of Kilauea, and it is gathered in large quantities by tourists as a souvenir of the visit to the volcano.

It is impossible to adequately describe the gorgeous terrors of Halemaumau; to picture the tremendous intensity of color upon the surface of the lake; to describe the varying forms of the rugged lava wall, which rises for hundreds of feet above its surface, and forms the enormous pit in which it seethes and boils, to the interest and terror of the beholder; to picture the varying shades of brilliant red, yellow, orange, and saffron with which the rugged walls are here and there be-pattered, and by which the dense blackness of the surface is intensified; and, above all, to be able to show that pall of translucent vapor which forever hangs over the surface and through which the remoter wall of the crater is indistinctly visible; and, too, that light, billowy cloud which ever hovers high in the air above Kilauea, and which is tinged with a rosy red, for a beacon light to seamen miles distant upon the ocean.

Kilauea is fascinating, yet terrifying, to him who gazes into its depths; but the longer one gazes, the more does the sentiment of awe and of wonder overcome that of fear. All are loath to leave it, and linger long upon the brink of Halemaumau, returning again and again to gaze into its awful depths.—*From the Boston Evening Transcript.*

COLORS ACCORDING TO LATITUDES.

An endeavor to find a cause for the predilection of certain peoples for a certain color, while such color is put under the ban in another latitude, must, we think, prove futile. Why is yellow, as a general thing, displeasing to us, while in Guiana and the Antilles it is the color preferred par excellence? Why do we like blue, and why do the Japanese detest red? This is a matter of surroundings and habits and also of fashion for certain countries.

But if the cause is of slight consequence, the fact is, nevertheless, of interest to note, and we have evidently here ideas of extreme importance to the exporting manufacturer whose products are designed for remote peoples having customs different from ours. At the epoch at which Japan opened its ports to European commerce, a certain manufacturer of Havre hastened to ship thither fabrics of the most beautiful red. This detail, of trifling appearance, had escaped him. It proved a disaster and the goods remained on his hands.

Dr. Felix Regnault has endeavored to put a little order into the nomenclature of such preferences, and finds, along with all anthropologists who have studied the question, that savages are especially fond of luminous and dazzling colors. If we turn to the negro, the North American Indian, or the Polynesian, we find that he always has a predilection for red.

According to Cook, the New Caledonian admires everything that is red and is prodigal of this color for the embellishing of the poles of his huts, his carvings, and his images.

In New Zealand it would only be necessary to paint an object red in color to have it become a taboo.

The only colors known to the natives of Gaboon, before the arrival of the whites, were, according to Dybbac, red, white and black. To-day they use blue as a color of mourning.

Capus remarks that the color preferred by the Siapoch Kafirs, a people of Afghanistan, is red, which is especially the color of certain ornaments of the chiefs.

Among the ancients the chosen color was purple.

On the contrary, the peoples of the north have a particular liking for somber colors.

We are especially partial to blue, and regard yellow as ridiculous.

In Japan, light Prussian blue and greenish blues prevail in clothing.

The savage Ainos of the island of Jesso, according to Dybowski, prefer blue and tattoo themselves with this color alone.

Let us now pass to the French colonies. In Congo, De Brazza always carried bright red cotton cloth for his exchanges. On the contrary, in the Soudan, we have to do with the Mussulmans, who are more civilized. The medium of exchange is here blue or long cotton cloth. The latter is dyed indigo blue in the Indies, and any other shade of blue would be rejected.

The Mussulman negro is distinguished from the fetichist negro by his love for blue, while the fetichist prefers red. The former tattoos himself with blue, while the latter smears his body with ocher.

In the French Indies, the clothing worn is especially red and yellow, while the blue finds little favor. One of the main affectations of the women is to color their skin with saffron.

In Cochin-China the colors most used are yellow and red, and then comes green. The gods are gilded.

The negroes and the natives of Guiana and the Antilles have an especial fondness for fabrics of a yellow ground. Fashion does not lose its rights and the ground always persists, but the designs upon it may be modified.

In Tahiti the aborigines adopt a pale rose color for their clothing.

The Germans make a singular deduction from the passion of savages for gaudy colors, and have concluded therefrom that they do not perceive violet, blue, or green. These colors, in fact, have no name in the language of some of these peoples. Without going farther, moreover, the ancients had no special names to designate all colors. The Israelites knew only white, black, green and red, and in Homer, according to Gladstone, we find special names only for green, blue, and violet. But why not simply admit that savages, having a language poor in precise terms, denominate only that which strikes them, and that somber colors being indifferent to them, they do not think to mention them by a specific name.

Thus, the Battas of Sumatra, in contact with the Dutch, have taken the term blue from the language of the latter to designate that color, which they distinguish perfectly. So, too, certain African peoples have borrowed the word blue from the English. They, therefore, distinguished the color previously, but did not concern themselves about giving it a name. The Cree Indians of British America call blue by a name signifying "dead man's country color," i. e., "sky color," the spirits of the dead being supposed to ascend to the sky.

The ancients had no special terms to designate certain colors, and yet they used them in profusion upon their monuments.

The Egyptians used yellow, red, blue, green, brown, white, and black, and had a correct perception of the harmony of colors.

The two colors that occupy most space in the decorations of the enameled bricks of the Assyrians are blue and yellow. Blue almost always furnishes the ground, while the majority of the figures thereupon are yellow.

The Persians made much use of these two colors, but they likewise employed green and red. Moreover, they set off their palaces with plates of gold, silver, bronze, ivory and choice woods.

Finally, the Greeks were fond of color. We know that they had the habit of painting the frieze of their structures blue. In the Parthenon, the front of the metopes was red, and blue and yellow were distributed throughout the rest of the edifice.

In our epoch, it seems that we are timidly returning to ancient practices. At the Universal Exposition of 1889, polychromy was tried, but blue always predominated.—*From "La Science en Famille."*

DISCIPLINE AND ORGANIZATION ON AN OCEAN STEAMER.

Just as the government of cities is divided among the Mayor, Aldermen, Boards of Commissioners, etc., of various departments, so the administration of a giant steamship is divided into specialties. The mayor is the chief officer of the city. The captain is the chief officer of the ship. He is more than that. From the time she leaves port until she enters port he is master of the life and liberty of every person aboard the ship, as well as of all the property in it. He is an autocrat. Of course, he must administer his authority wisely. Unwise autocrats don't last long, whether afloat or ashore.

The head of each department is responsible for all that goes on in it. The first officer is at the head of the crew, or navigating department. The chief engineer directs everything connected with the engines. The chief steward has full control of all that has to do with the comfort of the passengers and crew. Each of these chiefs makes a written report at noon every day. Thus the captain is kept informed of everything pertaining to the ship's welfare.

Every one of the senior officers of the ship is a duly qualified master, capable of taking her around the world if need be. The day is divided into "watches," or tours of duty, of four hours each. One junior officer is on the bridge with each senior officer on duty. The senior officer directs the ship's course. He never leaves the bridge while he is on watch. Should he do so he would be dismissed at once. There is no excuse possible. It would be just as if he had died suddenly. His friends would all feel sorry, but nothing could be done to help him. Two seamen are always on watch in the bow of the ship and two more in the foretop. Twice as many are on the lookout in thick weather.

Observations are taken every two hours. In the good old sailing ship days the captain was content to "take the sun" at noon every day. If the sky was cloudy for a day or two it really didn't matter much, for he could jog along on dead reckoning. But on an ocean greyhound, rushing over the course between New York and Europe at the rate of more than twenty miles an hour, it is highly important that the ship's position be known all the time. Fog may come down at any moment, observations may not be obtainable for ten or twelve hours. The positions of more than 100 stars are known. By observing any one of these the ship's whereabouts can be ascertained in a few minutes. Of course, the "road" becomes more or less familiar to a man who crosses the ocean along the same route year after year. Yet this familiarity never breeds contempt or any carelessness. No man knows all the influences that affect the currents of the ocean. You may find the current in one place the same forty times in succession; on the forty-first trip it may be entirely changed. Some times a big storm that has ended four or five hours before the steamship passes a certain place may have given the surface current a strong set in one direction. There is no means of telling when these influences may have been at work, save by taking the ship's position frequently.—*From Harper's Round Table.*

THE SHRIMP.

The shrimp is a scavenger; it will eat almost anything. It is a greedy creature; it may often be seen in aquarium tanks to seize a piece of food weighing more than itself. If this scrap should be lying on the bottom, the shrimp with its first effort upon swooping down upon it might raise it clear and then be compelled to drop it, or to sink with it again to the bottom, there to attack it piecemeal. The shrimp is often put in aquarium tanks to help keep them clean; it seeks out and eats neglected scraps and little bits of food put in for other marine animals, but which the others may have missed and which may have settled down in crevices or other by places. But while the shrimp is thus useful as a scavenger, it is necessary at feeding time to see that it does not get also the food intended for the other animals; the shrimp is exceedingly quick in movement and it may dart down and seize the food out of the grip of an animal much larger than itself, and it would be equally ready to take food from the helpless sea anemone or the fighting crab. A tiny shrimp would not for a moment hesitate to feed upon a dead fish held in the grasp of a lobster, trusting to its agility to escape if the lobster should resent the intrusion.

But while the shrimp is able to and does hold its own remarkably well for one of its size, life is by no means all plain sailing for it; there are other creatures of the sea that are quite as quick and quite as merciless, and that snap up the shrimp whenever they get a chance. Here may be a dead menhaden lying on the bottom with five hundred shrimps at work upon it pulling and hauling. One shrimp may get an extra big piece, only to be attacked by three or four other shrimps that leave the menhaden and fight with the shrimp that has the fragment for the possession of that. The water is alive with shrimps about the dead fish.

Along comes a big weakfish or a striped bass. The weakfish may see the shrimps feeding from a distance of ten or twelve feet away. If the weakfish ever laughs, it probably laughs on an occasion like this. It may approach along the bottom or it may dart down obliquely, and dash through the mass of shrimps with open mouth, sweeping away a dozen of them and dispersing the rest. The dispersal, however, is likely to be but temporary; the weakfish is not apt to return to this particular quarry; it seems to regard the meeting with the shrimps around the menhaden as only an incident of its day's meandering and it goes its way and the shrimps return to their prey.

But it might be that a little school of bass comes along, four or five or half a dozen of them, and these might follow up the first dash by pursuing the shrimps until, if they had not annihilated them, they had effectually dispersed them.—*From N. Y. Sun.*

CRIME AMONG ANIMALS.

Professor Lombroso and his disciples have long been trying to discover why, in the animal species, some are, as we classify actions, "good," and others "bad." Quite evidently there are, among the lower orders of creation as among men, certain individuals which do not seem capable of living and satisfying their wants without doing harm to their fellows. These are consequently criminals, and almost every variety of human wrong doing is to be found among them.

There are constantly cases of theft among bees. Thievish bees, to save themselves the trouble of working, attack well-stocked hives in masses, kill the inhabitants, rob the hives, and carry off the provisions. Then, having acquired a taste for robbery and violence, they form regular colonies of brigand bees.

It is a still more curious fact that these enemies to law and order can be produced artificially by giving working bees a mixture of honey and brandy to drink. They grow ill-disposed and irritable after a short course of it, and lose all desire to work. Finally, when they begin to be hungry, they attack and plunder the well-supplied hives.

In almost every dove-cote there are birds which try to obtain materials for their nests by abstracting straws that have been collected by others. These theives are not only lazy, they are untrustworthy carriers.

Murder is sometimes committed by animals; the kind of killing which has nothing to do with the struggle for life, but which arises from malice or passion. Storks often kill members of the flock which, at the time of migration, either refuse to follow them or are unable to do so. Parrots sometimes attack their companions, and crush their skulls by repeated blows of the beak, and even hens have been known to kill the feeble and lame among their chicks, and bring up only the strong.

A distinguished veterinary surgeon says that in every regiment of cavalry one may find horses which rebel against discipline, and let no opportunity escape them of doing harm either to man or to their companions. In dealing with them, it is always necessary to be on one's guard, and it is frequently imperative to separate them from the others in the stable, as they try to steal their companions' food. What is more curious still, their skulls all show a certain formation; the foreheads are narrow and retreating.

Every fact in regard to the morality of the beast, as in the case of man, goes to show how strongly actions are influenced by birth and training, and how reverent we should be in attempting to judge even our beasts of burden.—*From "The Forum."*

AFRICA'S WHITE NATIVES.

There have always been vague traditions of a white race locked up in the interior, but when the tales have come to be tested the white race generally turns out to be merely a tribe of lighter-colored Arabs, keeping all the characteristics of the race and having none of the white man's. But in this race we have something much more correct and precise.

Capt. Larymore, at present A. D. C. to Sir Francis Scott, was sent up to Koranza on a mission, and stayed a considerable time in the capital. He took advantage of the opportunity to inquire about this comparatively unknown race and its neighbors, and was surprised to find that there was an accepted tradition that there lived, an indefinite number of days' marches to the northeast, a tribe of white men. Further inquiry elicited the statement that they lived on the skirts of a desert, which was difficult and dangerous to cross. Attempts had been made to avoid this desert by passing through their country, but they were found to be so fierce and so absolutely devoid of fear that the caravans preferred the dangers of the desert to the hostility of the white tribe.

Such circumstantial statements induced Capt. Larymore to make stricter inquiries, and at length he found a Mohammedan priest and Hadji, a man of great integrity and considerable influence. He had been to Mecca, and it was on his way there and back that he actually saw with his own eyes one of this white tribe.

The man in question was armed only with a bow and arrow, but such is the reputation of fierceness possessed by the race that the caravan did not remain long in his vicinity, but left the place as quickly as possible. Al Hadji saw him distinctly. Capt. Larymore, who, by the way, is a type of the fair Saxon, interrupted the priest in his story, and said that the man must have been simply a light-colored Arab. "No," said Al Hadji, "I saw him close at hand and he had light hair and blue eyes, exactly as you have." This statement, and the confirmation it had received by many rumors and tales, was one of extreme importance, considering the strict integrity of the man who made it. Consequently, Capt. Larymore took down his testimony in writing. The existence of such a race is firmly believed in by most of the gold coast travellers, and, among others, by Sir Francis Scott.

Unfortunately, owing to the fact that the reckoning of the progress of the caravan is done in the most careless way, the spot cannot be located. Al Hadji says it is many days from Koranza, which might mean 100 or 1,000 miles.—*From the London Daily News.*

CABLE LINE TO BIG VOLCANO.

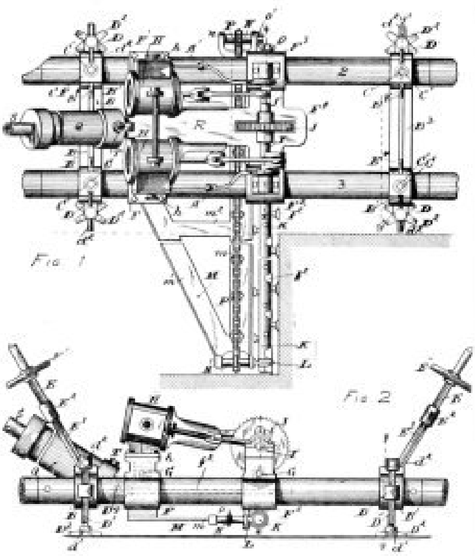
Engineers have completed the survey of the volcano Popocatepetl, for the purpose of determining the best location for an aerial cable railway to the summit. It has been determined to start the line from the ranch of Tlamacas, on the northeast, and tourists will be able to make the ascent to the summit, nearly 18,000 feet above the sea, with entire ease, and also descend into the crater, where the work of extracting sulphur is going on. The tram line will connect at the base of the cable line with the Interoceanic railroad, so that the business of shipping sulphur will be cheaply accomplished.

The drainage tunnel, now complete, measures 10,021 meters, or about six miles. The grand drainage canal, now substantially complete, measures 47 kilometers. The slopes at the sides require finishing and will be finished by next summer, and some more excavation, about 1,000,000 cubic meters, will be made, the total excavation being 11,000,000 meters.—*Exchange.*

New Inventions.

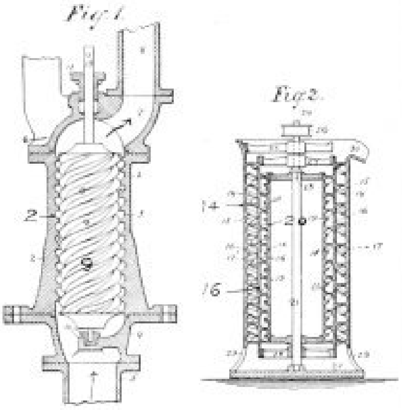
MINING MACHINE.

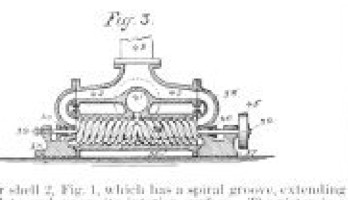
No. 551,508. Edward S. McKinlay, Denver, Colo. *Patented Dec. 17th, 1895.* Fig. 1 is a top view of the complete machine; and Fig. 2 is a side elevation of the same. The cutting is performed by a rotary bar *K* which is armed with detachable cutter bits. This bar is supported in bearings under the clamp boxes F^1, F^2, and at the outer end it is steadied and braced by the arm *M*. It is rotated by spur gearing *J*, which is driven by the engines *H*. The scraper chain *P*, is driven by means of bevel gears *O*, *O'*, from the rear end of the cutter shaft. The working parts are attached to a frame or cross-head *R*, which slides upon the guide bars 2 and 3. The machine is fed forward, upon its ways, by means of air pressure in the cylinder *Q*. This feed cylinder is attached by trunnions to the cross-girt *B*, and the piston rod is coupled to the cross-head *R*. The pressure of the cutters against the coal is thus made elastic, and of constant amount. The guide bars are tubular, and are jointed so that other sections may be joined to them, to any length desired. The cross-girts *B*, B^1, may be loosened and moved along the guide bars, and clamped fast in new positions, without withdrawing the machine from the cut, thus enabling the machine to work almost continuously.



PUMP.

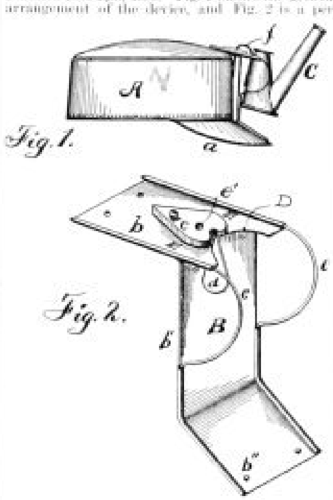
No. 551,853. Auguste Dessoffe, Odessa, Russia. *Patented Dec. 24th, 1895.* Fig. 1 is a vertical section, illustrating a simple form of the machine; Fig. 2 shows a double pump, and Fig. 3 shows a horizontal variety. The body of the pump is a circular shell 2, Fig. 1, which has a spiral groove, extending from end to end, upon its interior surface. The piston is a cylinder 9, having a similar spiral groove upon its exterior surface, but running in the reverse direction; thus, if the groove in the casing be right-handed, that in the piston will be left-handed. The most effective angle for these grooves has been found to be about 17½° between the axis of the pump and the tangent of any part of the spiral. The water is forced along in all the grooves of the case and piston, simultaneously, by revolving the piston. In Fig. 2 the piston is a hollow shell 16, having grooves upon both outside and inside. Counter grooves are formed upon the inside of the shell 14, and upon the exterior of the stationary drum 20, thus the capacity of the machine is doubled. In Fig. 3 the piston lays horizontally and has two sets of spirals which come together at the middle. Two sets of streams are thus set in motion at the same time, and the end thrust of the revolving piston against its bearings is balanced.





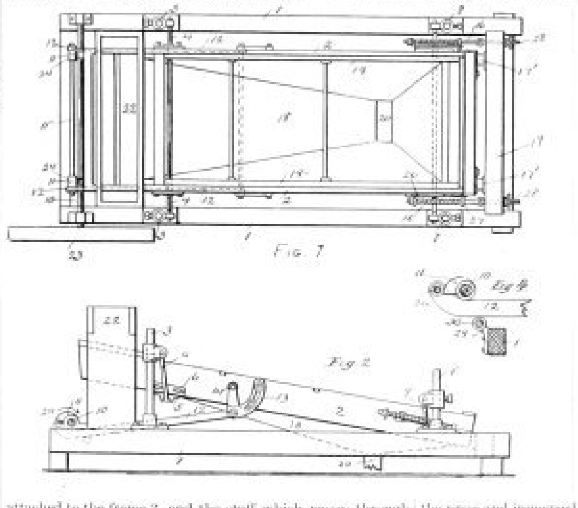
LAMP-HOLDER.

No. 551,818. Adam Good, Wilkes-Barre, Penna. *Patented Dec. 24th, 1895.* Fig. 1 shows the general arrangement of the device, and Fig. 2 is a perspective view of the holder, on a larger scale. The bracket is made of tin, in two pieces, *B* and *b*, which are stiffened along the edges with wires. A piece of leather, *e*, is riveted to the top plate *b*, and the hook of the lamp is inserted in the hole *e'*. The two wire guards *C* serve to prevent the lamp from swinging sideways, and the neck of the lamp is held steady by the curved notch *D*, in the top plate. A notch is cut in the upper part of *B*, at *d*, to allow the lamp hook to play through it, whenever the wearer of the cap stoops downward. Thus the lamp can swing forward only, and all side movement or turning is prevented.



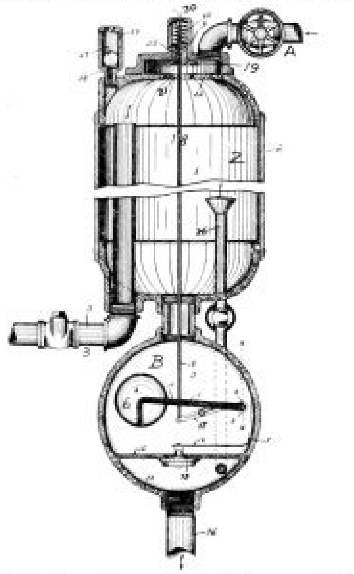
SHAKING SCREEN.

No. 552,585. Philip F. Poorbaugh, Allegheny, Penna. *Patented Jan. 7th, 1896.* Fig. 1 is a top view of the machine, the screen wires or riddle being omitted; Fig. 2 is a side view of the same; and Fig. 4 is a detail of the cam. The riddle is attached to the frame 2, and the stuff which passes through it is received in the hopper 18, and is discharged through the opening 20. The screen box 2 is suspended by swing links, 4 and 9, from collars, which can be adjusted to any height desired, upon the posts 3 and 8. The screen box is provided with bumpers 17', which strike the beam 17, when it is pulled forward by the recoil of the springs 16. The tension of these springs can be adjusted by means of the wheel nuts and eye bolts 28. The screen box is pulled back by means of cams 11, upon the rotary shaft 10, which engage rollers 24. These rollers turn on a rod 11', which ties together the pitmen rods 12. The pitmen are connected to brackets 13, which can be turned about the pivots 14. The stroke of the screen can be regulated by adjusting these brackets so that the rollers 24 are moved through a greater or less distance by the cams. The pitmen rods are supported on rollers 29, as shown in Fig. 4.



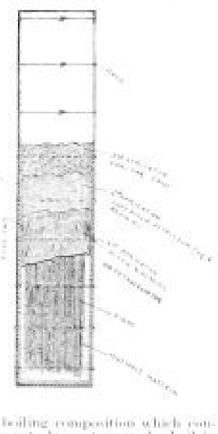
AUTOMATIC BOILER FEEDER.

No. 553,476. Orla J. Scott, Fairmount, Ind. *Patented Jan. 21st, 1896.* The tank 2 is made of any desired size. Water is supplied through the pipe 3; steam is supplied through the pipe *A*; and the water goes to the boiler by the pipe 16. The chamber *B* is comparatively small, being merely large enough to contain the float 6. A partition 12 divides this chamber into two parts, and the passage between them is controlled by the check valve 13. When the chamber *B* is full of water, the float 6 rises, and by means of lever 17 pulls down the rod 18 and thus opens a vent 20, above the steam valve 19. The steam pressure below the valve holds it up against the cover as shown, but if the vent 20 be closed by the dropping of the float, then the valve will drop and close the port 21. When 21 is closed the steam in the tank will cool and the pressure will diminish. Back pressure from the boiler will force the water remaining in the lower part of *B* up the spray pipe 26, and the spray will condense the steam, thus producing a vacuum in the tank. Water will then rush in from the feed pipe 3, and fill the apparatus. The float will rise and open the vent 20; the steam valve 19 will then lift, admitting steam above the water, and all parts will again be in equilibrium.



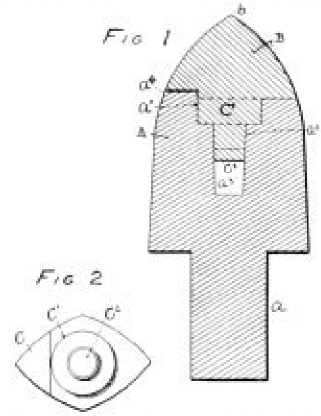
ARTIFICIAL TIMBER.

No. 553,821. Joseph H. Amies, Philadelphia, Pa. *Patented Feb. 5th, 1896.* This material is composed mainly of long coarse fibers such as sea grass, marsh reeds, salt hay, palmetto fiber, etc., which are laid parallel and with ends overlapping. They are mixed with a filling of sawdust or ground peat, and are pressed into approximate shape; the pressure being sufficient to give them a density of, say, from forty-five to seventy pounds to the cubic foot, so that the stick when completed will be sufficiently homogeneous to securely hold a nail or spike driven into it. While the fibers are still in the press they are bound with steel bands or wire, from three to eight inches apart. After having thus been compressed and bound, the article so formed is then taken from the press and immersed in a boiling composition which consists preferably of soft pitch, petroleum, tar, or dead-oil in the proportions of about one-eighth to one-twelfth of the pitch and from seven-eights to four-twelfths of the tar or dead-oil. This compound oil will penetrate the fibers to from one-eighth to one-fourth of an inch. To still further facilitate the penetration of said oil, the article is immersed in a second and heavier composition of soft pitch, petroleum, tar, and resin-oil in the proportions of about ten-twelfths pitch, one-twelfth tar, and one-twelfth resin-oil. This second composition will readily blend with the first and will cause the composition to penetrate from one to three inches. As the article thus produced would be very inflammable if left in this condition, a third application is used which causes the further penetration of the oil. This composition consists of any kind of oil which does not readily mix and blend with the former compositions—such as coal-tar, bitumen, or asphalt. This material is brought to the boiling point, a suitable quantity of sand or hydraulic cement is added thereto, and the articles are dipped and allowed to remain therein a suitable length of time. This application causes the first and second ones to penetrate very deeply. The surface of the article, while hot and gummy, is coated with dry sand and cement, which gives a surface like stone, and is very durable.



BREAKER TOOTH.

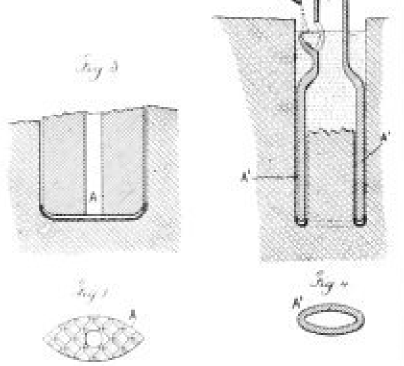
No. 550,255. George W. Cross and E. J. Touhill, Pittston, Penna. *Patented Nov. 26th, 1895.* Fig. 1 is a sectional side view; and Fig. 2 is a view of the under side of the top piece. The removable steel teeth, now commonly employed in crushing rolls for breaking coal and ores, are very expensive to maintain, because the points wear away quickly, and the removal and repair of the teeth requires much time and labor. The tooth here shown has a body and shank of tough iron or steel, and the point is made detachable. The apex is made pyramidal to suit the style of the body *A*. The top piece *B*, is attached to the body by means of a circular shank *C*, which is tightly driven into the socket a', made to suit. A tang C^2, extends downward into a transverse slot a^2. The top may be detached by driving a wedge through the slot and forcing the tang upwards. The body of the tooth *A*, is offset vertically at a^4, to suit a corresponding shoulder on *B*. The top, or point, is thus prevented from turning.



DRILLING STONE.

No. 553,307. George M. Githens, Brooklyn, N. Y. *Patented Jan. 21st, 1896.* Fig. 1 is an end view of an oval drill having a flat end and rounded edges as shown in Fig. 3. The face is scored with shallow grooves as shown. Fig. 2 is a section through a tubular drill, also of oval form, as shown in Fig. 4. These drills operate by percussion in the ordinary manner, but the drilling operation is aided greatly by the use of steel shot and similar abrasive material under the face of the drill.

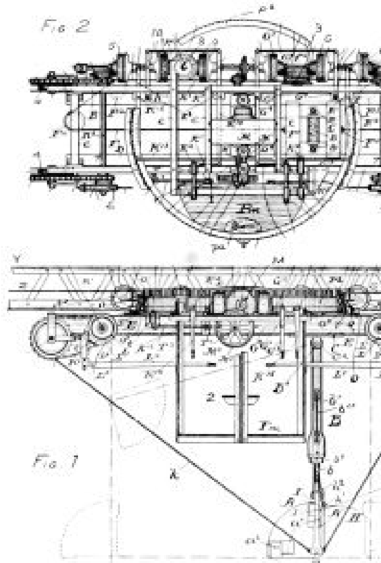
The stem *B* of the drill is of any suitable character and connected to the head of the drill by welding or otherwise, and at *C* is represented a water supply, and at *D* a means for supplying into the hole granular material—such as small pieces of hard steel, sand or other suitable substances—to be carried into the drill hole by the action of the water, and as the drill is reciprocated, the granular material intervening between the sides of the drill and the interior of the bore, the hole is enlarged sufficiently around the drill to allow the same to play freely without the risk of binding or wedging into the hole, and the granular material intervening between the end of the drill and the surface of the rock is driven into the rock by the concussion, and the water being present the particles of granular material are alternately loosened and driven into the rock in such a way as to abrade the rock with rapidity, and the pulverulent material is washed out by the action of the water; and when small pieces of steel are made use of, their gravity is usually sufficient to cause them to remain at or near the bottom portion of the hole until they are no longer useful for the purposes aforesaid.



It will be observed that as the drill approaches the bottom of the hole the particles of steel or similar material intervening between the drill and the stone are driven outwardly by the rounding portions of the edges, before the force of the blow is finally expended in driving such particles against the bottom of the hole. Hence the first portion of the blow is really expended in enlarging the hole so as to make the drill run freely. It is advantageous to score the face of the drill with comparatively shallow grooves or channels, which may be parallel or crossing each other, and these grooves promote the rapidity of operation in consequence of concentrating the force of the blow upon some of the particles of steel more than upon others, thus producing a movement between the particles themselves as they lie upon the bottom of the drill hole, and preventing such particles of steel or other material becoming packed and hard. Only a small quantity of such granular material is to be supplied from time to time, because too much of such granular material would interfere with the operation of the drill.

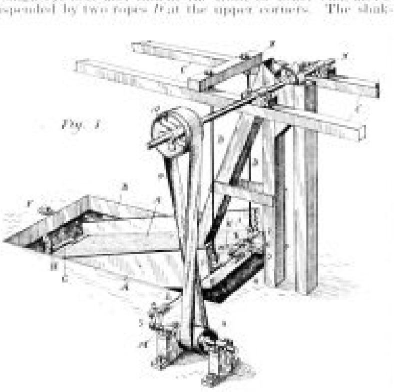
COAL HANDLING APPARATUS.

No. 553,082. Richard Tiehe, Cleveland, Ohio. *Patented Jan. 12th, 1896.* Fig. 1 is a side view, and Fig. 2 is a top view. This apparatus consists of a scoop or shovel *A*, which is suspended from a swinging arm *R*, and a sliding trolley *C*. The scoop is constructed to operate with either edge down, forward or back, and is provided with a suitable latch b^2, which can be released by means of a chain, from the operator's seat 2. The trolley slides upon the flanges of the beams *E*, and is moved back and forth by means of a rope *F*, drum 3, and clutches *G* G^2. The scoop is swung by four ropes, two at the front and two at the back. These are wound on drums 4, which are driven by sprocket chains from the clutches 5 and 6, by the shafts 7 and the bevel gears shown. Each shaft 7 is provided with a brake wheel *L*. The beams *E* are fastened to a large center ring, which turns on balls within a similar ring P^2. This ring is provided with an internal gear which engages the vertical pinion 8. The gear ring forms a large drum, around which a small cable is wound two or three times, and this cable *Z* extends to the ends of the runway or bridge *Y*. The stationary center ring is attached to a large trolley *N'*, which runs on suitable wheels upon the lower flanges of the runways *Y*. The pinion 8 is rotated by the clutches 9 and 10. When the gear ring is fastened to the trolley *N'* by a suitable locking pin, the shoveling apparatus can be turned in any direction by rotating the pinion 8; but when the beams *E* are locked to the trolley *N'*, then the gear ring will turn and operate as a large pulley, and the entire apparatus will be drawn along upon the runways by means of the standing cables *Z*. All of the clutch levers and latch handles are within reach of the operator's seat. Power is applied by means of an electric motor *M*, and the gearing shown.



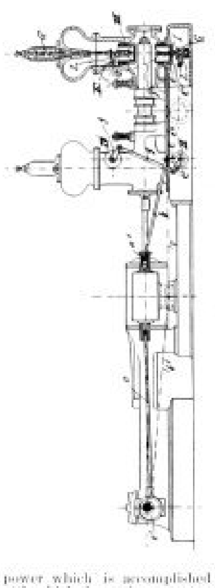
SHAKING SCREEN.

No. 553,360. W. D. Richardson and G. J. Holl, Cleveland, Ohio. *Patented Jan. 21st, 1896.* The screen is hung by a single eye bolt and link at the front or lower end, and is suspended by two ropes *B* at the upper corners. The shaking motion is imparted by means of a crank 5 and pitman *L*. The connection to the screen at 4 is a universal joint. The motion given to the screen is mainly lateral, being greatest at the head of the screen, where the material is supplied, diminishing to very little at the delivery end.



VALVE GEAR FOR PUMPS.

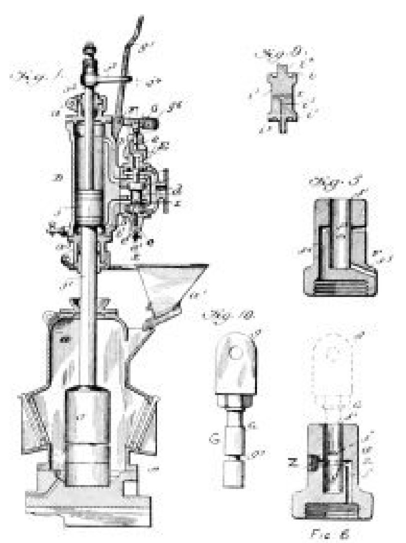
No. 553,878. John Stumpf, Charlottenburg, Germany. *Patented Feb. 4th, 1896.* This gear is designed to open the suction and discharge valves of a pump, by positive mechanical devices, and to allow them to be closed by springs and gravity. In the pump here shown the pump valves are operated by the same eccentric which moves the steam valves. Consequently the discharge valve is opened a little before the plunger reaches the end of the suction stroke; and on the forcing side, the suction valve is opened a little before the completion of the forcing stroke. In other words, the pump valves have about the same "lead" that is given to the steam valves. It is claimed that by letting in the pressure from the column, near the end of the suction stroke, the engine turns the centers easily, and the water barrel is filled with solid water, so that the return stroke is made without shock. This arrangement reduces the capacity of the pump somewhat, but it is claimed that the loss is overbalanced by the saving in power which is accomplished thereby, and the smoothness with which the engine operates.



STEAM ORE STAMP.

No. 553,291. Albert F. L. Reussner, Jersey City, N. J. *Patented Jan. 21st, 1896.* Fig. 1 is a vertical section of the complete machine. Figs. 5 and 6 are sections of the primary valve chamber. Fig. 10 is the primary valve, and Fig. 9 is a section of the main steam valve.

The main valve *I* is operated by means of a primary valve *G*, which is operated in one direction by the main piston rod, and in the reverse direction by a weight g^6. The main valve has a plunger rod at each end, the one at the top having about twice the area of the lower one, and these work in suitable cylinders formed in the ends of the steam chest. Steam is received at the middle port, and the exhaust goes off through the outlet *d*. As shown in Fig. 9, there is a hole in the valve *I*, which admits steam to the lower end *e* of the



lower plunger constantly. Steam is admitted or released from the end of the upper plunger by means of the primary valve *G*. Steam is supplied to this valve by a small pipe which enters the casing at *Z*. f^3 is the exhaust port. When the piston rises, the cam roller j^3 encounters the part g^5 of the lever, and lifts the valve *G*, so that the exhaust port is opened to the upper plunger of the main valve. The steam pressure on the lower plunger instantly raises the main valve and gives steam to the top of the cylinder. The piston makes a full stroke, steam following to the end of the stroke and giving a dead blow. The main valve, however, is not reversed until the weight g^6 pushes down the primary valve and gives steam to the top plunger. Being larger in area than the lower plunger, the steam pressure drives the main valve downward and gives steam to the under side of the main piston. The movement of the main valve being comparatively slow, the main piston will always make its full stroke downward before the steam pressure is reversed.

The Colliery Engineer

AND

METAL MINER.

VOL. XVI.—NO. 10. SCRANTON, PA., MAY, 1896. With Which is Combined THE MINING HERALD.

PLACER MINING.

A GENERAL AND SPECIFIC ACCOUNT

Of Placers, Their Formation, Distribution and the Construction and Development of the Different Machinery and Devices Used in Working Them.

Written for The Colliery Engineer and Metal Miner by Prof. Arthur Lakes.

To the glaciers of past and present time we mainly are indebted, not only for our placer deposits, but also for a large proportion of our workable mines. Glaciers were the pioneer miners on a broad and liberal scale, after them the rivers, and in a minor degree the waves of the sea.

Fig. 1.—Part of Witwatersrand Gold Basin, South Africa.

1, Granite; 2, Basalt; 3, Sheets of Volcanic Mud; 5, Slate; 6, Shale; 7, Quartzite; 8, Sandstones and Conglomerates; 10, Magnetic Quartzite; 11, Limestone; 15, Quartzite, Black Reef series.

Imagine if we can the mountains of the world without erosion. They would be vast, smooth, rolling waves of strata, occasionally broken by stupendous cliffs, the results of profound faulting. As mineral veins are due in most cases to the action of hot springs, geysers, etc., we should see here and there on such lines of fault fissure, smooth mounds of "tufa," like those built up by the hot springs and geysers of the Yellowstone Park. Some of these geysers might still perhaps be in action, as at Steamboat Springs, Nevada, where veins are already made, and others in actual process of formation. Not a mineral vein would appear exposed as we see them now. We should have to burrow deep down into the conduits of these springs to find them. Other regions would present blackened plains of horrible unbroken lava, with here and there, perhaps, hot and gaseous springs in action, or as before, tufa mounds spotted over the dreary landscape on lines of buried fissure. Such would have been the aspect of Cripple Creek and the great San Juan region in early times. On such an uneroded country let the glaciers be set to work. See them filling up every incipient ravine or rolling valley caused by undulations of the strata beneath. The ice sheet planes off the tops of mountains, and exposes the rings of strata of which it is composed, and the spring-formed veins—as we cut off the top of a water melon and expose its rings of fruit-like growth and seeds. The ice tongues or glaciers descending from the sheet cut long U shaped swaths down the sides of the hills and by mighty canyons expose the ribs and anatomy of the mountains and the strata and the gold veins they contain. The debris of this planing is distributed in windrows on the sides of the canyons and bottoms of the ravines, to be winnowed and sorted by subsequent streams and rivers, and to be carried out and distributed also over the plains as soil for the farmer, and to the ocean to form beaches and sea bottoms to be upheaved hereafter to form future continents and future mountains. If all the gold that has been spread far and wide in minute grains by these media could be collected, it would far exceed all that is or ever will be obtained by man's puny efforts at vein or placer mining.

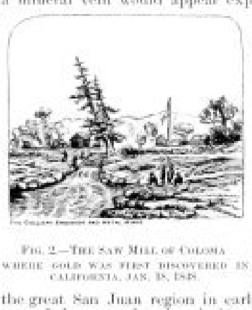


Fig. 2.—The Saw Mill of Coloma where Gold was first discovered in California, Jan. 18, 1848.

We must not suppose that all this gold distributed over the world and found more or less in nearly every stream, is derived exclusively from distinct gold-bearing fissure veins, but rather from the general breaking up of vast masses of crystalline rocks, such as granites, porphyries, and lavas, which are known to contain gold more or less distributed in minute particles throughout their mass.

VERY ANCIENT CONSOLIDATED PLACERS.

Though placer deposits are generally conceded to have been laid down by comparatively recent glaciers and streams in loose incoherent banks, yet there are other and far older formations, not generally included under the name of placers, which still have had much the same aqueous origin, and are withal gold-bearing. We do not refer to the "deep leads" or placers of hard conglomerate overlain by a protective cap of somewhat recent lava as in California and Australia, whose origin is obvious, but to beds of hard uptilted conglomerate sandstones, such as those worked at Leydenberg, in the Transvaal of South Africa. See Fig 1. These are but ancient consolidated placers or ancient river and sea beaches consolidated by time, heat and pressure into hard rock and thrown up nearly to verticality in the forms we in Colorado should call "Hog-backs."

Fig. 3.—Primitive Mining, the Old Rocker.

The Homestake mine in the Black Hills derives its gold from a hard consolidated placer of Cambrian age, and we believe and even know that gold may be found in many of the ancient coarse conglomerate rocks if looked for, and in cases they might be profitable if they could be worked wholesale by some cheap process.

GLACIATED REGIONS THE HOME OF PLACERS.

Since glaciers are the parents of placer deposits, we must look for such deposits principally in those northern and mountainous regions which have been most glaciated, such as Alaska, for instance, with its coast line torn into tatters, and its mountains cloven through and through by modern and ancient glaciers, and by a network of small and great streams, originating from them. So down the Pacific Coast to Southern California, along the lines of the Sierra and coast ranges, in British Columbia, Idaho, and Washington territory, in all these, the glacial placer deposits are to be estimated at hundreds of feet in thickness, whilst as we proceed inland to the Rocky Mountain range and retreat from the main centres and zones of glaciation the deposits grow less in size and thickness.

HISTORY OF PLACER MINING.

Gold washing of alluvial deposits has, both in ancient and modern times, preceded vein mining. In modern times placers have led up to the discovery of veins in place, but in ancient times it was all gold washing, and

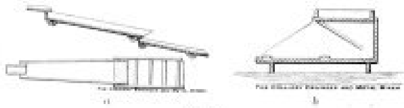

Fig. 4.

a, Plan and Section of Long Tom Sluice; b, Section of Rocker.

if by accident they found gold veins, they do not seem to have understood their value, or what to do with them. Nor is this greatly to be wondered at, seeing that in quartz veins gold very rarely shows itself on the surface and commonly not at all throughout the vein. The gold we read of in the ancient world was all derived from the sands of streams.

Fig. 5.—The First Attempt at Hydraulicking.

In recent articles we have told of the widespread distributions of gold in placers all over the world including Canada, Alaska and the northwestern part of the United States.

There are also extensive placer grounds in New Mexico along the Rio Grande river between the Sangre de Cristo and Continental divide. There is difficulty at times of bringing water to bear. The bed of the Rio Grande is a placer being worked by dredges. The discovery of gold at Coloma near Sutter's Fort, California, on January 18, 1848, by James W. Marshall is a trite story. Marshall while digging a race for a saw mill at Coloma, thirty miles east of Sutter's Fort, found some pieces of yellow metal which he supposed might be gold. Knowing nothing of chemistry or gold mining he could not prove the nature of his find, so his collection of specimens continued to accumulate. In February a man named Bennett employed in the mill went to San

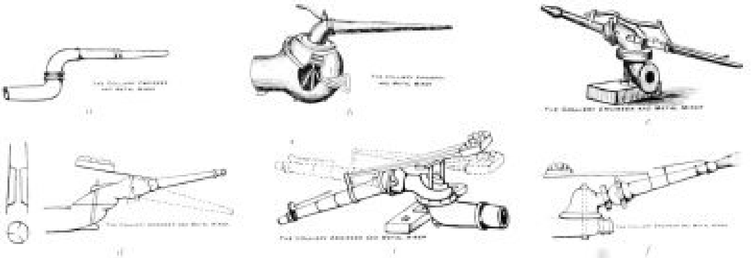

Fig. 6.—Evolution of the Giant.
a, Goose Neck; b, Craig's Globe Monitor; c, Hydraulic Chief; d, The Little Giant; e, Hydraulic Giant; f, Monitor Hydraulic Machine.

Francisco and returned with a man named Humphreys who had washed gold in Georgia and he declared the deposits richer than in his own state. By a rocker he obtained daily about an ounce of gold and soon all the mill hands were rocking for the precious metal.

Pierson Redding, a ranch man from Sacramento, visited Coloma and resolved to try the deposits about his own farm and opened a bar on Clear creek. John Bidwell followed suit on Feather river. So the work

Fig. 7.—Deep Lead Mining by Underground Sluice.

grew till on the cession of California in 1848 to the United States, miners were at work on every large stream on the western slope of the Sierra Nevada from Feather river to Tuolumne, 150 miles. The first printed notice of the discovery of gold was in the "Californian" newspaper, published in San Francisco, on March 15, 1848. On May 29 the paper suspended, as the whole force, together with the population, had gone to the mines. In 1849 the placers of Trinity and Mariposa and in 1850 those of Klamath and Scott's Valley were discovered. Water being a great desideratum, the first attempt at a ditch of any size was in March, 1850, at Coyote Hill, Nevada Co. In 1850, 50,000 men were placer mining in California.

At first it was all pick and shovel, rocker and pan. Then the Long Tom sluice box was introduced. Work on dry bars led to mining the river bottoms by wing dams. Later, entire streams were turned from their course by flumes and ditches. From the shallow placers the miners pushed back to the deep deposits worked by Long Toms and sluices. As the deep deposits of gravel were poorer than the shallow placers, open cuts were necessary and a larger supply of water originated the use of sluices.

Sluices ran dirt faster than shovellers could supply it. Edward Mattison of Connecticut used a stream of water under pressure conveyed in a rawhide hose and discharged through a wooden nozzle against the bank. So the earth was torn from the bank and carried into sluices, dispensing with shoveling. Thus began hydraulic mining.

EVOLUTION OF THE GIANT.

The evolution of the nozzle and discharge pipe is interesting. It commenced by using a simple canvas hose with an iron or tin nozzle; then a flexible iron joint, formed by two elbows, one working over the other, with a coupling joint between them, was invented. These elbows were called goose necks. (See a, Fig. 6.) But pressure caused the joint to move hard and the pipe when turned in a contrary direction "bucked."

This led to the Craig Globe Monitor (b, Fig. 6) a simple ball and socket joint, but hard to manage. Later Craig's interior tripod and a bolt were used, a tripod with center having a hole to take a bolt with knob in the end. The other end passed through the top of the elbows and had a nut with lever. Tightening the nut threw the strain on the bolt reducing friction on the joint proper; these were unwieldy and leaked at joints. The hydraulic chief followed, a knuckle joint and nozzle with two elbows placed in reverse position when in right line, connected by a ring in which are anti-friction rollers (c, Fig. 6). The ring is bolted to the flange on the elbow, but gives the upper elbow free horizontal movement, while vertical motion is obtained through a knuckle joint placed in the outlet on the top elbow. This joint is a concave surface fitted to a convex one, the former having an opening for the pipe to pass through. The interior is unobstructed by bolts, and the man at the pipe operates it by a lever. Vanes or riffles are inserted in the discharge pipe, to prevent a rotary movement of the water caused by the elbows, and to force it to issue in a straight concentrated and solid form. Hoskins' Dictator in 1878 was a one-jointed machine with elastic packing on the joint instead of two metal faces. The joint worked up and down on pivots, and rotating wheels ran around up against the flange. The "Little Giant" was a two jointed machine simple and durable with knuckle joint and lateral movement (d, Fig. 6). It has riffles and nozzles 4 inches to 9 inches diameter; five and one-half to 7 inches in nozzles and is commonly used. Giants must be firmly bolted to heavy pieces of timber braced against solid rock or gravel. The Hydraulic Giant (e, Fig. 6) is a modification of the Little Monitor with deflecting nozzle (f, Fig. 6) and the deflector, which is worked by a deflecting nozzle can be turned to any point.

Drift mining began in 1852 in the old river channels. Deep tunnels were due to a discovery on Table Mt. of gold gravel lying in channels under the mountain. After overcoming difficulties from a surplus of water, they were rewarded by in some cases finding 10 square superficial feet to yield $100,000, and it is said that on one occasion a pint of gravel produced a pound of gold. In 1853 there was a rush to the Comstock. Hydraulic mining and the working of old river deposits gained steadily from 1852, and forty-inch wrought iron pipes and masses of water discharged through nine-inch nozzles under 450 feet pressure were substituted for canvas hose and stove pipe and one-inch streams.

GEOLOGY OF CALIFORNIA PLACERS.

California is divided into four parallel lines or three great belts, consisting of the Sierras, Great Central Valley of California, and the Coast ranges. The Sierras of granite and igneous rock are the main source of the old river gravels. The Great Central Valley is the main belt of recent and alluvial placer deposits. Gold veins occur mostly in slates, both in Sierras and Coast ranges. The country covered by lava flows is in Trinity, Plumas and Butte, with Lassens and Shasta Peaks. Streams flowed from the latter over North California and Oregon and covered up some of the placer deposits of glacier and river. The gold area is limited north, not by thinning out of deposits, but by thickening of lava.

The old rivers eroded the slates with thin gold quartz veins and deposited the debris in beds from a few inches to 600 feet deep. Lava several hundred feet deep covers these in places. Fossil wood and leaf impressions and bones of land and water animals, together with

Fig. 9.—Caving Placer Banks in California.

elephant remains, and even the bones and implements of prehistoric man, are found, as in the case of the celebrated Pliocene skull of Calaveras county.

The following may be taken as a typical section of a placer at New Kelly as given in Bowie's manual of hydraulicking.

Dark gravel of granite, slate, porphyry, serpentine and quartz	13
	42.8

The greater part of the gold is found here, as elsewhere, in the lower strata of gravel and on bedrock associated with magnetite or black sand and some platinum. Gold is rarely disseminated through the beds. Sometimes it occurs in the upper alluvial portion in streaks of cemented gravel, but if this is of fine clay it is liable to be barren. Some gold is occasionally found at grass roots. Pay gravel may occur high above bedrock, but generally in the coarse material near bedrock and on the bedrock itself and in its crevices. The latter has often been dug up for some depth before all the gold in it was exhausted. In California and Australia these placer deposits are sometimes covered with lava but rarely so in other regions.

DIFFERENT KINDS OF PLACER DEPOSITS.

Shallow placers are deposits a few feet deep as distinct from deep placers several hundred feet deep. Hill claims are deposits on hill sides by glaciers or old extinct streams. Gulch diggings are in gulches and flat de-

Fig. 10.—High Placer Banks Worked in Benches, California.

posits on plains and flats. "Bar claims" are bars of gravel on sides of streams above water level. Beach sands are gold-bearing sands of the seashore largely consisting of grains of magnetite served up in windrows by the tide. Dry washing was practiced by Mexicans where water was scarce and deposits rich. After pulverizing and drying the richest they worked it in a wooden bowl or "batea." The earthy portions, by circular motion given the disc, were separated from the gold which was extracted by winnowing. Ground sluicing consists in treating the gravel excavated by pick and shovel by washing it in trenches cut in bedrock, the natural rock serving the place of riffles. Booming is by damming up a stream perhaps at a high level or forming a reservoir and then letting the water suddenly go. The rush carries off the big boulders and some gold into sluices leaving the heavy gold and black sand collected on bedrock floors. We remember a successful case of this booming in the San Juan district. Prospectors had for a long time observed and picked up very rich float on the slope of a steep mountain covered with loose debris but had failed in locating the vein or source whence it came. At the top of this mountain was a small lake fed by a stream. The miners dammed up one end of this lake till it was full then they cut through the dam and "let her go." The water rushed down the slope carrying debris before it and quickly cut a channel to bedrock and exposed the long looked for vein.

In deep mining for deep placer leads there are two methods, "drifting" and hydraulicking. In drifting the gold is mined in deep deposits by tunnels, (see Fig. 7) especially where these deposits are covered by lava and the the gold is concentrated in a well-defined layer or channel. In some claims shafts are sunk and gravel drifted out and raised to the surface. Drifts are run out on either side the shafts. Gravel, when too firmly cemented, is crushed in stamps.

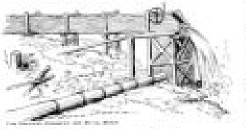

Fig. 11.—Head Box.

Hydraulicking is the best way for working deep deposits. For profit there should be ample facilities for grade and dump, and sufficient head and plenty of water. Miners in early days soon exhausted the bars above water level and turned their attention to deposits lying under water. Streams were dammed and sometimes turned into new channels at great cost. Beds of rivers in this way were laid bare as at Roscoe, Clear creek, Colorado, described in past numbers of the Colliery Engineer and Metal Miner, and claims were worked on the parts exposed. In this large scale of mining both losses and gains were enormous. To avoid turning rivers from their courses, dredging machines were built and used, as at present on the sands of the Rio Grande river in New Mexico, and tunneling under the surface of the river to get down to bed rock was contemplated. Hydraulicking is one of the best methods, though it employs twice the number of men that drifting does, yet it extracts four to six times the gold per lineal foot of channel. One mine by drifting took out $1.50 per foot, while hydraulicking the entire deposit yielded $7.50 per foot, according to Bowie. (See example of a placer bank and hydraulicking, Fig. 8).

MODE OF WORKING PLACERS.

After the flume and sluices are finished, water is turned into the pipes and washing commences. Sluices are run half a day to pack them. Water is then shut off and a charge of quicksilver put into the upper 200 or 300 feet of sluices. A small quantity is distributed along the entire line except the last 400 feet. In a six foot sluice, the first charge is three flasks of quicksilver. Undercurrents are charged at the same time, and a little quicksilver in the tail sluice. Quicksilver is added daily during the run in lessening quantities, the object being to keep the mercury uncovered and clear at the top of the riffles. So the charge is regulated by amount exposed to view. At North Bloomfield, Cal., the main sluice is cleaned up every twelve days. Eighteen flasks of quicksilver are used in a run. A 24 feet undercurrent takes 80 pounds of quicksilver. In charging riffles avoid splashing the quicksilver, as it divides itself into minute particles which are carried off by a swift stream or float off in clear water. So buoyant is quicksilver that it has been taken from the surface, containing particles of gold, 20 miles below where it was thrown in. At Roscoe we found plenty of quicksilver that had come

Fig. 12.—Ground Sluicing.

down from the stamp mills of Central, 20 miles distant.

Our readers will remember our description of the progress of the work at Alma, which appeared in the December, 1895, issue of the Colliery Engineer and Metal Miner, to which we refer them. The following additional note, we add from Bowie's manual, to whose excellent work on hydraulicking we are indebted for much of the material in these articles: The first work is started near the head of the sluice and the mine opened from that point. As banks are washed away bed rock cuts are driven towards the face of the work and sluices are advanced. To "cave" a bank two pipes are used, throwing streams from opposite sides forming a cross fire against the lower part of the bank (see Fig. 9). When washing with two pipes, and the dirt caves readily, one pipe should do the cutting, and the other wash the falling gravel into the ground sluices. The face of the bank should be kept square and a horseshoe form avoided. When a cut is pushed ahead and work not squared, men at the pipes are encircled by *high banks* and washing can no longer advantageously progress, and lives are endangered. Banks over 150 feet high should be washed in two benches (see Fig. 10). When the banks are about to cave, water should be turned away from falling masses. If the cave falls upon the water in the ground cut, a rush of debris ensues, and men at the pipe have to run for their lives. Caves are made in the evening the night shift running them off. Locomotive reflectors, bonfires or electric lights illumine the works at night. Washing should be continuous and no water go to waste, so several faces should be kept so that water can be used from time to time whilst cuts are being advanced and sluices lengthened.

These ground sluices (Figs. 12 and 13) are trenches in bed-rock toward the face of the bank washed, to collect water and materials and convey them to the sluices. Sometimes these cuts are 60 feet deep; sluices are run full of gravel before turning off the water. The length of runs may depend on the wear of the pavement. Some claims are cleaned up every 20 days, others in two or three months, others only once a season. Pavements should be cleaned up as soon as they wear in grooves. Where there is much water and ground, the clean up of first 1,000 feet paved with rocks, is every fortnight; tail sluices, once a year; undercurrents, when quicksilver is found spread over their ends. In cleaning up, bed-rock and cuts are piped clean, then only a small head of water is turned through the sluice. Blocks are taken out with bars, washed free of amalgam and laid by the

Fig. 13.—Bedrock Flume.

side of the sluice. This is done in sections of 100 feet. Between each section one row of blocks is left in the sluice. These rows prevent gold and quicksilver passing down the sluice. After the first section of blocks is taken up, men follow the gravel as it is slowly washed down the sluices and pick up quicksilver and amalgam with iron scoops and put it into sheet iron buckets. As each riffle is reached amalgan and quicksilver are collected, block riffles removed, and residue washed down to next riffle and so on down the sluice.

Water is then turned off, workmen attend to nail holes and cracks in sluices, "crevicing" them with silver spoons, to obtain amalgan. Side lagging is overhauled, and blocks replaced. In very long sluices the lower portions are lined with heavy rock, used for longer periods without cleaning. In very long sluices run at night, they clean up during the day as long a section as possible, and put it in order for further work, resuming washing at night, until the whole is cleaned up. In cleaning up sluices, 80 per cent. of the gold caught is found in the first 200 feet. Lessening of grades and use of undercurrents tend to diminish the loss of fine gold. Of the methods of retorting the gold from the amalgam we have spoken before.

Demand for water caused thousands of miles of ditches to be made in California. The immense cost was repaid, however. From the rugged character of the country, steep grades were used and high trestles supporting flumes at 200 feet. Wrought iron pipes carried water across canyons.

In locating a ditch the following points are to be observed: First, source of supply at sufficient elevation to cover the greatest range of mining ground and to give greatest pressure; second, abundant summer supply; third, water courses on line of ditch secured to add to supply; fourth, waste gate, at intervals not greater than half a mile; fifth, ditches preferred to flumes.

In surveying, the barometer is used to determine elevations of termini and intermediate points. The lines are staked out and bench marks placed every half mile. Size of ditch is regulated by its requirements. The form may be rectangular, trapezoidal, circular or square. Rectangular profile gives least friction. In mountainous districts narrow deep ditches with steep grade are preferable. In California, ditches with 80 cubic feet capacity per second and grades of 20 feet per mile are operated. Banks of solid untouched gravel are preferable to made banks. Large ditches may have a slope of 60° for upper and 65° for lower banks. Wooden flumes are set on grades of 25 feet per mile. They are made of 1½" pine planking, 12" to 24" wide and 12' long. At joining of boards, pine battens, 3 to 4 inches wide and ½ inch thick cover the seam. Sills, posts and caps are placed at every four feet. A flume 2½ feet square requires 3x4" scantling for posts and 4x6" for stringers. Posts should be set into caps and sills with jar of ¼" and not mortised. Sills extend beyond posts. Curves should be laid with care to ensure maximum flow of water. Boxes are cut in two, three and four parts. For good curving of

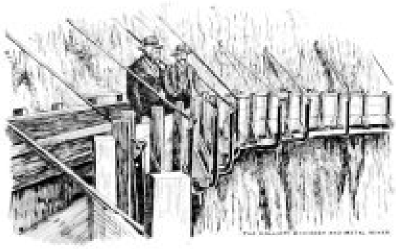

Fig. 14.—Method of Hanging Flume to Cliff by Iron Brackets.

side planks they are sawed partially through in places to bend easily. To avoid slack water, irregular currents, splashing, etc., the outer side is raised in accordance with curve. Waste gates are placed every half mile. In snowy regions it is difficult to keep flumes and ditches open during severe weather from anchor-ice forming on the bottom. When this happens water should be turned out. Freezing is often avoided by setting the flume in close to the bank. In building a line of flume, the bed being prepared, stringers are put in place, sills laid on them 4 feet apart, bottom planks are nailed to sills, and side planks to bottom planks and posts. Boxes set on grade are held in position by wedges. A flume rarely lasts twenty years. Flumes along cliffs are supported by brackets made of iron rails bent in an L shape (Fig. 14).

Iron pipes crossing large depressions are called inverted siphons. A supply pipe conveys water from pressure box to claim. Distributing pipes take water from distributor or gates at end of supply pipe and deliver it to discharge pipe or nozzle. Thickness of iron depends on pressure of water and diameter of pipe. Pipes may be 11, 15, 22 to 40 inches diameter. Air valves are provided in a long pipe for escape of air from the pipe.

The pressure box is at the end of the ditch above the claim, and from it water is delivered into the supply pipe. See Fig. 11. The sand box forms part of the pressure box, sunk below the level of the flume, arranged to catch gravel or sand carried by the current. The pressure box is a large wooden receptacle, deep and large enough to keep the head of the pipe entering it under water with steady pressure. A grating of bars catches floating matter. For 22-inch pipe, No. 14 B. G. is the lightest iron used. The main pipe should descend in as direct a line as possible to the diggings. At all angles the pipe is braced and weighted. Leakage is stopped with sawdust in slip joints. Branch pipes are smaller in diameter.

TUNNELS.

Tunnels are used to open gravel claims, where open cuts cannot be made, and to afford facilities for conveying washed material. A tunnel should be driven well into the channel before connection is made with the surface. A shaft connecting headings should be vertical and about 3 x 3 feet wide. Shafts are the best way for opening up hydraulic claims. In loose gravel, timbering is necessary. The size of tunnel depends on size of sluice, usually two or three feet wider than inside width

Fig. 15.—Block Riffles.

of sluice and 8 feet high. Locate the tunnel mouth at that point from which sluices running in a given grade can bottom the maximum extent of the pay channel.

SLUICES.

Sluice originally meant "sluice box"; when sluice boxes were joined together it was called a flume. Sluices should be as much as possible in straight lines. Where curves occur the outer side of the box should be slightly raised like a railroad curve, to cause more general distribution of material over the riffles. With frequent curves and long lines of sluices the grade is increased, and sluices with drops are desirable for saving gold. Movement of gravel depends on grade of sluices. Coarse wash or hard cement or much clay require heavy grades, and cemented gravel requires drops to break it up. A six and a half inch grade to a box six feet long is recommended.

By using too much water, masses of black sand are apt by the overlying pressure to pack the riffles. Shallow streams require a light grade. In washing heavy material the water in a sluice should be deep enough to cover the largest boulder generally sent down. As a larger body of water is sent through a sluice running heavy cement gravel, more material can be transported by a proper proportion of light and heavy gravel mixed. Size of sluice depends on grade, character of gravel, quantity of water. A sluice 6 feet wide, 36 inches deep, on a 4 per cent. grade, is enough for running 2,000 to 3,000 inches of water; one 3 feet wide, 30 inches deep, at 1½ per cent. grade, for 1,000 inches. Extend the sluice as long as yield exceeds expense. Sluices 4 feet wide are made of 1½ or 2 inch plank with sills and posts of 4 x 4 inch scantling. The bottom should be made of half-

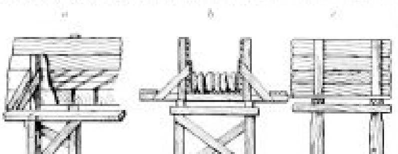

Fig. 16.

a, Squared Block Riffles; b, Stone Riffles; c, Side of Flume.

seasoned lumber free from knots, jointed and grooved, with soft pine tongue inserted; bottom and sides are spiked together, sills placed 4 feet apart, posts halved into the sills, spiked and angle-braced. The flume should be heavily weighted down by loading the ends of sills with stones.

RIFFLES.

Riffles date back to the earliest days of gold-washing. Blankets, hides with hair uppermost, reeds and grass sods were used; also slips cut in the bedrock. Wooden blocks and rocks are now used. Scale gold associated with much black sand or pyrites escapes riffles for long distances. Block riffles are square wooden blocks 8 to 13 inches deep set on end in rows across the bottom of the sluice, each row separated by a space of 1'' to 1½''. They are kept in position by riffle strips 1½'' thick and 2'' wide held crosswise on the bottom between rows by pine wedges driven between blocks and sides of sluice. A side lining is required in sluices. In cement claims blocks 3'' thick covering 18'' to 20'' (in depth) of the side are used for side lining. At Alma, South Park, Colo., the riffles are made of the round sections of trunks of pine trees laid down like a "Nicholson" pavement, the interstices filled with small stones. Cobblestones or rocks are sometimes used for sluices with steep grades and abundant water. Wood such as pitch pine, which is long-grained and "brooms up," makes the best riffles. The wear on riffles by heavy stones and gravel pounding on them is considerable. Block riffles after much use are often found to carry a certain amount of gold in them, which is obtained by burning the old, used-up riffle. After each run the blocks are turned and replaced in the sluice. In repairing with old blocks the edge worn down most is placed up stream. Both blocks and rocks are sometimes used together on alternate rows, which reduces the wear and tear of the blocks. Sometimes bedrock itself is a sufficient riffle. In dumping, the "turn out" rather than the "turn in" sluice is used when the dumping ground is limited.

UNDERCURRENT SLUICES.

To relieve sluices of finer material and aid in saving the gold, "undercurrent" sluices are introduced into the sluice line, such as we described in the Roscoe placer. The following additional notes from Bowie's Manual may be useful on this subject: "Undercurrent sluices are broad sluices set on heavy grade at side of and below the main sluice. Where a drop-off can be made on the main line, parallel steel or iron bars 1x4'', with intervals of 1'' between, and 10 to 20 in number, according to size of undercurrent, are placed edgewise across the sluice. This is called a grizzly. It is set 1'' below the sluice pavement. Coarse material passes over the grizzly, and is dropped and picked up again in sluices at a lower level. Finer gravel drops through the bars into a box 20'' deep lined with blocks set at right angles to the main line. This box carries the material to the sluice at the upper end of the undercurrent. It has a 2 to 3 per cent. grade, narrowing toward the lower end. The undercurrent

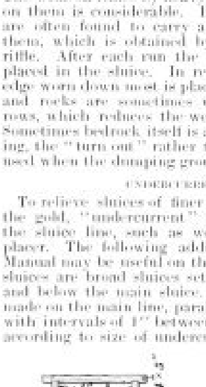

Fig. 17.—Flume Construction.

proper is a shallow wooden box, 20 to 50 feet wide and 40 to 50 long, with sides 16'' high, ten times the width of the main sluice. The bottom is of eleven and half inch plank, tongued and grooved, set on a grade 8 to 10 per cent., according to the smoothness of the riffles employed. It is paved with cobbles, wooden rails shod with strap iron, or small wooden blocks. With the smooth rails a grade of 12'' in 12 feet is enough, but with blocks 14'' in 12 feet. Gravel escaping from undercurrent is led back to the main sluice.

TAILINGS AND DUMP.

Tailings are the refuse from quartz drift, hydraulic mines and stamp mills; debris is another term for the refuse of hydraulic mines. The accumulation of these and the amount thrown into rivers is sometimes prodigious. It is estimated that between 1880 and 1881, in one year, there were discharged into the streams and valleys of California, between Chico creek on the north and Merced river south, 47,000,000 cubic yards of debris from gravel mines and stamp mills. The tailings from stamp mills consist of finely comminuted quartz and in some cases pyrites carrying some fine gold. That from placer and gravel washing is of all forms, kinds and dimensions. Light particles of soil, loam, sand, are easily carried forward by running water, while rocks and boulders escaping from sluices soon find bottom and lodgment. By far the greater part of the material washed remains comparatively near the ends of the sluices in the canyons until removed by heavy freshets. Farmers therefore have less cause to complain of placer workings than of stamp mills on these rivers. It is the finest and lightest material, such as the tailings from stamp mills, that is held in suspension until the velocity of the water carrying it is greatly reduced.

The depositing of this material on lands overflowed during high water was one of the original causes of the disputes between placer miners and farmers that, brought before the law courts, has stopped placer mining in California for so many past years.

DUMP.

This is a very important consideration in hydraulic mining. Where thousands of cubic yards of gravel are being washed daily from their position, places must be provided at lower elevations where the gravel can be deposited. A larger superficial area is required than that occupied by the material before removal. The want of dump room is remedied in some cases by discharging into a mountain torrent as in the first pit at Roscoe, and where placers are on the borders of large rapid streams. To show the evil, however, of dumping into streams, Bowie cites the case of the Light claim, which was worked in 1873, and up to June 23, 1874, had discharged 720,086 cubic yards of gravel into the stream; 975,064 cubic yards were at the same time dumped from the Kelly and French hill properties. At the end of twenty-one months the channel opposite the Light claim was filled up, sluices run out of grade, river bed shoaled on all sides, and the water of a formerly rapid stream struggled over the accumulated debris with a barely perceptible motion and the claim had to be closed.

Where a small amount of tailings is discharged into narrow and steep canyons as, for instance, Clear Creek canyon, Colorado, winter rains and spring freshets suffice to clear it out, but where the quantity is large, in spite of the water, the ravines fill up gradually and hydraulic mining in these localities ultimately ceases. Sometimes, the want of dump room is obviated by a tunnel, by means of which tailings are conveyed into large and precipitous ravines, where they are easily removed.

Iron and Steel Roofing and Siding.

We have received from the Garry Iron and Steel Roofing Co., of Cleveland, Ohio, a copy of a handsome catalogue of their products. The corrugated iron and steel roofing manufactured by this company is recognized in many mining regions as the most durable and convenient for mine buildings and we heartily recommend the Garry roofing and siding to our readers.

"P & B." Paint.

It seems almost useless to mention the old reliable "P. & B." paint to mine owners and mine managers as a most efficient means of economizing at the mine.

However, there are many mine owners and mine managers who have never had any experience with it, and some who have probably never heard of it. We therefore briefly call attention to it, as we consider it the province of such a journal as this to keep its readers informed on all first-class appliances or means, for securing greater economies in mining.

"P & B." paint has for its base a mineral pronounced by chemists to be practically indestructible. When dry on exposed surfaces it is more fire-proof than many of the so-called fire-proof paints. Neither salt nor fresh water, alkaline or acid solutions of any kind make any impression on surfaces coated with it. It preserves iron and other metals from rust, and when applied to clean surfaces completely arrests oxidization. One of its chief ingredients is the most volatile liquid known to chemistry. This liquid evaporates immediately after the application of the paint and causes the mineral to penetrate deeper into the pores of the metal than any other coating. In consequence, the expansion and contraction and the ordinary cracking and breaking of other coatings do not occur with this paint. For this reason it is especially well adapted for metal, etc., which is called upon to stand fluctuations in temperature. It absolutely fills the outer pores of any substance, and being in its nature very elastic, makes an absolutely preservative coat. This paint sets quickly and as soon as dry is tasteless and odorless. It is put up in liquid form of the proper consistency for application with a brush. In color it is a good black, leaving a coating similar to Japan.

It has been in use since 1885 and experience has demonstrated it to be an invaluable article for use around mines. As a protection to iron or metals of any kind in resisting the corrosive elements in mine water it has stood all kinds of tests in a satisfactory manner; on working barrels and chambers of pumps, on both the inside and outside of column pipe, on discs of fans, on screen segments, etc., it has been used to very great advantage. The latter will last much longer if coated with "P. & B." paint than they will otherwise. It is an excellent coating for telephone wires, bell wires and steam pipe covering where they are carried in the mines as well as above ground. Steam pipe covering, whether of asbestos, cement or almost any other non-conductive material, will absorb moisture if not coated with such a paint, and the pipes will corrode under the covering.

Its use on such parts of mine pumps and column pipe as are exposed to the action of acidulated mine water will result in very materially lengthening their life at a very insignificant cost.

This paint is manufactured by the Standard Paint Co., of No. 2 Liberty street, New York, and is guaranteed by them to meet all claims made for it. In view of the long and successful use of this paint by many mine managers such a guarantee seems unnecessary, but it is made for the benefit of those who have never tried this excellent article.

THE DAYTON, TENN., DISASTER.

Full Particulars and Descriptions of the Mine Previous and Subsequent to the Explosion.

Written for The Colliery Engineer and Metal Miner by W. M. Gibson, E. M., Supt.

The Nelson mine, the scene of the terrible disaster on the morning of the 20th of December last, whereby twenty-eight men and boys lost their lives, is owned and operated by the Dayton Coal and Iron Co., Ltd., and is located on the eastern side of Walden's Ridge, about 1½ miles northwest of the town of Dayton. The seam belongs to the lower coal measures, is of a dry and gaseous nature, and has an average thickness of five feet, with a slight general dip to the northwest. The overlying strata, or covering of sandstones and shales, varies in this locality from 350 feet to 1,200 feet in thickness. At some time in the remote ages the main body of the mountain, which is here twelve to fourteen miles wide, has evidently subsided, throwing the measures on the eastern side into a series of ridges or terraces, and bequeathing to future operators every roll and twist known to the geologist and mining engineer, and every degree of inclination from the horizontal to the vertical. These ridges or terraces run nearly parallel with the mountain and vary in height from 5 feet to 125 feet.

Operations were first commenced in the fall of 1886, and have continued almost without interruption since, the developed territory up to present date amounting to nearly four hundred acres.

For some time previous to the disaster, the daily output was about 350 tons, and the number of employes inside the mine amounted to 130. The system of working may be described as that of the single entry, pillar and stall, but, under the peculiar conditions, method is out of the question, and modifications to suit the different circumstances are frequent.

There are three entrances, known as the "Main," Entry E" and Dixon Slope,"

The first named has an altitude of 982 feet above sea level, and 280 feet above the valley in which the town of Dayton stands, and it is the principal artery of the mine. Through it all the coal is delivered to the tipple, which is located close to the entrance.

Entry E entrance is situated 1,500 feet, and Dixon Slope entrance 4,300 feet northeast of the main entrance, their altitudes above sea level being 924 feet and 891 feet respectively. These two entrances are merely used at present for ventilating, traveling and pumping purposes.

The mine is divided into districts, numbered from 1 to 10 inclusively, but of these only Nos. 1, 2, 7, 9 and 10 have been at work for the past few years. The coal is brought from the working places by mules to the main side track in each of these districts, and from there taken to the outside by rope haulage. The longest pull is from No. 10 side-track, a distance of 3,500 feet, the difference in levels being 376 feet. This gradient is not regular by any means, but varies from nil to 35°. On a branch haulway known as Entry O, there is for a distance of 350 feet, a gradient varying from 26° to 37°.

The ventilation was secured by a 7 ft. Sturtevant steam fan, placed near the main entrance, giving 35,000 cubic feet per minute, with a W. G. of .8 and 190 revolutions.

The current for Nos. 1 and 2 districts enters at the main entrance, that for 7 and 9 districts at Entry E entrance, and that for No. 10 district at the Dixon Slope entrance.

Two shifts were employed in the mine—the first entering at 6:30 a. m. and the other at 6 p. m., the latter shift, however, only comprising a few men and confined to No. 10 district.

For the past seven years careful inspections have been made, by competent fire bosses, of all working places, and roadways leading thereto before each shift entered, also at noon each day after shot firing—this latter precaution being necessary to avoid fires. Miners were allowed to fire their own shots twice each shift, but were limited to a certain hour each time, except in special cases.

Naked lights were used exclusively, with the exception of one short section of Entry D, in No. 9 district, that adjoined some old workings that were difficult to ventilate on account of the top having closed in. One end of this section was guarded by a trapper, and the other by a deputy fire boss named Tom Hawkins, whose duty it was to attend to a trap door at his station and to carefully watch for any symptoms of fire-damp, and, in conjunction with the trapper, see that only safety lamps were used by those who had occasion to pass that way. This fire-damp was about forty feet from the entry, and only showed its presence in the test lamp once in a while, but there were no means of knowing its volume, hence the above precautions.

The morning of the disaster was wet and stormy, but the fire boss and his assistant on their tour of inspection found nothing unusual inside the mine to arouse their suspicions of any lurking danger. The air currents were traveling in their usual volumes and customary courses, and the roadways and working places (excepting rooms Nos. 1, 2 and 16, off Entry K, see plan) were safe and free from fire-damp. In each of these he found a very small quantity of fire-damp, so small, in fact, that he hesitated a little about marking them as dangerous. However, he did so in the customary manner, and after completing his rounds notified the miners at the stations as to the condition of their working places, and returned to the outside to make his report in the book kept for that purpose. While doing so, information came to the mine boss that an explosion had occurred in or near No. 10 district, and this was soon confirmed by the rush of excited employes from the other districts to the outside. This was about 7:30 a. m.

A search party was immediately organized and sent in to investigate, but they were unable to get beyond No. 9 side-track on the main entry on account of the after-damp. Meanwhile some men from No. 9 district reached the outside, with one of their number scorched and bruised considerably.

On the writer's arrival two other parties were organized—one to enter at the Main entrance and the other at the Dixon Slope entrance. This second party did not succeed in getting beyond No. 10 side-track, on the main entry, but a third party, which was organized in the interval, by following the intake current of No. 7 and No. 9 districts, succeeded after several unsuccessful attempts in reaching the body of Tom Hawkins (No. 7 on plan) about 2:30 p. m., which they found thirty feet or so south of his station, on Entry D.

This was the first body recovered on this side of the mine. There were no signs of burns on his person or clothes, but a large gash on the left side of his head showed that he had been knocked down by the force of the explosion, and in this way made an easy victim to the after-damp. Several miners passed him while he was still conscious, but he made no request for help, and they, believing he would follow them, went on. An empty car stood in the doorway at his station, and the mule lay dead immediately in front of it.

The Dixon Slope party succeeded in reaching the bodies of the men numbered 1, 2, 3, 4, 5 and 6, on plan, in the rooms to the east of Entry K, about 9:30 a. m., and soon afterwards had them removed to the outside. These men had evidently endeavored to reach Entry K, but being in the dark and doubtless excited, they became confused and wandered aimlessly around until overcome by the afterdamp. Small (No. 1), as will be seen from the plan, almost succeeded in reaching the desired point.

Heavy falls prevented further progress being made on that side that day, and all attempts on the other side were rendered futile by the after-damp, until about 3:00 p. m., when the body of Washburn was reached, No. 8 on plan. Nos. 9, 10, 11, 12, 14 and 15 were also reached a few hours later, and by early morning No. 13 was found. Thus, in less than twenty-four hours' time, fifteen bodies had been recovered and removed to the outside.

Nos. 8, 9, 10, 11 and 12 were drivers, and their mules were found close to their bodies. This is the principal gathering point or side track for this district, and appearances would indicate that these drivers were on the eve of starting out on their day's routine.

Several very heavy falls were encountered on Entries L and K between Entry G and the entrance of No. 3 room, and a considerable quantity of the debris had to be removed before some of the bodies could be recovered, also before further advance could be made. All these bodies were more or less burned and bruised.

Early next morning a search party succeeded in crossing the fall, and immediately at the entrance of No. 2 room found the body of Henry Williams, (No. 16 on plan), face downwards and lying diagonally across the entry, his face and head considerably bruised. Continuing their explorations, they soon afterwards found those of T. Lane and son (Nos. 17 and 18 on plan) lying side by side. In the former's pocket was a watch, the hands of which pointed to 7:22½, evidently the time at which the explosion occurred. A little later the body of trapper Morgan (No. 19 on plan) was found near his station or door. An attempt was then made to explore No. 7 room, but fire-damp was encountered 300 feet above its junction with Entry K, rendering further advance impossible. They then returned and had the bodies removed to the outside.

Later in the evening two other parties entered—one at the main entrance and the other at Dixon Slope entrance, and met on Entry K, and thus for the first time since the disaster established communication between these two entrances.

A little later the Dixon Slope party discovered and removed the bodies (Nos. 20, 21 and 22 on plan). All that night a crew worked on the falls on Entry L, and next day, Sunday, the bodies of three mules were removed and the other two on the day following.

All energies were now directed to the removal of the large accumulation of fire-damp on the west side of Entry K, amounting to nearly 400,000 cubic feet, and for this purpose three shifts of men, varying from five to seven in number, each in charge of a competent foreman and equipped for restoring brattices and doors and cleaning up debris, were detailed for duty each day. This gas was exceedingly strong, and evidently contained a considerable quantity of carbonic acid gas. Consequently progress was slow, but finally, on the morning of the 27th, Nos. 7 and 8 rooms were cleared and the explorers were able to advance. The bodies (Nos. 23, 24, 25 and 26 on plan) were found in an advanced stage of decomposition. Each was lying face downward, head toward Entry K, and their faces showed signs of having been subjected to intense heat. The first was partially raised on his elbows, as if in the act of making a final effort for life. The body of the mule driven by him was found at the face of No. 8 room, lying in front of the rear end of the empty car, the tail chain stretched across it and fastened to the front end, showing that the driver had reached there just as the explosion occurred. The cap of one of the other victims was found close to the face of the room, also some clothes and dinner buckets at their "box" or resting place, a short distance back from the face.

Entry P was then attacked, and after a bitter fight the bodies of the last two remaining victims (Nos. 27 and 28 on plan) were found and removed on the night of Jan. 4th, sixteen days after the disaster. At this point there was an overcast, and as the bodies of these two victims were found on top of the fallen timbers, it is evident they had passed this point and been blown back by the force of the explosion. Both were lying prostrate on their backs and at right angles to each other. The head of No. 28 was crushed flat by a large rock weighing 150 to 200 pounds, which had fallen from the roof. The odor from the bodies of these last two victims was no worse than that from the four found the week previous. This was rather surprising to the rescue party, who anticipated something worse and were fully equipped with sponges, camphor and carbolic acid. Probably the fire-damp had some preservative action.

In addition to the falls already referred to, there were several very heavy ones on Entry K, between Nos. 7 and 13 rooms, also in Nos. 9, 10 and 11 rooms. These rendered the work of the rescue parties extremely perilous, and it was only by the exercise of the greatest possible care that accidents were avoided. Slight falls were frequently met with in other sections of the district.

The explosion evidently originated in No. 2 room and radiated in all directions therefrom. The fallen props, blown out brattices, doors and gobs, and collections of dust on the standing props, and loaded cars in this and adjoining rooms, all point to this conclusion. The coal on the rib sides in this room was slightly charred, and several of the props had a thick caking of charred dust on the side next to the "face." This charred dust was also found adhering to the props in Entry P_2 air-course near to its junction with No. 7 room, in No. 1 room near face, in No. 7 room about 200 feet back from face and at various other points throughout the district.

The "blast" evidently traveled on the north side against the air current, along Entry K, No. 7 room and Entries P_1 and P_2, and on the south side with the air current, along Entry L, and the haulway to No. 10 side-track and up the branch haulway to Entry D.

A young man, named Oscar Hawkins, who was passing this point on Entry D, just at the time with his mule and car, was blown out of the latter by the force of the blast, and considerably bruised, also severely scorched about the face and neck.

Another young man who was in front of him some distance and going in the same direction, was also blown from the car in which he was seated, over and beyond the mule, but escaped with merely a few scratches.

Both describe the blast as a terrific gust of hot air, filled with dust, resembling a thick, black rolling cloud. The destruction of the brattices was very complete, especially in Entry P_2, where it was difficult to find a piece of plank larger than 6″ x12″. This, of course, can be easily accounted for by its being a "butt end" and the space very limited.

There are indications of there having been but little flame at any point in the entire district. Pieces of paper and brattice cloth were found unscorched even within a very short distance of the point of origin, also kegs of powder; and all the physicians in their depositions stated they were inclined to believe that the burns on the victims were the result of intense heat only. This belief is strengthened by the fact that few of their clothes were even scorched.

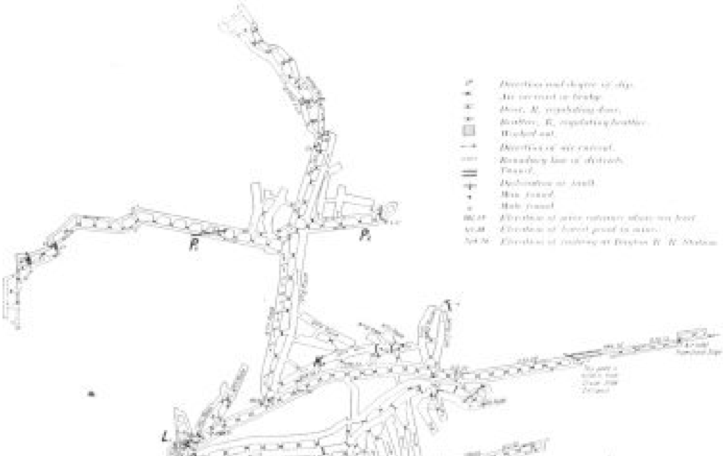
Several theories have been advanced as to the cause of the explosion, but the only feasible one to the writer's mind is that it was the result of some one crossing the danger mark, in No. 2 room, with a naked light, and setting fire to the small accumulation of fire-damp there, which communicated with the dust, causing the fearful carnage referred to. This opinion is shared by all the officials of the mine, also by State Mine Inspector Clute, who was on the ground during the rescue work and made a thorough investigation into the cause and origin of the disaster.

An ordinary miner's lamp, with Williams' name cut on the lid, was found in this room, about fifteen feet from his body, and this, together with the position of his body, makes us believe he was the transgressor. This room was Bennett's and Williams' regular working place. Two other men had worked in it with naked lights within twenty feet or so of the face, on the previous shift, until 3 A. M.

On the morning of the disaster, 113 men and boys and 20 mules entered the mine, to be distributed as follows:

District.	Men.	Mules.
No. 1	22	5
No. 2	14	1
No. 7	13	2
No. 9	20	5
No. 10	28	6
Miscellaneous	16	

These last named belonged to no particular district.



Plan of Districts Nos. 9 and 10, Nelson Mines, Dayton, Tenn. Scale, 1 in. = 400 ft.

One of the number bound for No. 10 district was detained on the way, and thus escaped the fate of his comrades.

Six of the mules were rescued on the day of the explosion, and one four days later. This one was overlooked in some way, and given up as being dead. When found, it was gnawing at some cross ties in No. 1 district, and in a very weak condition. How it escaped, is a mystery.

There have been two or three slight explosions of fire-damp in different working places in this section in the past, burning the occupants to some extent, but never extending beyond a very small area each time. In fact, the district was considered one of the safest in the mine. It is very gratifying to be able to state that none of the rescuers received the slightest injury during their perilous work.

On the 23rd of September, 1889, an explosion of fire-damp occurred on the main entry, between Nos. 7 and 8 side-tracks, burning nine men severely, three of whom died shortly afterwards. This was caused by carelessness on the part of the inside foreman, who, in making his rounds, neglected to extinguish the naked light on his head. He was seriously burned himself and died a few days afterwards.

This department is intended for the use of those who wish to express their views, or ask, or answer, questions on any subject relating to mining. Correspondents need not hesitate to write for supposed want of ability. If the ideas are expressed, we will cheerfully make any correction in composition that may be required. Communications should not be too lengthy, and personal reflections should be carefully avoided.

All communications should be accompanied with the proper name and address of the writer—not necessarily for publication, but as a guarantee of good faith.

The Editor is not responsible for views expressed in this Department.

☞ Correspondence should be in as simple language, and as free of technical terms and formulæ as possible, consistent with clear solution.

Questions on subjects not directly connected with mining will not be published.

The Fifth Root.

Editor Colliery Engineer and Metal Miner:

SIR:—If I am not intruding too much on upon your time, I wish to ask if Ajax is not giving us a rule that will not work as well as Dr. Halley's, *i. e.*, the rule which I sent for your February number. I have tried ten or twelve questions by Ajax's rule and could not get over two right. I wish to give Ajax two questions to work, and if he gets them as correct by his rule as by the rule which I gave, I will admit its correctness, as it is much easier to work than mine. Will Ajax kindly work the "fifth" root of 9 and "fifth" root of 21035.8? By my rule I get for $\sqrt[5]{21035.8} = 7.321590$, and the fifth power of 7.321590 = 21035.789. Now, I took 7.2 and 7.4 as trial roots, and I find it wrong. I have tried $\sqrt[5]{9}$ with the same result, and fear that Ajax has not proved his rule, and he will oblige me if he will work them out for your next issue. Yours truly,

THOS. HANNAH, Dunlo, Pa.

The Fifth Root by Arithmetic.

We are in receipt of a method of finding the 5th root of any number by means of arithmetic, submitted by Mr. J. Bucher, of Dysart, Pa., but do not publish it, as his solution is the same as that submitted by Mr. Robert Hinning, of Carterville, Ill., which appeared in our September, 1895, issue.

Broken Shaft.

Editor Colliery Engineer and Metal Miner:

SIR:—I would be obliged if you would insert the following in reply to Mr. Noll's inquiry in the March issue:

QUES.—At Kangley Mine No. 2 we are using an endless rope system of haulage with 2¼ miles of ⅞" crucible steel wire rope worked with an engine of the Litchfield pattern with 12"x20" cylinders and a 7 foot cog-wheel to which is attached a 4 foot drum. Placed 3 feet behind this drum is another drum which is equipped with Walker's slide rings. This drum is not connected with the engine, but is worked by the rope passing from the forward drum back over the Walker drum with five laps, thence to the tension wheel, and on to the inside. The shaft, which is a six-inch one, has broken at two different times within four months. What would cause the breakage of such a large shaft, it being only 4 feet long? Could the variations in the grooves of the drum made by the wear of the rope cause the fracture?

If the drums were not set true with each other, would that cause the break?

ANS.—The Walker drum is used as the idler, and in this case only does away with half the crave on the drums. It would be better if there was another Walker drum connected with the engine, as that would reduce more of the craving.

If the drums were loose on the shaft and made tight enough by friction, instead of by a key, to pull the working load, then, in case the cars should be derailed, the drums would stop and leave the engine in motion; then no sudden strains could be thrown on shafts, which accounts for broken shaft. Yours truly,

SAMUEL G. MORGAN,

Nanticoke, Pa., April 9, 1896.

Answer to Geometrical Problem.

Editor Colliery Engineer and Metal Miner:

SIR:—Please publish the following solution in answer to question asked by J. S. P., of Reynoldsville, Pa., in the April issue of your valuable journal. "A tree 120 feet high stands on the bank of a river 100 feet in width. At what distance from the ground should the tree be cut so that, in falling, the top will just reach the opposite bank of the river?"

In analytical trigonometry we have the following rule: Half the perimeter of a triangle is to its excess above the base, as the cotangent of half either of the angles at the base is to the tangent of half the other angle. As one of the angles at the base is a right angle, we have $\frac{90}{2} = 45°$ and cot. 45° = 1. $\frac{100 + 120}{2} = 110$ feet. 110 − 100 = 10 feet = excess of perimeter above the base.

110 : 10 :: 1 : .09, .09 = tan. 5° 11' 40" nearly, and 5° 11' 40" × 2 = 10° 23' 20" = angle of fallen tree with the base.

Therefore, tangent 10° 23' 20" = .18334. .18334 × 100 = 18.334 feet. Ans.

Proof: $\sqrt{18.334^2 + 100^2} = 101.666$ feet and 101.666 + 18.334 = 120 feet. Yours etc.,

J. G. WILLIAMSON.

Scammon, Kans., April 14, 1896.

Let x = fallen tree from point cut to top, y = part of tree standing, and z or 100' = stream.

Then $x + y = 120'$.

$x^2 + 2xy + y^2 = 14,400$.

$x^2 - y^2 = 10,000$ (the difference of the squares of hyp. and perp. = square of base.

$2x^2 + 2xy = 24,400$.

$2x^2 + 2xy = 240x$. (Multiplying the first equation by $2x$.)

$240x = 24,400$. (Axiom—Things equal to the same thing are equal to each other.)

$x = 101.66\frac{2}{3}$.

$y = 120 - 101.66\frac{2}{3}$ or $18.33\frac{1}{3}$. The point above ground that tree must be cut. Yours,

WM. MACTAGGART.

Jeanesville, Pa.

I beg to submit the following rule: Square the height of the tree; from the product, subtract the square of the base; divide the remainder by twice the height of the tree. The quotient will be the leg of the triangle or the height, from the ground, at which the tree must be cut in order to just reach the opposite bank of the river. Also total length of tree minus the height at which the tree was cut is equal to the hypothenuse of the triangle.

Solution: $[(120)^2 - (100)^2] \div 2 \times 120 = 18\frac{1}{3}$ feet, or height at which the tree must be cut.

WM. DUNCAN.

Dunbar, Pa., April 16, 1896.

Ventilation.

Editor Colliery Engineer and Metal Miner:

SIR:—In going over my copies of THE COLLIERY ENGINEER AND METAL MINER, on page 129 of the January, 1895 issue, I notice the following question and answer, the latter given by one of your staff of writers:

"If you had 150,000 cu. ft. of air passing per minute through an airway 8'x10' what would be the H. P. of the ventilation apart from friction?"

ANS.—"In this case the H. P. would only be required to set the inert air in motion at the mouth of the shaft. Then let v = velocity in feet per second and $\frac{150,000}{80 \times 60} = 31.25$ and let .077 be the weight of a cubic foot of air, then $\frac{v^2 W}{64.3} = F$, or F is the foot-pounds of work per square foot of area; and as there are 80 square feet in area of section, it follows that $\frac{31.25^2 \times .077 \times 80}{64.3 \times 550} = .01701$ or the required H. P. is .01701."

Now it is manifest that there is something radically wrong in the above if the following reasoning is correct:

150,000 cu. ft. of air passing through an airway 8'x10' would have a velocity of $\frac{150,000}{(10' \times 8') \times 60} = 31.25$ per second. The head due to such velocity expressed in inches of water gauge is (assuming air to be .0766 lbs. per cubic foot),

$$W.G. = \frac{\frac{31.25^2}{64.4 \times 5.2}}{.0766} = .223.$$

The H. P. of ventilation then apart from friction must surely be $= \frac{q \times W.G. \times 5.2}{33,000} = \frac{150,000 \times .223 \times 5.2}{33,000} = 5.27$ H. P. Ans. Authority, "The Colliery Managers Handbook."

Let us take another arrangement of the same result: $\frac{150,000}{(10' \times 8')60} = 31.25$; $\frac{v^2}{2g} = \frac{31.25^2}{32.2 \times 2} = 15.16$.

The weight of a cubic foot of air at 62° under ordinary pressure = .0763122 lbs., consequently, 15.16 × .0763122 lbs. = 1.1569 lbs., the force engendering the motion of the air. Since $\frac{q \times p}{33,000}$ = H. P. then $\frac{150,000 \times 1.1569 \text{ lbs.}}{33,000}$ = 5.27 H. P. Ans. Authority, Wm. Fairley on "Ventilation."

Let us take another. In the example given the quantity passing per second $= \frac{150,000}{60} = 2,500$ and the velocity is consequently $\frac{2,500}{10 \times 8} = 31.2$. If friction be absent, $v^2 = 2gh$. In this case h, or head, $= \frac{31.2^2}{64.4} = 15.2$. To completely solve the problem the temperature and pressure must be assumed. At the normal temperature, pressure of 13' of air column weighs 1 pound and therefore, in this case, the pressure per square foot producing the velocity is $\frac{15.2}{13} = 1.16$ lbs.

The H. P. required is the quantity per second × pressure ÷ 550, or $\frac{2,500 \times 1.16}{550} = 5.27$. Ans. Authority, "A Text-Book of Coal Mining."

The question may be solved by finding the theoretical water gauge necessary to produce a velocity of 31.25 feet per second.

$$W.G. \text{ (in inches)} = \frac{\frac{1.3253 \times H}{459 + t} \times \frac{v^2}{2g}}{5.196},$$

v = velocity in feet per second, g = gravity, h = height from which a body must fall in order to generate v, and H = height of barometer.

In this case the above formula will give W. G. = .23 lbs., consequently

$$\frac{2,500 \text{ cu. ft. per second} \times .23 \text{ lbs.} \times 5.2}{550} = 5.26 \text{ H. P.}$$

If the value of coefficient of friction could be accurately determined, then, strictly speaking, this value or H. P., or whatever it may be, should be added to the value for frictional resistance. For example: If in the preceding example it was found that 50 H. P. was developed in overcoming frictional resistance and the H. P. due to the quantity is 5.27 H. P., then the true answer would be 55.27 H. P.

When it is noted how very small is the pressure required to produce velocity, and also the fact that the resistances are only estimated approximately, it is not surprising that the pressure to produce the velocity is neglected. The calculations are made easier by each neglect.

I have not been very particular in extending my figures or in using precisely the same values in the different cases to get the answers, my object being merely to show the principle. Yours truly,

W. D. L. HARDIE.

Birmingham, Ala., April 11, 1896.

[NOTE BY THE EDITOR:—On examination of the question and answer we find that Mr. Hardie is correct, and that the error in our answer was due to two errors. One in placing the decimal point incorrectly, and making 0.1701 read .01701, and the other in failing to multiply the 0.1701 × 31.25, which would have given a result of 5.3156. This practically agrees with Mr. Hardie's answer.]

PRIZE CONTEST.

Prizes Given for the Best Answers to Questions Relating to Mining.

For the best answer to each of the following questions, the value of $1.00 in any of the books in our book catalogue, or six months' subscription to THE COLLIERY ENGINEER AND METAL MINER.

For the second best answer to each question, the value of 50 cents in any of the books in our book catalogue or three months subscription to THE COLLIERY ENGINEER AND METAL MINER.

Both prizes for answers to the same question will not be awarded to any one person.

Conditions.

First—Competitors must be subscribers to THE COLLIERY ENGINEER AND METAL MINER.

Second—The name and address in full of the contestant must be signed to each answer, and each answer must be on a separate paper.

Third—Answers must be written in ink on one side of the paper only.

Fourth—"Competition contest" must be written on the envelope in which the answers are sent to us.

Fifth—One person may compete in all the questions.

Sixth—Our decision as to the merits of the answers shall be final.

Seventh—Answers must be mailed us not later than one month after publication.

Eighth—The publication of the answers and names of persons to whom the prizes are awarded shall be considered sufficient notification. Successful competitors are requested to notify us as soon as possible as to what disposal they wish to make of their prizes.

Competition Questions for May.

QUES. 223.—In trying to find out the combustible substance that would give the best results in generating the flame in our new safety lamp, I have fallen across the following facts that completely puzzle me, and as I am afraid that any further attempts to solve the riddle would drive me to distraction, I will be obliged to you if you will show to me how it occurs that when two volumes of pure hydrogen combine with one volume of oxygen, more heat is given off than when one volume of marsh gas combines with two volumes of oxygen. One thing I have noticed that may help you to find an answer, and that is, the hydrogen and oxygen produce water that is a liquid, whereas the marsh gas and oxygen produce liquid water and a permanent gas, and, strange to say, coal gas that contains a high percentage of C_2H_4 gives off less heat than CH_4, and oils, such as are burned in lamps, give off less heat per unit of weight than any of the gases under notice, and yet we know that a large percentage of energy is concealed somehow in burning these hydro-carbons, but it is not given off as heat, but I have no doubt you can tell me something that will remove the mystery.

QUES. 224.—All the plants in the vegetable kingdom of life are grouped under four distinct divisions, as Thallogens, Acrogens, Endogens, and Exogens. Will you, therefore, name for me a single example in each division that flourished during the Carboniferous period, and also a single example in each division of plants that are living now in your state or country?

QUES. 225.—A mine shaft is 3,000 feet deep, and I wish to know what weight a first-class steel rope, 1½ inches in diameter, will safely carry in hoisting coals up this shaft.

QUES. 226.—Will you explain to me, with a neat drawing, how it occurs that the horizontal planes at the two ends of a perfectly straight line of sight are never parallel, although the telescope is set truly level at the ends in question? Again, while you are busy, you might show me how it is that we cannot get a "perfectly straight" line of sight, and the longer that line is, the greater is the divergence. Further, make a bold finish by showing the reason why a sight made over a surface heated with the rays of the sun can never be trusted for accuracy.

QUES. 227.—To work a valuable coal seam, we must deliver onto the nearest railway with a branch road of our own, and as the surface is very uneven, and the possible duration of the seam does not warrant the making of cuttings and embankments, we will deem it a favor if you will advise us about the haulage we should make to be cheap in construction and efficient in action, and, if possible, please support your conclusions by reference to actual cases, and be careful to note that we have decided against every kind of locomotive traction.

QUES. 228.—Sometimes in mining, where the seam is situated above the drainage level of the district, water can be collected at the surface and conveyed down the shaft in pipes to do the work required in pumping, hauling and ventilating. This great water power is applied through the medium of hydraulic engines, in which a stream of high pressed water is projected onto reaction blades, whose surfaces are curved to secure total reflection instead of simple deflection. Now, to make sure that we all understand the explanation given, will you still further assist us by answering two questions?

First—What are the curves that are given to the inside surfaces of the reflecting cups, of the reflex water wheel.

Second—Show by a sketch and the necessary explanation, that with total reflection more power is obtained than could be secured with a deflection of 90° from the plane of the wheel's rotation.

Answers to Questions which Appeared in the March Issue and for which Prizes Have Been Awarded.

QUES. 211.—As we are striving to make our proposed new safety lamp the best in the world, it certainly should be of some service in testing for gas, and as we require some additional information to enable us to make it so, let us band ourselves together for mutual help and we are sure to succeed. Then let us know at once what makes the gas cap tail up in a blue stream above the ordinary flame of the safety lamp?

ANS.—The blue cap is a blue lambent flame characteristic of carbon monoxide burning into carbon dioxide. Its presence on the flame of the safety lamp is due to imperfect combustion, for as little as 3 per cent. of marsh gas in air produces this effect. The marsh gas on contacting with the bottom of the flame burns off so much oxygen that the remainder in the air is not sufficient to fully burn the carbon of the oil into carbon dioxide, and, therefore, when the carbon monoxide reaches the higher stratum where more oxygen is available it burns into the dioxide and in so doing produces the characteristic blue cap.

D. J. LEWIS,
Elliott, Randolph Co., Mo.

QUES. 212.—When an explosion of fire-damp occurs in a coal mine, immense volumes of gas and air rush up and out of the shafts, and at the same time the expanded air and gas rushes into and becomes compressed in the gobs, do you think then that a correct sample of the after-damp produced by the explosion is procurable, and if so, where would expect to find it? And while so doing, will you explain the recoil, or back rush of air into the levels, rooms, etc., after the blast has expended itself?

ANS.—A correct sample of the after-damp cannot be obtained because a considerable proportion of the products of combustion has been ejected from the mine by expansion, as proved by the outrush, and what remains has been diluted by the back rush, therefore the best approximate sample could only be found in such rooms as would be subject to a back rush of nearly pure after-damp. The back rush is caused by the partial vacuum resulting from the cooling of the after-damp.

JAMES TASKER,
Old Forge, Pa.

Second Prize, JOHN FLETCHER,
428 Tonti street, La Salle, Ill.

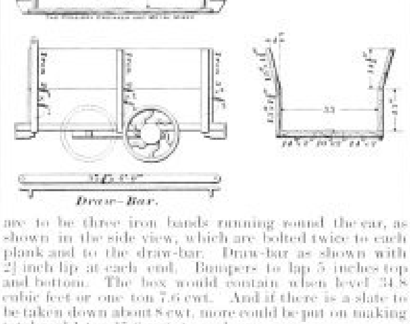
QUES. 213.—I am a mine superintendent for the Black Band Coal and Iron Co., and the principal director has requested me to read a paper before a meeting of the mine foremen of the district on the principle of construction and the mode of action of the electric motor, such as is used for mine haulage. He says the description must be brief and applied entirely to the magnetic field, and must only mention the commutator by a reference to its use. Now, as electrical appliances have come to the front for mining, I must either write this paper or lose my position, and I do think you will therefore make an effort to help me. Then, please give me the principal points required for a good paper.

ANS.—To illustrate the subject more clearly take the T. M. M—25, 100 H. P. locomotive now manufactured by the General Electric Co., and follow the current from the trolley wheel to its return to the rails. The current runs down an insulated wire connected with the brass wheel on the trolley arm, the other end connecting with the controller (the current being a direct one), which connects the current with the two motors on the driving wheels. The controller has a reversible lever which allows the locomotive to run in either direction. The principal features here are the five notches used in starting, each notch, like the notches of the lever bar in a locomotive, only allows so much current to pass to the motors, the remainder going to the rheostats, of which there are four. One notch throws into the circuit the four, two notches throw out one, three notches throw out two, four notches throw out the third, and the fifth notch throws them all out. The rheostats are built up of sheet iron ribbon packed in asbestos and mounted in fire brick, so as to be absolutely fire-proof. This is to take up in resistance the surplus current, not allowing the whole current to be exerted on the motors. When the controller is thrown wide open, the current passes direct to the motors, part of the current goes to the field or magnetic poles, to excite the field magnets and the remainder goes to the commutator to be changed to positive and negative electricity, the current then passing round each section of the armature as they come under the brushes. The armature is composed of a number of flat coils of copper wire placed on their edge against the core, and insulated from each other; one end of each of these coils is connected with a segment of the commutator, and the other end is fastened to the next segment, and so on round the commutator, and then each segment of the commutator is connected to the one on the opposite side by short insulated wires. The direct current can be changed to an alternate one by passing through a commutator or *vice versa*. The current flows in through the brush to a section of the commutator. Thence round a coil of the armature, back to the next section of the commutator and is returned through the other brush to the wheels, and thence to the rails, which are again connected with the generator, thus completing a ground circuit. When the field magnets are excited and a current flows through a coil of the armature, the magnet attracts this coil till it is directly under the magnet; then the next one is attracted, thus causing revolution of the armature, which is geared by pinions to the driving wheels. The motor used is the bipolar water proof, with only one spool-piece.

H. K. MOBERLY, West Newton, Pa.

QUES. 214.—We are about to open out a fine seam of bituminous coal that is 5 feet thick; and to work it we are going to sink shafts that will be 820 feet deep. Before, however, fixing on what should be the sizes of the shaft sections, we wish to determine what have to be the dimensions of the cars. The specific gravity of the coal is 1.27, and we want an output of 1,000 tons per day; will you then, give us a sketch in elevation of the car you would recommend, and be careful to give the dimensions and capacity of the box, the sizes of the details of the bottom frame, and the sizes of the wheels and axles.

ANS.—Would use Phillips Mine Supply patent wheels 18'' diameter and 2'' axles placed 22 inches apart. There



Draw-Bar.

are to be three iron bands running round the car, as shown in the side view, which are bolted twice to each plank and to the draw-bar. Draw-bar as shown with 2½ inch lip at each end. Bumpers to lap 5 inches top and bottom. The box would contain when level 34.8 cubic feet or one ton 7.6 cwt. And if there is a slate to be taken down about 8 cwt. more could be put on making total coal 1 ton 15.6 cwt. to each car.

H. K. MOBERLY, West Newton, Pa.

QUES. 215.—In surveying around the bottom of a mountain, we made all the necessary levels and insets to determine the correct figure of a truly horizontal base that was just touched by the western side of an outcropping coal seam. From the plat we found the figure to be practically that of an ellipse, with its major axis coursing from south to north 6,012 feet, and the minor axis coursing from east to west for 2,842 feet. The mountain is 1,800 feet high. The coal seam is 4 feet thick, and is overlaid with a strong sandstone. We leveled our transit at a distance of 64 feet eastward of the eastern end of the minor axis, and with the center of the telescope at an elevation of 4 feet 1 inch above the calculated level of the base, the bottom of the coal seam here made an angle of elevation of 38° 26', and the distance, measured in a straight line from the plumb point on the ground to the bottom of the coal seam, was found to be 1,026 feet. Now, I wish to know three things that I am sure you will calculate for me.

First.—What is the pitch of the seam?

Second.—What is the area of the seam?

Third.—What percentage of this seam could be reasonably worked? Show with a sketch how you find the pitch.

[Not one of our many able competitors have supplied us with the correct solution of this question.—ED.]

QUES. 216.—One of the air-ways in a mine is 6 feet high and 9 feet wide, and formerly a large volume of air was passed through it with a ventilating pressure of 1.2 inches of water gauge. Afterward a regulator was fixed in this air-way to reduce the quantity passing to one-third of the former volume, and recently a new ventilating fan has been started at this mine, and it is treble the power of the former one. Now I will be obliged if you will determine for me five things:

First—What is the length of the air-way, taking the co-efficient of resistance at .00000001?

Second—What was the original quantity passing through the air-way?

Third—What is the difference of pressure on the two sides of the regulator now, and what was it before the new fan was started?

Fourth—What is the height of the water gauge now for the drift?

Fifth—What is the quantity now passing through the regulator in cubic feet per minute?

ANS.—Another factor is required for the solution of this question, and that is the velocity, and therefore I assume it to be 1,000 feet per minute, and on this basis the answers to the sub-questions will be as follows:

First—The length of the air-way l.

$$l = \frac{p\,a}{K\,v^2 \times 30} = \frac{1.2 \times 5.2 \times 54}{.00000001 \times 1000^2 \times 30} = 1123.2 \text{ ft.}$$

Second—The original quantity is 54 × 1,000 = 54,000 cubic feet per minute.

Third—Difference of pressure now 11.537 pounds per square foot.

Difference of pressure before, 5.5406 pounds per square foot.

Fourth—The height of the water gauge now with the increased power is $\sqrt[3]{3^2} \times 1.2 = 2.496$ inches.

Fourth—The quantity passing through the regulator now is $\sqrt[3]{3} \times 18,000 = 25,960$ cubic feet per minute.

ADOLPHE COOK, Houtzdale, Pa.

Second Prize—JOHN VERNER, Lucas, Iowa.

The aggregate increase in the population of Europe from 1885 to 1895 was 29,922,800. Russia added 12,510,-800 to her existing population; Germany, 4,522,000; Austro-Hungary, 3,502,200; Great Britain, 2,452,400; Turkey, 1,100,000, and France, 67,100.—*European Economist.*

Semibronze Packing.

This is the name given to a new high grade packing for engines and pumps, manufactured by N. J. Car Spring & Rubber Company, Jersey City, N. J.

The core, which is the foundation of the packing, is a lubricator reservoir, and is composed of loosely spun asbestos thoroughly saturated with high grade cylinder oil, pressed into the desired shape and coated with pure foliated graphite. The covering consists of alternate strands of hemp and asbestos, loosely spun, each braided over with an open work of very fine brass wire.

SEMIBRONZE PACKING.

All of the strands are very loose and fluffy, so that they will readily soak up oil and hold it, and the braiding of the wire being quite open permits the oil to flow readily from the fiber and carry along with it the graphite to the piston rod when heated. Besides serving to hold the soft fluffy materials together, the wire adds to the lasting qualities of the packing, both by its own resistance to wear when properly lubricated and by reason of its protection of the fibers from being blown out of the stuffing box by steam or water pressure.

This packing is used in the same way as common fibrous packings, and needs no special handling or care.

The value of Semibronze packing has been fully proved by actual practice in hard service. It has given entire satisfaction wherever put in, both as to its lasting qualities and the bright appearance of the piston rods.

Most of the piston packings on the market are made without a full knowledge of the requirements. The Semibronze is the result of years of experience of a practical and well-known engineer and pump builder. It is put up in twelve feet lengths, each length in a separate box, labeled, and sells at a popular price. Two brands are made, viz: "Gilt Edge" and "Combination."

Circulars and further information will be furnished our readers upon application to the N. J. Car Spring & Rubber Co.

Compressed Air.

Compressed Air is the title of a neat little monthly publication edited and published by Mr. W. L. Saunders, 26 Cortlandt street, New York. A copy of the first issue is before us, and we take pleasure in testifying to its interest and value. We republish the editor's announcement as a very brief and comprehensive statement of the character of the publication:

"The appearance of this little magazine, published for the purpose of disseminating information regarding this important branch of science, will, we trust, be received with gratification. Thus far the subject has been treated in only a fragmentary way. An occasional book, lecture, essay, or articles in trade papers have been the extent of its promotion.

"Only a small amount of literature on this subject has been separated from trade interests, and the information given has been chiefly of value when examining the relative qualities of the manufacturer's product.

"Compressed air, as a useful power, demands attention. Its scope of usefulness is each day widening, and its possibilities are beyond conjecture. The era of compressed air is even now upon us, and its claims must be placed beside electricity and other great scientific auxiliaries that have been developed in this age of progress.

"We believe that the development of the science of compressed air has suffered for want of publicity. Discussion, controversy, advertising—all lead to a better knowledge of the subject and point the way to larger fields of usefulness. It is this condition which *Compressed Air* seeks to bring about."

The subscription price of *Compressed Air* is $1.00 per year.

An Important Change.

An event of no little interest to mine managers is the recent reorganization of the Dickson Mfg. Co., Scranton, Pa., a company which has a most excellent and wide reputation for its mining and other types of machinery.

The facilities of the company will be greatly enlarged by the addition of much heavy machinery, the erection of larger buildings, and the establishment of new departments. These improvements are being made at once, and the works being put in condition to compete in the open market for all kinds of machinery and locomotives. Large engines for electric light plants, blowing engines and forgings of all sizes will be made specialties. At the same time the manufacturing of first class hoisting, haulage, ventilating and breaker machinery will be given close attention. Prices will be as low as is consistent with first class work, and "up to date" methods will prevail. The new management is composed of men whose names are familiar as successful business men and engineers in all parts of the country.

With the advantages possessed by this company in location, there seems to be no reason why it should not assume greater prominence than ever before, and become an important factor in the manufacture of heavy machinery.

The present organization is as follows: President, C. H. Zehnder, formerly President of the Jackson & Woodin Mfg. Co., Berwick; Secretary and Treasurer, L. F. Bower, formerly General Manager and Treasurer of Carlisle Mfg. Co.; General Manager, De Courcy May, for many years with the I. P. Morris Co., and recently in charge of the work for Cataract Construction Co. at Niagara Falls.

THE COLLIERY ENGINEER

AND

METAL MINER.

WITH WHICH IS COMBINED THE MINING HERALD.

Established 1881. Incorporated 1890.

PUBLISHED MONTHLY AT SCRANTON, PA.

Entered at the Post-Office at Scranton, Pa., as second-class matter.

THOS. J. FOSTER, RUFUS J. FOSTER, MINING ENGINEER, } EDITORS.

THE COLLIERY ENGINEER COMPANY, PUBLISHERS.

DENVER OFFICE, 502 Boston Building.
PROF. ARTHUR LAKES, Assist. Editor in Charge.
POTTSVILLE, PA., OFFICE, 12, Morris Building.
BAIRD HALBERSTADT, E. M., Special Representative.

TERMS.

Subscription, (Postage in the U. S., Canada, and Mexico, prepaid.) **$2.00 a Year.**

To Foreign Countries in the Universal Postal Union, $2.50.

THE COLLIERY ENGINEER AND METAL MINER and HOME STUDY, $3.00 per year.

Remit by P. O. Order, Express Money Order, Bank Check or Draft or Registered Letter.

P. O. Orders.—You can buy a Money Order at your Post-Office payable at the Scranton Post-Office.

Express Money Orders can be obtained at any office of the American Express Company, the United States Express Company, and the Wells, Fargo & Co.'s Express Company.

Registered Letters.—If a Money Order Post-Office, or an Express Office is not within your reach, your Postmaster will register the letter you wish to send us on payment of eight cents.

We Cannot Be Responsible for money sent in letters in any other way than by one of the four ways mentioned above.

EXPIRATION OF SUBSCRIPTION.

The date after your name on the wrapper of THE COLLIERY ENGINEER AND METAL MINER shows to what time your subscription has been paid.

RENEWALS, ETC.

If you do not want THE COLLIERY ENGINEER AND METAL MINER continued for another year after your subscription has run out, notify us by postal card to discontinue it. The courts have decided that subscribers to newspapers who do not order their paper discontinued at the expiration of the time for which it has been paid, are held liable for the payment of their subscriptions up to the date when they order the paper discontinued.

NOTICE OF DISCONTINUANCE.

THE COLLIERY ENGINEER AND METAL MINER is sent to subscribers until an explicit order for its discontinuance is received by us, and all payment of arrearages is made, as required by law. *Papers returned are no notice of discontinuance, as we cannot tell where they are from.*

CHANGES OF ADDRESS.

A subscriber wishing to have his address changed should be careful to give his *former* as well as his present address; otherwise we cannot find his name on our mailing list.

All communications should be addressed,

COMPRESSED AIR AS A MOTIVE POWER.

THE use of some safer, more economical and more convenient motive power than steam, for use in many parts of a mining plant, is a recognized necessity. While electricity meets the want in many instances, there are, undoubtedly, serious objections to its use in some instances. It is not our intention in this article to go into the conditions which enter into a decision as to whether compressed air or electricity should be adopted in any particular instance, but rather to give some few instances of successful installations of compressed air plants and the opinions of mine managers thoroughly conversant with their practical use.

In another portion of this issue we print a detailed account of the compressed air haulage plant at the Susquehanna Coal Company's No. 6 shaft, Glen Lyon, Pa. That this installation has proven successful, is evidenced by the fact that the officials of the company have recently ordered a second compressed air locomotive, and sufficient pipe to largely extend the scope of the haulage by the use of compressed air. Some months ago we published a detailed description of the compressed air pumping plant at the Lehigh and Wilkes-Barre Coal Co.'s Nottingham colliery at Plymouth, Pa. This plant, which is the largest compressed air pumping plant in the world, has given most excellent satisfaction.

The use of compressed air as a motive power for coal mining machines has been eminently successful during the past few years, and has proven both economical and safe.

The compressed air haulage plant at Glen Lyon, while by no means the first, contains some essential improvements in the details of installation that especially commend it. It is the perfection of these details that in a large measure determines the efficiency and economy of a plant.

Compressed air as a power for rock drills in shaft sinking, tunneling, and in ore mining generally has largely superseded steam on account of its great superiority.

The use of compressed air in Cape Breton and Nova Scotia coal mines is ably discussed by three prominent mining officials in a recent issue of our contemporary, *The Canadian Mining Review*.

In discussing the plant at Sydney mines, Cape Breton, Mr. R. H. Brown states that there are two accumulations of water in the workings—one of several million gallons at a distance of 3,580 ft. from the shaft bottom, and at a level of 209.9 ft. below it; the other, a much smaller quantity, at a distance of 1,700 ft. from the first accumulation, and 155 ft. below it. Compressed air is used as a power to actuate the pumps used in draining these distant sumps. The air compressor used is an Ingersoll-Sergeant, Class A, straight line, piston inlet machine. The steam cylinder is 14 in. diameter, air cylinder 14¼ in. diameter, and stroke 18 in. It is erected on the surface 104 ft. from the head of the shaft. It is supplied with steam by one steel tubular boiler, 14 ft. long x 54 in. diameter, having 54 tubes, each 3½ in. diameter. A steel air receiver, 10 ft. long x 30 in. diameter is placed on end outside of the compressor house, and is connected with the compressor by a short pipe 3½ in. diameter.

The water supply for the boiler and compressor is very ingeniously arranged. A small reservoir, 24 feet square, was constructed at a distance of 100 ft. from the compressor, and two lines of 4 in. pipe were laid therefrom to the compressor house. These pipes are underground. One line, 140 ft. long, leads the water direct to the compressor house, where a small duplex Blake pump, having 3 in. steam cylinders, 2 in. water plungers, and 3 in. stroke, elevates into an iron tank placed over the compressor. The bottom of this tank is 9 ft. 10 in. above the center line of the air cylinder of the compressor. The water from this tank supplies feed for the boiler, and cooling water for the jackets of the air cylinder. The other line of pipe, 240 ft. long, takes the cooling water by a circuitous course back to the reservoir. The water is thus kept circulating, and is cooled by its passage through the pipes underground.

The intake air enters the compressor through a short length of pipe 4 in. diameter, projecting through the building into an external box or shaft 12 in. x 22 in. in section and 16 ft. high. The air is thus drawn from a point above the roof of the building, and is free from dust and smoke.

The wrought iron pipe line for the compressed air consists of 2,467 ft. of 6 in. pipe, 1,152 ft. of 5 in. pipe and 860 ft. of 4 in. pipe, from the air receiver on the surface to the air receiver No. 2 in the mine. No. 2 receiver is made of steel plates, and is 8 ft. long by 30 in. diameter, and near it stands pump No. 1. This pump, located 4,479 ft. from the air compressor, is a Northey duplex pump having 7½ in. air (or steam) cylinders, 4½ in. plungers, and 10 in. stroke. It runs at an average speed of 100 strokes per minute, and raises the water to an elevation of 209.9 ft. through 3,580 ft. of 5 in. delivery pipe. It delivers, deducting 5% from the calculated delivery for slip of pump, 64.9 gallons per minute.

From air receiver No. 2 there is a line of 4 inch pipe 1,150 feet farther, down a slope, and thence 400 feet more of 3 inch pipe to air receiver No. 3, which is a counterpart of No. 2. From air receiver No. 3 there is a line of 120 feet of 3 inch pipe to a Worthington duplex pump having 4½ inch air (or steam) cylinders, 2¾ inch plungers and 4 inch stroke. This pump, located 6,149 feet from the source of motive power, works at 90 strokes per minute and forces 8.76 gallons of water per minute to an elevation of 155 feet through 1,700 feet of 2½ inch delivery pipe to pump No. 1, which forces it to the shaft bottom. Besides doing the pumping, air from the compressor is used to run a small pair of hoisting engines near the Worthington pump, and two coal mining machines, one an Ingersoll-Sergeant, the other a Harrison, which work at the coal faces, about 500 feet from the Worthington pump. The air for the mining machines is conveyed to them through 1½ inch pipe.

In commenting on this plant, Mr. Brown says:

"It has been often stated that compressed air is a wasteful power and shows a low percentage of useful efficiency. I can hardly think that such would be found to be the case with our plant. I have not had time to make any calculation of the horse-power applied, and the useful horse-power obtained in our case. I only know that our compressor is a small affair, but does a big amount of work, considering the great distances between the source of the motive power and its points of application.

"In the matter of air used, I should like to say that our No. 1 pump uses 70 cubic feet of free air per minute; the air hoist at full work uses 608 cubic feet; and the two coal cutters, working at 200 strokes each per minute, use 157 cubic feet; a total of 835 cubic feet per minute. As the Ingersoll catalogue only claims that our compressor should compress 798 cubic feet per minute, it appears that the compressor is well up to its work. Of course the delivery of 835 cubic feet per minute cannot long be maintained, but it can be depended on for a 'spurt' when desirable.

"The question of pressures is interesting. With a steam pressure of 62 lbs. at the boiler, and the engine going at 83 revolutions per minute, we get a pressure of 80 lbs. of air in the receivers at the compressor, and from 81 to 82 lbs. of air in the receiver at No. 1 pump; and practically 80 lbs. at No. 2 pump, 6,149 feet distant from the compressor.

"With a temperature of 28° Fah., at the intake on surface, 43° in the air at pit bottom, and 51° at No. 1 pump, we find the exhaust from that pump to be 30° at the distance of 12 inches from its exit, and 2° below zero at 2 inches from the exit.

"I may add that the consumption of fuel by the boiler which actuates the compressor averages 248 lbs. of slack coal per hour worked."

In considering the question of compressed air for pumping, Mr. H. S. Poole, of Stellarton, Nova Scotia, asks the question, "Is full advantage taken of the compressed air as at present generally applied?" and replies—"Judging from my own experience, I should say, far from it." Continuing, Mr. Poole, judging by the result of enquiry and some experience, says, "I am now satisfied that the majority of users of air, in Nova Scotia, are more wasteful than they suppose, and that a consideration of the question cannot but be beneficial." He therefore offers the following five points for the consideration of engineers:

"1. It is evident that the clearance in the cylinders of direct-acting steam pumps, often 12 per cent. of the stroke, represents a large loss.

"2. It is very possible the ports also are unnecessarily large.

"3. It may be that where the mine water has a temperature above 60° Fah., as in deep coal pits, a water jacket would raise the mean temperature of the cylinder and reduce the tendency to make ice in the cylinder and ports.

"4. Then if the air cylinder and the water plunger be not proportioned to the work to be done, and the air has to be throttled down to the required pressure, it is clear there is a loss in consequence of the cooling of the air, unless the throttling is done at such a distance from the pump that the compressed air can recover from the surrounding air the heat which it has lost.

"5. The prints in catalogues of compressors seldom show (I have yet to see one that does show) the inlet taking air otherwise than from the compressor house, and yet as the air in the house is always warmer, and generally also more moist than the external air, the loss incurred from so taking the air is well worth looking after. At 60° Fah. a difference of 5° is equal to 1 per cent. of the coal consumption, while the actual difference of the mean of the year cannot be less than 20°, or equal to no less than 4 per cent. of the fuel consumption in favor of taking in air through a properly constructed duct free of dust."

Mr. Chas. Fergie, of Westville, N. S., in stating his experience with the air compressing plant at Drummond colliery says:

"The underground pumps at this colliery until quite recently were driven by steam taken from the surface along an incline having a pitch of 16 degrees and some 4,200 ft. in length.

"In consequence, however, of the loss of power in carrying steam that long distance, the great heat produced in the pipe road and pump room, the latter 110 F., the bad effect of heat and moisture on the roof and sides of the roads, and consequent expense of maintaining the same in a safe and satisfactory condition, the interference of heat with the ventilating currents, and the many other sources of trouble due to the use of steam underground, led the management to substitute compressed air for steam as the motive power at the pumps."

Mr. Fergie's experience at first was rather unsatisfactory, but by making certain changes he has been able to secure better results than were formerly obtained, by the use of steam. The compressor used at Drummond mine is a duplex 14″x 22″ Rand with steam expansive cut off, Halsey's positive air valve motion, and the cylinders are water jacketed. The boiler pressure is 110 lbs. and steam is cut off in the cylinder at ¼ stroke. The air supplied to the compressors is taken from outside the compressor house.

The compressors were purchased with a guarantee to drive two separate pumps at the same time, and each capable of throwing 40,000 gals. in a shift of eight hours, one against a vertical head of 600 ft., and the other against a head of 300 ft. These pumps were the steam pumps already in use. One, known as No. 9 pump, is a duplex compound straight line pump, with cylinders 8 and 14 in. x 18 in. stroke; clearance ½ in. at each end; plungers 4½ in. This pump has the 600 ft. head to force against. The other, known as No. 11 pump, is a single straight line plunger pump, 14 in. cylinders by 12 in. stroke; clearance ½ in., and plungers 5 in. This pump works against a head of 300 ft. The air was conveyed through the old steam mains, which were 5 in. diameter for one-fourth the distance, and 4 in. for the remainder.

The first trial of the air was made on the No. 9, or compound pump, using the low pressure cylinder only. With an air pressure of 95 lbs., and a piston speed of 60 ft. per minute, the pump did its work satisfactorily. In consequence of the cylinders being out of proportion to the water ends at that pressure, the air had to be wire drawn.

The other pump was then started up to work at the same time as the No. 9, but a sufficient speed to throw the stipulated quantity of water could not be maintained, and the pressure fell from 95 lbs. to 36 lbs. at this pump, and to 43 lbs. at No. 9 pump. The pressure at the surface fell to 40 lbs., the speed of the compressors remaining at 85 revolutions.

The two pumps were run together for three or four days, but the work was far from satisfactory, as it took 16 hours, instead of 8 hours, to pump out the water, and considerable difficulty with freezing was experienced. To overcome the freezing, receivers were placed, one close to each pump. This resulted in considerable improvement, but did not altogether prevent the freezing. No. 9 pump was then run alone, with a steady pressure at the surface of 85 lbs., but wire-drawing the air at a point about 300 ft. above the receiver, with a view of allowing the moisture to drop before reaching the pump. This prevented the freezing. Indicator diagrams showed that the compressor engines developed 128.49 H. P., as against 16.45 H. P. at the pump, a useful effect of only 12¾ per cent.

A similar test with No. 11 pump running alone showed an indicated H. P. at the compressor engines of 83.13, and at the pump 10.77, a useful effect of 13.11 per cent.

Having got over the difficulty of freezing, attention was then turned to the more economic problem of finding out by what means the two pumps could be run at the same time and the water taken out in the stipulated eight hours, and without making any change in the cylinders of the pumps, which are out of all proportion to their work when using air, having been built for low pressure steam. To do this it was decided to try compounding with the No. 9 pump. This, however, was not successful as a steady pressure of 75 lbs, with 90 revolutions of compressors could not be maintained, and indicator cards showed that though there was an average pressure of 62 lbs. in the high pressure cylinder, after release it fell to an average of 6.28 lbs. in the low pressure. The effect of introducing "live" air into the exhaust chamber connecting the high and low pressure cylinders, was then tried and proved successful, notwithstanding that by so doing considerable back pressure was thrown on the high pressure cylinders. This also gave a more uniform stroke of the pumps.

Indicator diagrams were then taken both at the compressors and pumps, and showed that the useful effect by the above change had been increased from 12¾ per cent to 25.93 per cent.

Commenting on his figures, Mr. Fergie makes the following observations:

"There is no question that this useful effect can be considerably further increased by making use of pumps properly proportioned to their work and expressly designed for the use of compressed air, and of the rotary type. The exhaust ports should be large and as straight as possible and the air should be exhausted above and below.

"An interesting feature observed by admitting 'live' air into the exhaust passages, as mentioned, is that all traces of frost around the exhaust passages disappear. This is no doubt due to the expanding air taking up heat from this 'live' air introduced.

"Speaking of freezing at the motor, it may be mentioned that glycerine has a most beneficial effect in its prevention.

"The great objection to the use of straight line pumps is in the large amount of clearance to be found in the cylinders; also that such a pump seldom makes two consecutive strokes alike, and that it is impossible to make use of any expansive force there may be in the air and cut-off before the end of the stroke. In the No. 9 pump above referred to the length of the stroke varies all the way from 16¾ inches to 18 inches, according to the conditions under which it is working. Considering these imperfect conditions it is no wonder that so small a percentage of useful effect is found in mine pumps using compressed air.

"The question may be asked: 'Is air as economical as was steam, considering that only 25¾ per cent. of the work developed in the compressor engines can be shown at the pumps?' In this particular case it certainly is, and as a matter of fact 1 ton 8 cwt. less coal is now being consumed in 24 hours than was the case with steam to do precisely the same work.

"There is also the beneficial effect of introducing cool air into the mine and the saving of expense in repairs due to the injurious effects of steam on the roads, etc. The pipe line is not nearly so costly to maintain as with steam, and so much steam sent into the mine means so much extra water to be pumped.

"Another important advantage gained at the 'Drummond' by introducing compressed air is that the total volume of air circulating through the mine has been increased by 16,800 cubic feet per minute.

"This increase is not due to the amount of air delivered by the compressors, but from the fact that when using steam the No. 2 slope could not be used as an intake, whereas now both Nos. 1 and 2 slopes are intakes."

THE UTILIZATION OF SMALL SIZES OF ANTHRACITE.

THE rapid increase in the utilization of the small sizes of anthracite during the past few years has been remarkable. In his annual report to the Board of Directors of City Trusts of Philadelphia, Mr. Heber S. Thompson, engineer of the Girard estate, analyzes the shipments from collieries on the Girard estate, from 1863 to 1895 inclusive, and a study of his tables furnishes the following interesting data:

From 1863 to 1866 inclusive, the smallest size of anthracite coal sent to market was chestnut, and the proportion of chestnut coal shipped ranged during those four years from 8.2 to 10 per cent. of the total shipments. In 1867 there were 1,800 tons of pea coal shipped or 0.34 per cent. of the total, and the percentage of chestnut coal shipped rose to 12.17 per cent. In the eleven years from 1867 to 1877 inclusive the proportion of pea coal shipped to market ranged from 0.34 per cent. to 9.3 per cent. of the total, and the percentage for 1877 stood at 9.19. In the same years the shipments of chestnut coal ranged from 11.19 to 14.51 per cent. of the total, and stood at 13.68 per cent. for 1877.

The shipment of buckwheat coal commenced in 1878, when 696 tons or 0.07 per cent. of the total shipments were sent to market. In the same year the shipments of chestnut coal were 12.52 per cent. of the total. From 1878 to 1894 inclusive no sizes smaller than pea coal were shipped. During this term the shipments of chestnut coal constituted from 9.44 to 20.15 per cent. of the shipments, the smaller percentages being shipped in 1882 and the larger in 1894. During the same period the percentages of shipments credited to pea coal ranged from 9.44 to 20.15, the lowest percentage being credited to the year 1892 and the highest to the year 1894.

During the same period the shipments of buckwheat coal ranged from 0.07 per cent. to 15.13 per cent. From 1884 to 1888, inclusive, there was practically no gain in the shipments of buckwheat coal, which for these five years averaged 5.76 per cent. of the total shipments. From 1888 to 1894 the percentage of buckwheat shipped jumped from 5.67 per cent. to 15.13 per cent. of the total. In 1895, 50.64 per cent. of the shipments were of coal larger than chestnut, 20.31 per cent. was chestnut, 16.54 per cent. was buckwheat, and 1 per cent. was rice coal. During the period from 1865 to 1895 the shipments of coal larger than chestnut dropped from practically 90 per cent. to 50.64 per cent. of the total. In 1895 the percentages of the various sizes were as follows:

Lump	3.60
Steamboat	8.57
Broken	10.42
Egg	10.90
Stove	17.15
Chestnut	20.31
Pea	11.51
Buckwheat	16.54
Rice	1.00
Total	100.00

In commenting on these figures Mr. Thompson says:

"The remarkable decrease in the percentages of large sizes and increase in the percentages of small sizes of coal shown by these tables is the result of two causes operating together, viz., first, the change by furnaces, iron mills and steam vessels, formerly using lump and steamboat sizes of anthracite, to the use of bituminous coal, the breaking of these large sizes of anthracite into stove and other small sizes for domestic use and the incidental production thereby of the very small sizes of buckwheat and rice coal; and, second, the increased favor with which the use of the smallest sizes of anthracite is regarded, following improvements in mechanical facilities for their handling and use in base burning stoves and by automatic stokers."

Of the total production of the eleven collieries on the Girard estate in 1895, 196,293 tons, or an amount equivalent to 13.18 per cent. of the shipments, were consumed in operating the collieries. This coal was mostly of rice and buckwheat sizes, and some of the larger sizes known as "slate picker stuff," which is "bony" coal and coal streaked with slate, unattractive in appearance, but not inferior for practical use. The eleven collieries on the Girard estate are representative ones, therefore the proportions given as to the shipment of small sizes to market are practically the same as the proportions for the whole region would be, if the same class of figures were available for the whole region.

THE NEW PRESIDENT OF THE L. C. & N. CO.

THE selection of Mr. Lewis A. Riley as president of the Lehigh Coal and Navigation Co., vice Mr. Calvin Pardee, who resigned so as to devote more of his time to personal interests, is a remarkably good one.

Mr. Riley is by profession a mining engineer and he is thoroughly familiar with the management of anthracite collieries. Since 1864, when as a very young man he became a member of Messrs. Harris Bros.' engineer corps at Pottsville, he has been directly connected with the anthracite coal industry, either as a mining engineer or an operator. Coupled with his practical experience in mining, he possesses fine executive ability and good business judgment. These qualifications eminently fit him for the position of executive head of one of the great anthracite companies. We sincerely congratulate him on the honor of his selection and also the directors of the company on their wise choice.

PERSONALS.

Mr. G. W. Bird has been appointed superintendent of the Savanna Coal Mining and Trading Co., at Savanna, Indian Ty.

Mr. Alex. Dick, manager of the Joggins mines, Nova Scotia, was a recent visitor to our offices, accompanied by Mr. John B. Law, superintendent of the Old Forge Coal Co., and Newton Coal Mining Co. of Pittston, Pa.

The Johnson Coal Co. of Scranton, Pa., has placed an order with Mr. Jos. R. Wilson, Mutual Life Bldg., Phila., for a 400 H. P. "Climax" boiler for the utilization of the waste heat from twelve cylinder boilers.

Mr. Wm. Mason, manager of the Scranton station of the Atlantic Refining Co., has been transferred to an extended field in New York State. Mr. L. W. Chase, manager of the Wilkes-Barre station, has assumed the management of the Scranton station.

Mr. Wm. H. Booth, who on several occasions, contributed valuable articles to our columns, has resigned his position of managing engineer for the Le Grand and Sutcliff Artesian Co., and has taken offices at Picadilly Mansions, No. 17 Shaftesbury Ave., London, W., England. He will in the future do a general engineering business, and make specialties of steam engineering, water supply and electrical transmission of power, paying special attention to artesian work, questions of hydrogeology, electric transmission and the introduction of good American patents to manufacturers and financiers in great Britain. He will be glad to receive all American catalogues and is desirous of taking up the representation of good American houses, his offices being central.

Mr. S. W. Douglass, mining engineer, of Ashland, Pa., who has had twenty-five years successful experience in mining engineering and prospecting with diamond drills, announces that he is prepared to do surface tracing and prospecting with diamond drills for coal, phosphate, iron and other minerals, and to prepare accurate maps, sections and reports, showing the location of veins and value of deposits. In his long experience Mr. Douglass has done satisfactory work in drilling, surveying, etc., for the following prominent concerns: Lehigh Valley Coal Co.; The Santa Fe R. R. Co.; Panama Canal Co.; Croton Aqueduct; Locust Mt. Coal Co.; Philadelphia & Reading Coal & Iron Co.; Virginia Mining Co., and many others. We can heartily commend Mr. Douglass to any of our readers requiring his services, as a thoroughly competent engineer and prospector, our acquaintance with him having been of an intimate nature and of over twenty years duration.

Prof. Justus Mitchell Silliman, M. E., of Lafayette College, died at his home on the college campus at Easton, Pa., on the 15th ult., after a few day's illness. He was born at New Canaan, Conn., Jan. 25, 1842. He served three years in the United States army during the Rebellion, and from 1865 to 1870 was a teacher at the Troy (N. Y.) Academy, at the same time taking a course in Rensselaer Polytechnic Institute. In 1871 he went to Lafayette College as an instructor, and for a quarter of a century held the chair of professor of mining engineering and graphics. He was a fellow in the American Association for the Advancement of Science, and a member of the American Institute of Mining Engineers.

Professor Silliman, though strict and exacting in the class-room, resulting in a high grade of work among his students, was an advocate of all that conduced to make college life pleasant. He encouraged athletics by his presence, and took pleasure in the successes of the college students in this line. He frequently conducted expeditions of his students into the coal fields for the purpose of giving them practical work in mining engineering, and at all times showed himself warmly interested in their success. He was active in church work and a much esteemed citizen. He is survived by his wife and two sons.

COMPRESSED AIR HAULAGE.

Description of the Plant at the Susquehanna Coal Co's. No. 6 Colliery.

Some Novel Features Peculiar to This Plant Which Successfully Meet Conditions Existing in Many Coal Mines.

Written for THE COLLIERY ENGINEER AND METAL MINER.

Some months ago we published a brief description of the compressed air locomotive at the Susquehanna Coal Company's No. 6 colliery, Glen Lyon, Pa. That description, owing to the fact that the haulage plant had just been installed, was rather incomplete, and there were several statements in it that were somewhat misleading. Through the courtesy of Mr. J. H. Bowden, Chief Engineer of the Susquehanna Coal Company, under whose supervision the plant was installed, and whose ideas incorporated in some portions of the plant materially increased its efficiency, we are able to give our readers a detailed description of the plant and a record of what it is accomplishing.

The Susquehanna Coal Company's No. 6 colliery is located at Glen Lyon, Luzerne county, Pa. It is one of the largest collieries in the Wyoming region. The mine openings consist of a shaft, a slope, and a water level tunnel. The output of the three openings, which is prepared in one breaker, amounts to about 350,000 tons annually.

The compressed air locomotive is used in the shaft workings. Fig. 1 shows a plan of the air pipe line and haulage road, together with a profile of the haulage road. By referring to Fig. 1, the outside arrangement of the buildings can be understood by the following reference letters: *A*, is the shaft; *B*, the compressor house; *C*, the carpenter and smith shop; *D*, the boiler house, and *E* the timber plane engine house. The air pipe from the compressors to the head of the shaft is 291′ 10″ long; the length of pipe in the shaft is 728′ 2″, and the length of pipe from the foot of the shaft to the end of the pipe line is 3,349′, making a total length of air pipe of 4,369′. By referring to the plan, Fig. 1, three charging stations marked *F*, *G* and *H* will be seen along the haulage road. The first of these charging stations *F*, is 112 yards from the foot of the shaft, and the second *G*, and the third *H*, are 437 yards and 1,116½ yards from the foot of the shaft. The pipe line ends at the third charging station *H*, but the end of run for the locomotive is 217 yards further in the gangway, at *I*.

The track over which the locomotive runs is shown by solid lines in the gangway, (see plan, Fig. 1), and is 36″ gauge. About 400 feet from the shaft it makes a turn of a half circle through a tunnel by two right angle curves of 23 feet and 35 feet radii, respectively, with a 70 foot tangent between. The balance of the track is comparatively straight, and all the curves are of easy radius.

By reference to the profile of the track, it will be seen that there is an average grade of 1.07%, and a maximum grade of 2.8% in favor of the load. The following table shows in detail the grade of track, beginning at the foot of the shaft:

+1.63 per cent. for	300 feet.	+0.61 per cent. for	200 feet.
+1.21 " "	132 "	+1.04 " "	150 "
−.84 " "	363 "	+0.71 " "	100 "
+2.0 " "	200 "	+0.5 " "	250 "
+.75 " "	100 "	+1.09 " "	100 "
+1.79 " "	150 "	+0.24 " "	100 "
+.63 " "	150 "	+0.64 " "	150 "
+1.51 " "	100 "	+1.76 " "	250 "
+.47 " "	150 "	+2.79 " "	100 "
+1.5 " "	200 "	+1.37 " "	100 "
−0.06 " "	100 "	+2.39 " "	100 "
+0.61 " "	100 "	+0.7 " "	100 "
+1.04 " "	150 "	+0.38 " "	113 "

The air compressor used (shown in Fig. 2) is a three-stage compressor built by the Norwalk Iron Works, South Norwalk, Conn. The air is drawn into an intake cylinder 12½″ diameter with 24″ inch stroke, shown near the center of the machine, where it is compressed to a comparatively light pressure and delivered hot into one of the intercoolers, shown on top of the machine, consisting of an iron casing filled with thin copper tubes, through which cold water is constantly circulating. In this intercooler the air parts with the heat attained by the first compression. It then passes to the second compressing cylinder, 9¼″ diameter, in which it is further compressed, sent on through a second intercooler, and finally further compressed to its final pressure of 600 pounds per square inch, in a third cylinder, 5″ diameter, from which it is delivered to the line pipe, which forms a receiver, 5″ diameter, and 4,369 feet long, as well as a conductor for the air. All the air cylinders are water jacketed, to assist in reducing the temperature of the air during compression, and are of very solid construction. The air valves are of special design, forged in one piece to prevent any part working loose, and valves and seats may be removed from the outside of the machine for adjustment and repairs. The steam cylinder of the compressor is 20″ diameter by 24″ stroke, provided with a "Meyer" cut-off valve, and it is directly connected to the three air cylinders which are all of the same stroke, and also connected to the two large and heavy fly-wheels shown. The entire mechanism is mounted on one heavy bed plate, making a very smooth running machine.

As the atmosphere in the vicinity of collieries is usually charged with a considerable amount of dust, the air is supplied to the compressor through a washer designed by Mr. J. H. Bowden, by means of which all dust and grit are removed from it before compression. This results in a great saving of wear on the valves, cylinders and other rubbing surfaces of both the compressor and locomotive, and prevents enlargement of leaks caused by dust in the air, which, under the high pressure used, cuts like a sand blast.

The capacity of the compressor is 275 cubic feet of free air per minute compressed to 600 pounds per square inch, with the compressor running at 100 revolutions per minute. As this quantity is more than sufficient for two locomotives, the compressor is operated at an average speed of only about 40 revolutions per minute, the speed being controlled by an automatic regulating valve, which allows a speed just sufficient to maintain the required pressure in the air main. As mentioned before, the air from the compressor goes to a line of 5″ wrought iron pipe 4,369 feet long. Attached to the pipe line at the foot of the shaft is a heavy cast tee with several feet of pipe below it to collect any condensed moisture; the bottom of the separator thus formed being provided with a water waste valve. At each of the three charging stations along the gangway, there is a gate valve in the main pipe, which enables any section to be cut off in case of accident, and the air can be blown off to permit of repairs without the necessity of blowing off the entire main and consequent stoppage of work, and saves the time required for pumping up the entire main to 600 pounds.

The 5″ main has a capacity of 580 cu. ft. of air at 600 lbs. pressure, equivalent to 23,000 cu. ft. of free air. The use of the pipe itself as a reservoir is a novel feature of the plant, dispensing with large and costly receivers underground, and admitting of as many charging stations as may be desired, and their location at any point along the main. The size of the pipe was naturally determined by the length of the line and the required reservoir capacity. Extensions can be made with much smaller pipe drawing from the large pipe as a reservoir. The pipe used was purchased from the American Tube and Iron Co., and each length was tested to 1,500 pounds per square inch before shipment. The majority of the joints are coupled by the extra heavy wrought coupling, shown in Fig. 3, the ends of which are counterbored to allow caulking with lead or copper if desirable.

At all the charging stations and special castings, as well as at intervals of two hundred feet along the line, flange couplings as shown in Fig. 4 are used. These consist of heavy cast flanges 12″ diameter and 2¼″ thick, with finished faces, rough bored to take the pipe, which is then expanded into them by a special tube expander. The ends are riveted into the recess shown and are hammer-faced flush with the centerbore. The flanges are counterbored 1/16″ deep and 7″ diameter to retain the gaskets which are of lead or "Vulcanized Fibre."

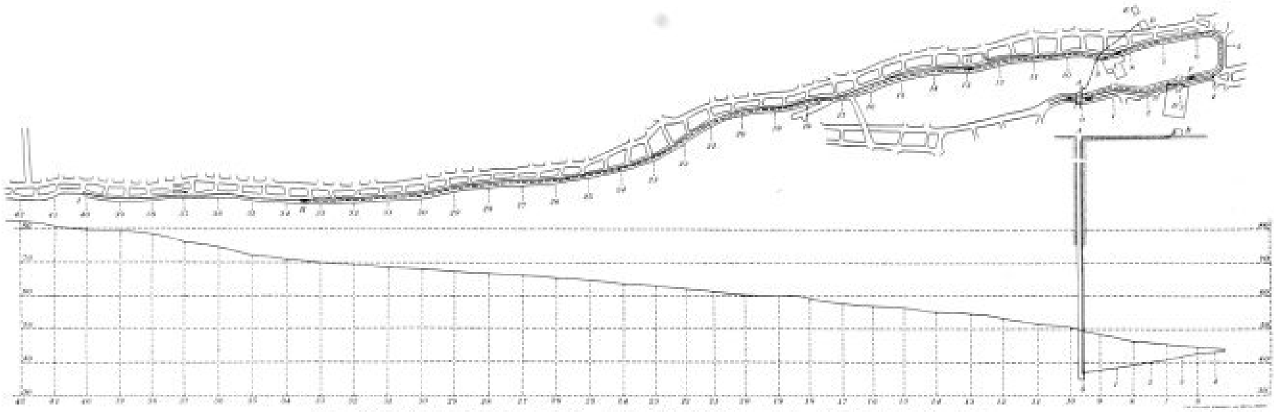

FIG. 1. PLAN AND PROFILE OF HAULAGE ROAD. HORIZONTAL SCALE 1 IN. = 400 FT. VERTICAL SCALE 1 IN. = 40 FT.

The charging connections as shown in Fig. 5 consist of a cast tee on the main pipe with 1½″ opening on which is placed a heavy gate valve *A*, and a right angle flexible coupling *B*, with a sufficient length of extra heavy 1½″ pipe ending in a half screw coupling *C*, to reach the charging pipe of the locomotive. The latter contains two flexible joints, *D* and *E*, and with the other half of the screw coupling, the whole is so flexible that a considerable latitude is permissible in stopping the locomotive in position to connect to the charging pipe. As will be seen by reference to Fig. 5, there is a combination check and stop valve *F*, on the locomotive. The whole operation of charging the locomotive consumes but 1½ minutes, and reduces the pressure in the main from 600 to about 570 pounds. On the outlet side of the charging gate valve is a ⅜″ bleeder valve, *H*, which is used to exhaust the compressed air from the coupling pipe after charging and before the screw coupling is opened. The pneumatic locomotive shown in side and end views in Figs. 6, 7 and 8, consists essentially of a 7″ x 14″ cylinder locomotive with the boiler replaced by air storage reservoirs. It is 62 in. wide, 60 in. high, and 17′ 6½″ long over the bumpers, and weighs 18,400 pounds. The port openings in the cylinders were specially designed for the use of compressed air, being much larger than the standard for steam locomotive practice, with the result that there is practically no back pressure in the cylinders, and no trouble has been experienced from freezing in the exhaust. The air for propelling the motor is stored in two large steel tanks, located between the cylinders, on a saddle, much after the manner of a steam boiler. These tanks are built for a working pressure of

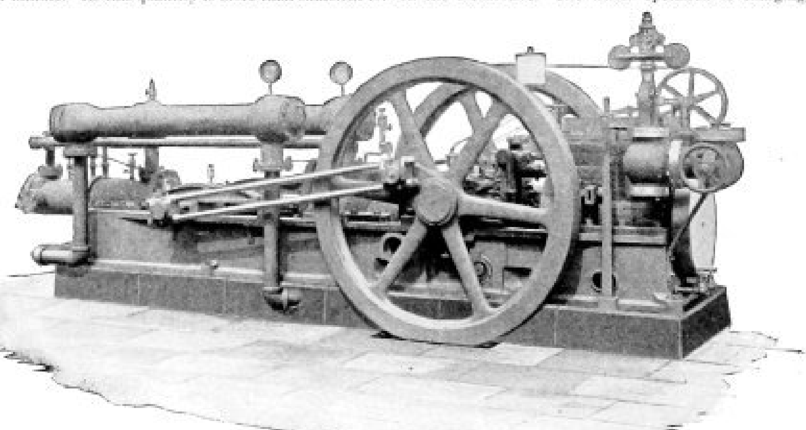

FIG. 2. NORWALK THREE-STAGE AIR COMPRESSOR.

600 pounds per square inch, and were tested to hydraulic pressure of 1,000 pounds before being placed in service, and made absolutely tight under this pressure. Convex heads are placed at both ends of the storage tanks, the front heads being furnished with large manholes reinforced with steel castings, and all connections screwed into the tanks are reinforced with cast steel flanges. All parts carrying pressure were tested to from 35 to 50 per

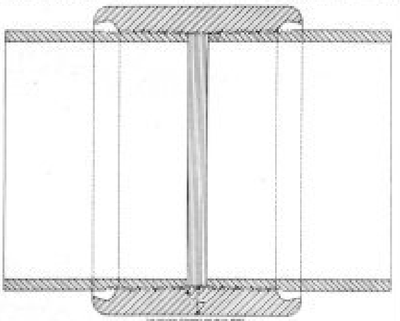

Fig. 3. Heavy Wrought Iron Joint Coupling.

cent. above working pressure, and are absolutely tight at such pressure.

The tanks are constructed with a large factor of safety, and are so designed as to insure absolute safety at a much higher working pressure than they are designed to carry. The air from the two main storage tanks is conducted through connections to an auxiliary reservoir of much reduced diameter, placed below and between them. The pressure in this auxiliary tank can be regulated anywhere from 30 up to 140 or 150 pounds, as required, the air being reduced from the main storage tanks by a specially designed reducing valve, which can be regulated to any pressure at a moments notice, and when

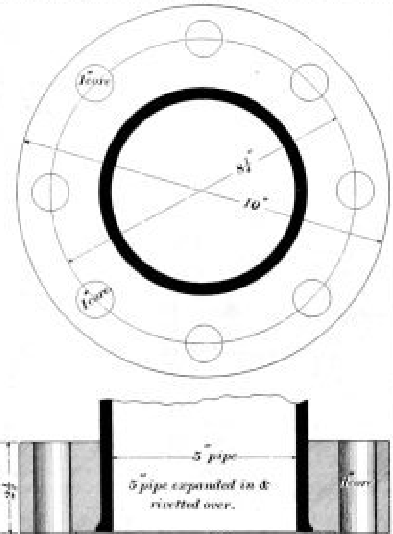

Fig. 4. Cast Iron Flange Coupling.

once set maintains a constant fixed pressure in the auxiliary reservoir, thereby preventing any undue waste of air by injudicious handling, etc. In case only light loads are to be handled, the pressure can be materially reduced on the auxiliary reservoir, thereby securing a decided gain in the economical use of the air; or, on the other hand, in emergencies almost any pressure can be at a moment's notice utilized, and this without any undue heating or loss. In the auxiliary reservoir the air is controlled by a specially designed differential throttle, admitting the air to the cylinders.

The motor at present in use has a capacity for hauling a trip of 16 empty cars from the foot of the track, 3,700 feet in to the gangway and a trip of 16 loaded cars back to the foot of the shaft with one charge of air, starting with a pressure of 575 pounds in the reservoirs and ending with a little over 100 pounds remaining in them, the heaviest work of course being in hauling in the empty trip up grade. The weight of each empty trip of 16 cars, including the locomotive, is about 60,000 pounds, and of the loaded trip, including the locomotive, is 166,000 pounds. The locomotive will make from 25 to 50 miles per day, depending upon the length of run and the time required for making up trips.

The cost of operation of this plant has been found to vary from one to one and one-half cents per ton-mile, including all expense, interest and depreciation of plant, varying with the character of the rolling stock used. The depreciation on the locomotive is very low, there being no boiler to wear out, and the tanks, having nothing to corrode them, should, if kept well painted, last almost an indefinite time. In this case the condition of the car wheels owing to spragging is bad, there being

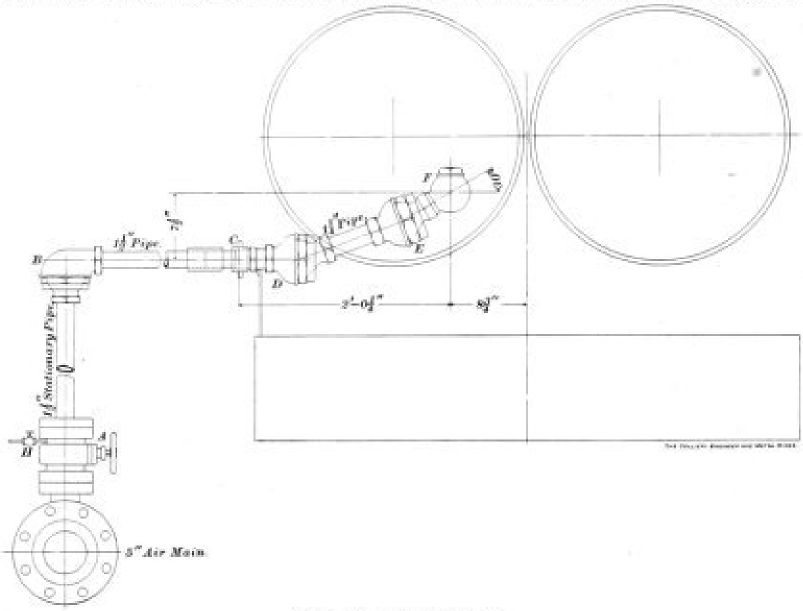

Fig. 5. Recharging Connections.

many flat spots caused by sliding, and the frictional resistance per ton on the track is excessive, but these cars are gradually being equipped with self-oiling wheels and brakes, similar to those in use at the Nanticoke collieries, which wheels give good lubrication and low frictional resistance, while the brakes besides being much more easily handled than sprags, give absolute immunity from flat wheels. When this change, which was commenced only a few months before this haulage plant was put in operation, is completed, it is expected that the cost of haulage by this system will be still further reduced.

Compressed air haulage, of which this is the first example in the anthracite regions, has much to recommend it, being cheaper than wire rope haulage except perhaps under the most favorable conditions for the latter, and very much more flexible, as the locomotive has a considerable radius of operation beyond the charging stations and can run anywhere on the track without previous preparation, provided only that there is sufficient room for it. Extensions of the pipe line are easily and cheaply made, and its absolute freedom from fire puts it beyond comparison with electric haulage or steam locomotives in gaseous mines, and indeed anywhere where avoidance of danger from fire is of importance.

The Susquehanna Coal Company intends very shortly to put another pneumatic locomotive in service in this colliery, using the present compressor, and the 5 inch pipe line as a reservoir and extending a three inch line about 4,000 feet with three charging stations, to supply the new locomotive.

As will be seen by reference to Fig. 1, the compressor is located on the surface, and receives its steam supply from boilers which were previously installed for operating other engines. The compressor house and the engine house for operating the timber plane are close together, and one engineer operates both the hoisting engine for the plane and the compressor. Owing to the compressor being controlled by the pressure regulator, it requires very little attention.

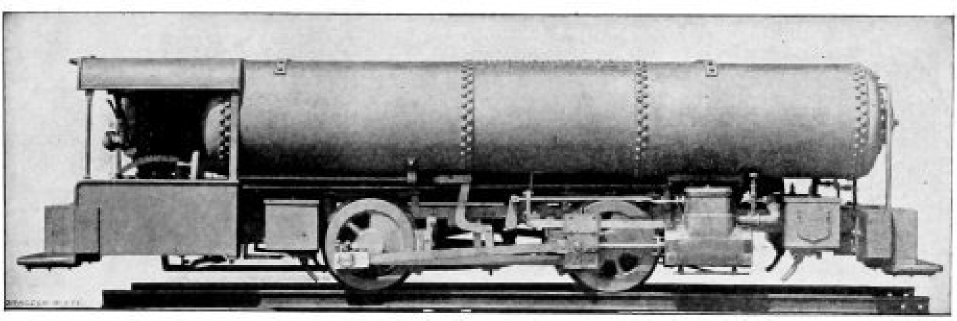

Fig. 7. Side View of Locomotive.

Compressed air haulage is being recognized more and more as a successful competitor for public favor, both as a means of transmitting power and operating machinery.

Messrs. H. K. Porter & Co. have for a long time advocated the use of compressed air motors for mine haulage, surface railways and other places where steam power is not desirable, and they have installed a number of successful plants. Compressed air especially commends itself on account of economy, perfect safety, simplicity in operation, convenience in handling, and freedom from delays due to break-downs, etc. The light repairs required, cost of maintenance and freedom from fire of any character, specially commend compressed air for haulage for mine service, particularly where much gas is encountered.

Its economy is determined by the cost of installation, cost of operating, mileage and tonnage. The cost of maintenance of the locomotive, including depreciation and repairs, should not exceed 4½ %. This figure may

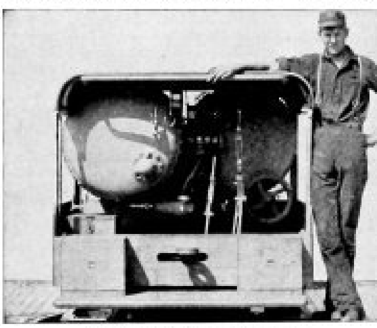

Fig. 6. Rear View of Locomotive.

appear rather low, but when it is considered that the only parts requiring replacing are a few wearing surfaces, such as rod and driving box brasses, link motion, etc., there is very little to require replacement. The tanks and all connections, if given a coat of paint occasionally, should last an indefinite period, as they are not exposed to the corrosive action of water and fire, and are not subjected to constant expansion, contraction, etc., which is always the case with steam boilers.

Before this plant was installed Mr. Bowden, in company with Mr. George T. Morgan, superintendent of the Susquehanna Coal Co.'s collieries, visited H. K. Porter & Co.'s locomotive works, at Pittsburg, Pa., and one of W. H. Brown's Sons' bituminous mines in the Monongahela valley at which a "Porter" compressed air locomotive, using 300 lbs. pressure, was in use. Then, with the assistance of Mr. E. P. Lord, superintendent for H. K. Porter & Co., this plant was designed and installed.

Since the above article was written, we are informed that the Susquehanna Coal Co. has given Messrs. H. K. Porter & Co. an order for a second locomotive and the

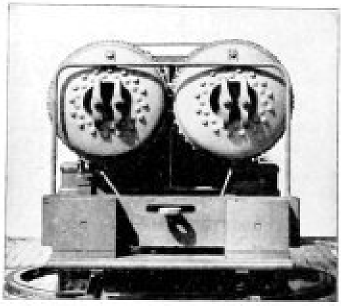

FIG. 8. FRONT VIEW OF LOCOMOTIVE.

American Tube and Iron Co. an order for 4,000' of 3" tubing for a branch line to supply the new locomotive, which is to be fitted up in a similar manner to the 5" tubing described above. This is a strong practical endorsement of the success of Messrs. H. K. Porter & Co.'s compressed air locomotives and of the American Tube and Iron Co.'s tubing.

METAL MINING.

ARTIFICIAL MEANS OF VENTILATION.

Special Conditions in Metal Mines as Distinguished From Collieries—Different Devices Used—Foreign and Obsolete Methods—Water Blowers, Tromps, Furnaces, Etc.—Compressors as Auxiliary Ventilators—Blowers—The Conditions for Use of Different Styles.

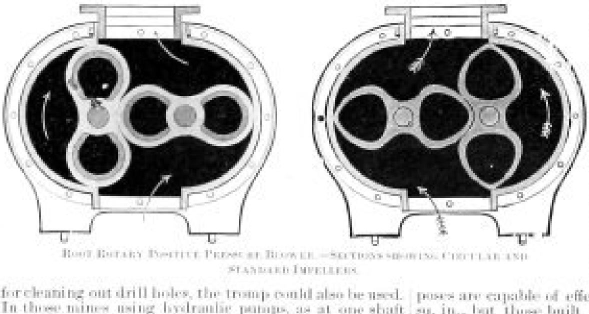
Written for THE COLLIERY ENGINEER AND METAL MINER by Albert Williams, Jr., E. M.

Where natural draft (assisted by the simple devices already described) is insufficient, metal mines require artificial ventilation, though to far less extent than collieries. As the conditions are quite different in the two classes of mines, the means employed are different, though the underlying principles are the same. Some of the appliances still mentioned in text-books as used in metal mines are obsolete, dangerous and wholly out of place in modern practice. It is worth while to notice one or two here, to explain why their use is unadvisable.

The tromp is a simple application of the injector prin-

ROOT ROTARY POSITIVE PRESSURE BLOWER.—EXTERNAL VIEW.

ciple, water falling in a pipe or cylinder carrying with it air and creating a small intake draft. The volume of air is so small as to be insignificant unless a large quantity of water is used. One of the main objects in mining being to get rid of water, it is manifestly absurd to introduce any from the surface. Occasionally there is a small flow in a shaft between pump stations which might be utilized if it were worth while; and in about one mine in a thousand, so dry that water is sent down



ROOT ROTARY POSITIVE PRESSURE BLOWER.—SECTIONS SHOWING CIRCULAR AND STANDARD IMPELLERS.

for cleaning out drill holes, the tromp could also be used. In those mines using hydraulic pumps, as at one shaft on the Comstock and one at Eureka, Nev., and a few in Europe, it is possible that part of the power water might be so used, but it is not easy to see how this could be done without interfering with the hydraulic system.

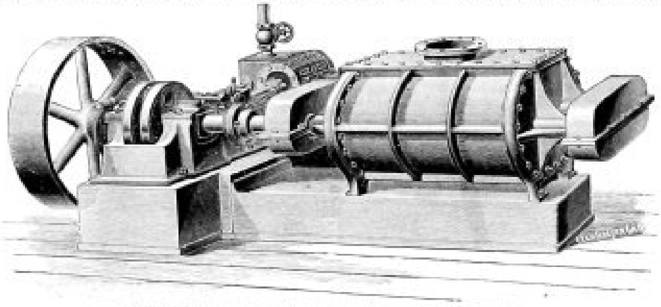
Furnaces are not used in American metal mines, and should not be. They are dangerous, even where little timber is used; not very effective, and a nuisance. It is conceivable that an exhaust pipe might be fitted from the bottom of a mine, leading to the boiler furnaces at the surface, thus creating a small upcast draft, but such an arrangement is not known.

Hartz and Cornish Water Blowers.—Where the mine has a Cornish pumping system, an apparatus worked by the reciprocating pump rod is sometimes used abroad, but not in the United States. It consists of a fixed outer tub, half filled with water (to make an air joint), and an interior moving tub with its mouth downward. A pipe leads through the bottom of the outer tub, its mouth being just above the water and its other end being at the place to be ventilated. Both tubs have flap valves of leather. The inner tub is connected to the pump rod and moves up and down with the latter. It thus forms a sort of air pump, and acts as an exhauster or forcer, according to whether the valves open upward or downward.

On this principle a very large blower, double-acting, called the Struve, has been constructed in Europe, but is not known in the United States. The objections to it are that it is cumbersome and obstructs the shaft, if the shaft is a working one. If, however, the shaft is used only as an air shaft, such a machine might be used were there not better.

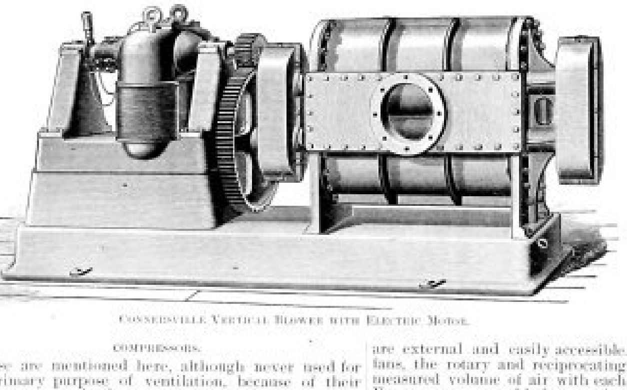
MACHINES USED IN AMERICAN PRACTICE.

These may be grouped into three broad classes: (1) compressors, (2) blowers, either rotary or reciprocating, and (3) fans of two sorts, centrifugal and propeller. Some of the fans are called "blowers" by their makers. The practical difference between the three classes is in



CONNERSVILLE HORIZONTAL BLOWER AND ENGINE ON SAME BED PLATE.

the pressure of the air and its volume (at atmospheric pressure). The mechanical differences will be seen further on. Compressors are forcers; blowers and fans can be built to act either as forcers or exhausters, and, in some of the patterns the same machine will act either way, by simply reversing the direction of rotation.



CONNERSVILLE VERTICAL BLOWER WITH ELECTRIC MOTOR.

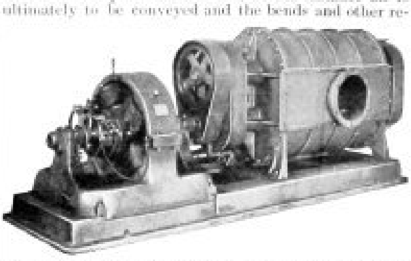
COMPRESSORS.

These are mentioned here, although never used for the primary purpose of ventilation, because of their great importance in that respect, as a secondary result. They are used to drive power drills, baby hoists and other light underground machinery, and will be described in their proper place. One advantage of compressed air ventilation in hot mines is that the exhaust from the drills, etc., in expanding to normal volume is greatly cooled. Another is that the air is delivered where most needed, at the working faces; and another is that no special attention is given to ventilation and no separate arrangement of air pipes and joints is called for or trouble about extensions of air pipes—the apparatus moving about with the advance of the workings. But there are many mines equipped with power plant which do not use air-drills, and there are others, especially very large and hot mines, which call for ventilation on a larger scale.

Compressors for special purposes are capable of effecting a pressure of 2,000 lbs. per sq. in., but those built for mine work give a comparatively low pressure, say 70 or 80 lbs.

BLOWERS.

The best blowers also produce higher pressures than are needed for ventilation, running up to ten pounds per square inch, whereas mine ventilation requires an initial pressure to be measured rather in ounces or in inches of water. The high-pressure blowers are used for blast furnaces, in iron, copper and lead smelters and cupola melting furnaces; those for mine ventilation are of less power or are driven at lower speed. It is always well to have a reserve power in a blower, as the distance air is ultimately to be conveyed and the bends and other re-



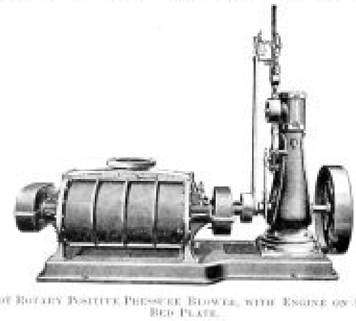
ROOT BLOWER, WITH SLOW SPEED ELECTRIC MOTOR (GENERAL ELECTRIC CO.)

sistances in the pipes are not always known in advance of the extension of the workings. This of course also applies to fan installations.

There is sharp competition between the makers of the numerous types of rotary blowers, blowing cylinders and fans. It would be improper here to compare their relative merits, and it is possible to mention only a few of the many kinds and to but briefly touch upon points of difference. The general statement is in order here, however, that excellence is by no means confined to one or even a very few of the styles of blowers and fans. Evidence of this is given by the variety of machines doing similar duty at different mines and selected by mine managers of unquestioned judgment. At the same time, intending purchasers of ventilating machinery should bear in mind the special conditions involved in the case in hand, and compare the machines accordingly. The present and probable extent of the workings, determining the volume of air and pressure needed to overcome resistance in long distance transmission, are the first points to be considered. Blowers for mine ventilation are best fitted for very large mines and extra long tunnels, and are not suited to small ones, where cheaper fans would suffice.

As compared with blowing cylinders, it is claimed for the rotary blowers that they have much greater capacity on account of the higher speed at which they may be run, for equal sizes and spaces occupied; that they have no receivers, valves or their equivalents, as are needed with piston blowers; that the wearing parts and those needing attention are external and easily accessible. As compared with fans, the rotary and reciprocating blowers discharge a measured volume of air with each revolution or stroke. For some purposes this feature gives them a great advantage, but for metal mine ventilation it is not of much importance under ordinary conditions.

This machine consists of two interlocking impellers, revolving side by side in very close connection, but

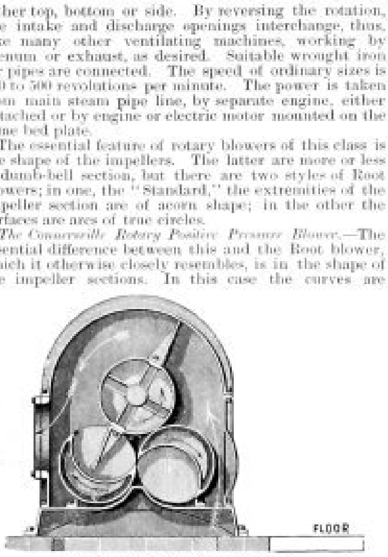


ROOT ROTARY POSITIVE PRESSURE BLOWER, WITH ENGINE ON SAME BED PLATE.

without actually touching each other or the containing case. They and the case are of cast iron accurately bored and dressed to true surface, so that while practically no air escapes there is no internal wear. They are driven by a pair of external equal gears, the only wear coming upon these gears and the shaft journals. At each revolution an equal volume of air is taken in and exhausted. The discharge opening is either top, bottom or side. By reversing the rotation, the intake and discharge openings interchange, thus, like many other ventilating machines, working by plenum or exhaust, as desired. Suitable wrought iron air pipes are connected. The speed of ordinary sizes is 250 to 500 revolutions per minute. The power is taken from main steam pipe line, by separate engine, either detached or by engine or electric motor mounted on the same bed plate.

The essential feature of rotary blowers of this class is the shape of the impellers. The latter are more or less of dumb-bell section, but there are two styles of Root blowers; in one, the "Standard," the extremities of the impeller section are of acorn shape; in the other the surfaces are arcs of true circles.

The Connersville Rotary Positive Pressure Blower.—The essential difference between this and the Root blower, which it otherwise closely resembles, is in the shape of the impeller sections. In this case the curves are

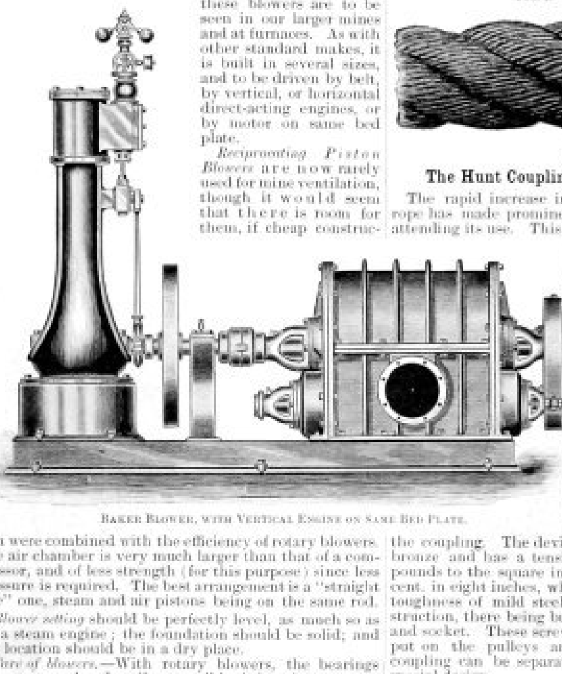


Baker Rotary Blower.—Section.

cycloidal and not arcs of circles. On this head controversy is very warm, and a just exposition of the theoretical considerations cannot be given within reasonable space. Those interested should consult the catalogues of the two companies. This form is also largely used. Two styles are made; in one, the vertical, the impellers are over each other; in the other, the horizontal, they are side by side. They are driven either by belt from separate engines or by engines or electric motors on the same bed plate.

The Baker rotary forced blast blower.—This blower stands between the impeller blowers and fans. Like the Root, the Connersville and the reciprocating piston blowers it takes and delivers a measurable volume of air at each revolution, while the blades on the main drum look somewhat like fan vanes. The action, however, is different, being positive and not dependent on centrifugal or screw action. This blower is made entirely of iron. It has no internal friction and is driven by one belt and without gear wheels. Inside the casing are three drums, each of which is a single casting, truly turned and balanced to ensure steadiness of motion. The upper drum, to which the pulley or direct acting engine or electric motor is attached, does all the work of blowing or exhausting (according to direction of revolution). The two lower drums serve as valves to prevent the air from escaping or returning. It can be driven at high speed, delivering or exhausting large volumes of air. Many of these blowers are to be seen in our larger mines and at furnaces. As with other standard makes, it is built in several sizes, and to be driven by belt, by vertical, or horizontal direct-acting engines, or by motor on same bed plate.

Reciprocating Piston Blowers are now rarely used for mine ventilation, though it would seem that there is room for them, if cheap construc-



Baker Blower, with Vertical Engine on Same Bed Plate.

tion were combined with the efficiency of rotary blowers. The air chamber is very much larger than that of a compressor, and of less strength (for this purpose) since less pressure is required. The best arrangement is a "straight line" one, steam and air pistons being on the same rod.

Blower setting should be perfectly level, as much so as for a steam engine; the foundation should be solid; and the location should be in a dry place.

Care of blowers.—With rotary blowers, the bearings being external and easily accessible, it is only necessary to see that the oil supply is abundant. They usually have good protection from dust. Several styles of self-oiling journals are in use, and in some the parts run wholly in oil. The best makes have an indefinitely long life if properly cared for.

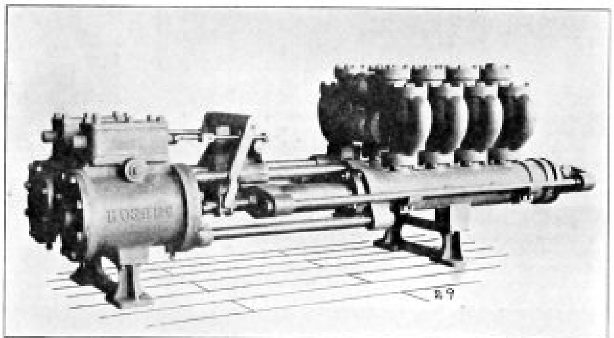
Power required.—This depends on the volume and pressure; consequently on the speed and interior air space. The rule usually followed in computing net power for given volumes at different pressures is: Multiply the number of cubic feet delivered per minute by the pressure in ounces per square inch (at the blower) and the product by .003; divide the last amount by 11; the quotient will give the net horse-power. This rule, that adopted by the makers of the Baker blower, does not include power for running belts, blower, etc., or for overcoming friction and resistance of air in pipes, for which a very liberal allowance must be made. As to power consumed in merely running the blower and belts, this is small, as the best rotary blowers run very light.

(To be continued.)

A Good Steam Pump.

We illustrate herewith a 12″x6″x12″, outside packed plunger pump, which has the valve chambers all separate. The valves are accessible through hand-hole plates. They are made of brass with leather faces. This pump will handle 300 gallons of water per minute against a head of 400 feet, with 80 lbs. steam pressure. The arms and valve gearing on this pump are made of steel, and all parts are interchangeable.

The manufacturers of this pump, the Hughes Steam Pump Co., of Cleveland, Ohio, will hereafter keep their manufactures prominently before the mining fraternity through their advertisement in The Colliery Engineer and Metal Miner. This concern is already too well known to need any special introduction here. Suffice it to say they are prepared to furnish pumping machinery for any service and up to any demand as to capacity. They have had such experience in building mining pumps as to have a thorough appreciation of the severe conditions imposed on such, and to be able to cope with such problems. The catalogue issued by the Hughes Company, (sent gratuitously to mining men) describes the various machines built by the concern, and besides, contains considerable information on matters germane to pumping machinery in convenient form for reference. Send for it.



Hughes Steam Pump, 12″x6″x12″.

The Hunt Coupling for Transmission Rope.

The rapid increase in the transmission of power by rope has made prominent one of the minor difficulties attending its use. This is the gradual lengthening of the rope which increases the sag until it becomes necessary either to resplice the rope or to use a take-up sheave with a very long range of motion. Rapid wear of the rope from slipping on the pulleys is frequently caused by lack of sufficient tension.

The Hunt Rope Coupling, which we illustrate, is designed to do away with all necessity for resplicing, etc., as it will keep a rope at exactly the right tension for the most effective service and long life, and do this with little or no extra time or attention being given the matter and with no expense other than the first cost of the coupling. The device is made wholly of aluminum bronze and has a tensile breaking strength of 60,000 pounds to the square inch, and an elongation of 20 per cent. in eight inches, which is equal to the strength and toughness of mild steel. It is very simple in its construction, there being but two parts consisting of a screw and socket. These screw together when the rope is first put on the pulleys and lock securely, so that the coupling can be separated only by using a wrench of special design.

A very important and interesting feature of the coupling when screwed together is an internal swivel and ratchet, which we show in Fig. 3. The swivel permits the joint to yield to the curvature of the pulleys while the ratchet holds the parts from revolving on each other and untwisting the rope.

The Hunt coupling is made smaller in diameter than the rope with which it is to be used, in order that it may not touch the grooves of the pulleys, even when the rope is worn.

The rope of the correct length for the drive when connected up, is spliced into the coupling, and as it wears longer, more "turns" are put into it by revolving one part of the coupling, the ratchet automatically holding all secure when the rope has the proper length and tension.

Where several independent ropes are run side by side on a pulley, all can be kept at the same tension with the greatest exactness by putting a few more turns in the slack one when such a condition is noticed. By using this coupling, in a multiple rope drive, any single rope can be taken off in a few minutes, and the work done by the remaining ones until it is convenient to put on a new rope, which can be done with equal dispatch, and, what is of greater importance, the tension adjusted to correspond exactly with the other ropes. The cost of a rope drive, with this coupling spliced in and installed in position on the pulleys, is usually less than that of ropes spliced on the spot by the purchaser in the ordinary manner, and it is also less than a rope drive with a tension pulley which, in addition to its cost, frequently requires space that is useful for other purposes. When we consider that a rope requires to be spliced two or three times during its life, while the couplings having no wear, are permanent, with no further expense after once installed, it will be seen that this method is much the cheaper, as well as the better one.

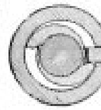


Fig. 3.

Fig. 1.—Hunt Rope Coupling Before Being Adjusted on the Pulleys.

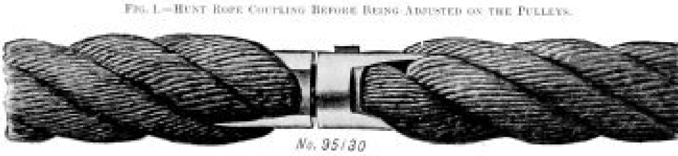

Fig. 2.—Hunt Rope Coupling Mounted on the Drive.

The advantage, both in the convenience of installation, the facility of adjustment of tension, the perfect control of the sag, and the increased life of the rope from a more equal tension, are sufficient to justify an expenditure of many times their cost.

The C. W. Hunt Company, 45 Broadway, New York City, are the exclusive licensees in the United States for the patent on this coupling, and are prepared to furnish transmission rope of the well-known "Stevedore" brand and of the usual sizes, with the couplings spliced in position.

"Hercules" Wire Rope.

With this number of the Colliery Engineer and Metal Miner the A. Leschen & Sons Rope Co. of St. Louis, Mo., begin an advertisement of the wire rope made by them. One pattern of rope of their manufacture for which special merit for mining service is claimed, is their "Hercules" patent flattened strand.

The peculiar advantage claimed for this rope is that the strands instead of being circular in cross-section, have an outer approximately flat surface, with the result that there is a plurality of wires to take the surface wear instead of one external wire as in ropes of ordinary construction. By this plan, a comparatively smooth surface is presented even while the rope is new, and the wear being distributed over a number of wires the tendency to become brittle in service is greatly lessened.

These ropes are made either with the wires in the strands and the strands in the ropes in the same direction (Lang's lay), or reversely.

The makers of this rope state that by this construction they produce a rope without any tendency whatever to spin or kink, a feature of great value when used for sinking ropes or for hoisting in tubs from ore mines.

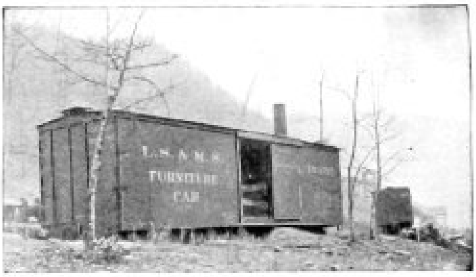
In addition to this special form, Messrs. Leschen manufacture a complete line of wire ropes of all kinds and for all classes of service. A postal card to their home office, 924 N. Main Street, St. Louis, Mo., or to their recently established branch at 19 S. Canal Street, Chicago, will secure their catalogue and detailed information concerning these ropes.

ELECTRIC MINING MACHINES.

A Novel Method of Proving Their Efficiency.

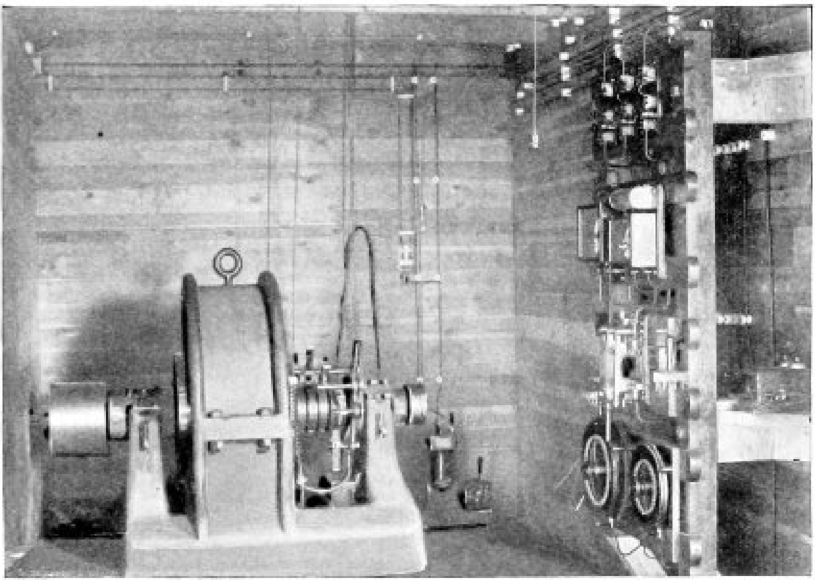
A novel scheme has recently been adopted by the Power and Mining Department of the General Electric Co., in its campaign to introduce electric mining machinery for the operation of coal mines.

The question of coal cutting by machinery, instead of by hand, is a simple one of dollars and cents to be saved by adopting mechanical methods, but conviction is difficult owing to the limited experience of operators with electrically driven machinery and the skepticism natural under such circumstances. Something more conclusive than simple argument or experience in other mines is necessary, as, for instance, a careful test under actual working conditions.



Exterior View of Car Containing Engine, Boiler, Dynamo, Etc.

But such a test would require a complete installation, and neither mine operator nor manufacturer has cared to undertake the installation of a temporary plant, necessitating considerable outlay, with only a chance of an eventual sale. This fact has consequently hitherto militated against the experiment.



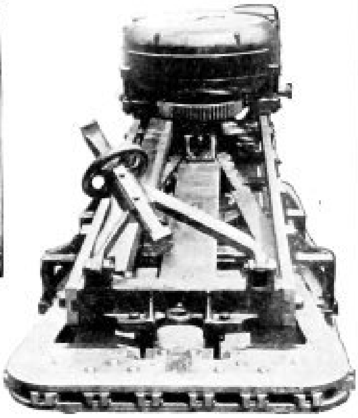
View of Interior of Car.

To enable the operator to judge from actual observation of the merits of machine mining as compared with pick mining in his own coal, the General Electric Co. has devised a complete and compact portable power plant, susceptible of installation near the mine mouth. It includes all the necessary electrical apparatus, and the operator is called upon to furnish nothing more than the water and fuel.

The generating plant occupies the interior of a box car, 40 ft. 8 in. long, 8 ft. wide and about 9 ft. high. It consists of a specially designed water tube boiler of a capacity of 40 horse-power at 100 pounds pressure, furnishing steam to a high speed automatic engine running at 300 revolutions and exhausting into the boiler flue.

The electric generator is a three-phase machine of 75 K. W. or 100 horse-power capacity, wound for 550 volts and running at 900 revolutions. It is belt driven from the engine. A small bi-polar generator serves as an exciter. Although in this case it only runs one coal cutter, it has sufficient generating capacity to supply current to a plant of five or more, the capacity, of course, depending upon the hardness of the material to be cut.

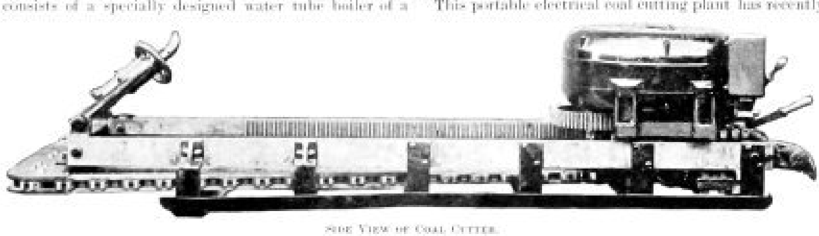
To the right of the generator is a skeleton switchboard, equipped with the necessary switches, rheostats, measuring instruments, etc.



End View of Coal Cutter.

The coal cutter, which forms a part of the plant, is the first known adaptation of the multipolar motor to the coal cutting machine. This motor is ironclad and is completely enclosed and protected from moisture and injury. It has neither commutator nor brushes and no moving contact. It stops operation as soon as it has reached the limit of its power, and thus is not exposed to accident in case of overload. Furthermore, it is sparkless, and this fact only needs attention to find full appreciation of its value from mining men.

The cutter itself is a chain machine making a cut 3 ft. wide, 6 ft. deep and 4½ inches high in about 3½ minutes; it withdraws in about 10 seconds. The capacity of the motor is 20 horse-power, but the consumption of power under ordinary conditions is between 6 and 7 horse-power.

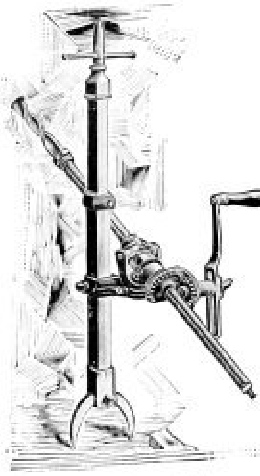


Side View of Coal Cutter.

This portable electrical coal cutting plant has recently been operating in the mines of the Peerless Coal and Coke Co. at Vivian, W. Va., where the record for machine coal cutting has been established. The amount of cutting showed the remarkable average of 7.6 runs or cuts per hour. Taking the depth of cut at 5½ feet, the width 36 inches and the thickness of the coal 5 feet, for a period of two weeks, the average weight of coal undercut per hour was not less than 23 tons. At the mines of the Sterling Mining Co., Cannelton, Pa., a contract for several of these coal cutters was given to the General Electric Co. after exhaustive examination of the multiphase system in operation. It was awarded in face of the most severe competition and also in face of the fact that Mr. W. H. Warner, the general manager of that company, had been using for a number of years a mine plant operated by direct current.

McNelly Coal Drills.

The accompanying engraving, and that in the advertisement of W. A. McCune & Co., of Sterling, Ill., illustrate patterns of the McNelly patent coal drills recently put on the market by the firm named.



The salient features of these machines are the telescope pipe posts, with sliding bridge and jack screws to compensate for settlement in soft floor. The double post drill shown in advertisement is of special advantage in close work, as with side-gear a hole can be driven within two inches of the rib. The gear can be used on either side, on top, or directly under the driving screw, and can be changed from one position to another almost instantly.

The square pipe post drill shown herewith is the same as the double post, save in the post itself.

The McNelly square pipe grip drill in its parts is the same as the post drills, except that a grip post is substituted for the vertical post. By ordering a grip post with either of the two drills first described the miner can have two complete machines at nearly the cost of one.

Full descriptions of these machines, prices, capacities, etc., are given in a circular of the manufacturers above named, and which will be sent free on application.

Fighting Mine Fires by Direct Process.

Experience with mine fires has proven conclusively that the most effective work can be done by the direct process, if the fighters are able to approach the location of the fire with safety. The Vajen & Bader Co., of Indianapolis, who primarily put forth the Bader patent fireman's smoke protector, as a means to enable firemen to enter and work in burning buildings regardless of smoke and gases of combustion, and in which use it has met with unqualified success, now bring it to the attention of mine owners and mine officials through an advertisement in The Colliery Engineer and Metal Miner.

Fig. 1 illustrates the Bader helmet as improved and perfected by Mr. Willis C. Vajen. It consists of a well-formed helmet, which is placed over the head and face, constructed of a special asbestos tanned leather, or asbestos cloth, rendering it proof against fire, heat, steam, boiling water, and all poisonous pervading aeriform fluids; the helmet sets down close upon the shoulders and is held firmly by two straps under the arms. The occupant is supplied with fresh air from a scientifically constructed metal reservoir located at the back of the helmet, with a capacity of 100 pounds pressure of compressed air, always rendered pure by a certain material used for the purpose. The amount of air in store can always be seen upon the gauge attached to the reservoir, which is easily charged by a special air pump in less than fifteen seconds, and retains the same pressure of pure air for months; it is always ready for service. A lever operated on top of the reservoir forces the air through the supply tubes to a point inside, directly in front of the nostrils and mouth, and in sufficient quantity to render the occupant perfectly comfortable for one hour or longer, as desired for the purpose intended. The fresh air being constantly forced into the inside, creates an outward pressure, and the foul air escapes through the neck gear and around the bottom of the helmet, which is lined with lamb's wool under the lower edge. The two lookouts are constructed of clear mica and protected by four cross-wires. The side or ear plates are constructed with a special diaphragm, so as to render the hearing perfectly distinct. One can plainly hear "the clock tick," and "the pin drop," furnishing all the advantages of one on the outside. The horn, located below and in front of

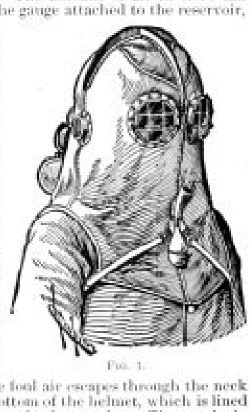


Fig. 1.

the helmet, is used for a call, and is convenient to signal at any time when desired. The Bader Smoke Protector furnishes full protection for the head from falling debris, is graceful in appearance and easily adjusted. The helmet weighs five pounds, is quite ornamental, offering perfect ease and comfort to the wearer and safety from the evil results of smoke, gases and chemicals, all of which must be penetrated to render the vision clear.

The eyesight and the breathing are fully protected by this invention. The nose and mouth are perfectly free, having no connections, affording perfect respiration, without incumbrance of any kind.

Mine owners and mine managers can readily see the advantage of having so effective a device at the mines, whereby they may protect their property and possibly save the lives of endangered employes.

A New Recording Thermometer for Atmospheric Ranges of Temperature.

The novel and especially valuable feature of the recording thermometer herein described is that the recording portion may be located at a distance of twenty-five or thirty feet from the point at which the temperature is to be measured.

This makes it possible to obtain a continuous record of the outside temperature while the recorder is located at a convenient point within doors where it may be readily observed and its mechanism is not exposed to the detrimental influences of inclement weather.

For cold storage plants where closed rooms are to be maintained at a constant temperature for the preservation of meats, fruits and vegetables, an instrument of this kind is of great value, as the temperature may be observed without opening the doors.

FIG. 1.

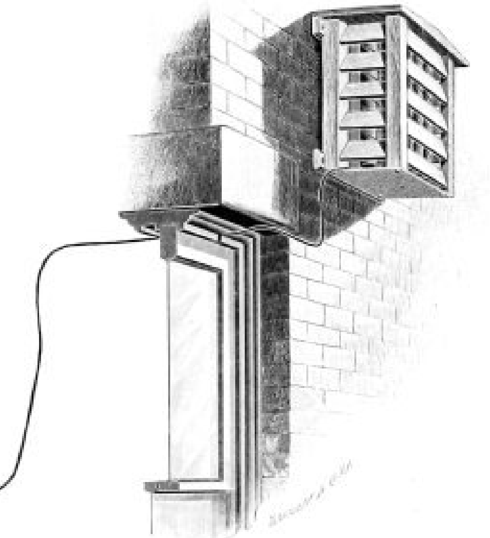

FIG. 2

The recording part (Fig. 1) is an application of one of Bristol's recording pressure gauges. Fig. 3 shows an interior view of the recorder, which consists of a pen arm directly attached to the free end of a tube of flattened cross-section bent into helical form.

FIG. 3.

The bulb portion (Fig. 2) is placed at the point where temperature is to be measured. It consists of a series of helical tubes constructed on the same principle as that in the recorder. The helical coils are suspended in a vertical position with their lower ends free, the upper ends opening into the capillary tube connecting them with the recorder.

The system of helical tubes forming the bulb portion, the pressure tube of the recorder and the capillary connecting tube are completely filled with alcohol under pressure and permanently sealed. As the temperature rises and falls where the bulb is located, there is a corresponding expansion or contraction of the alcohol which is communicated to the recorder and registered on a seven-day chart graduated to read in degrees Fahr.

Excessive pressures due to increased volume of the non-compressible liquid are provided against by the expansible form of the system of helical tubes of which the bulb is constructed.

The total volume of the bulb portion is very large as compared with that of the tube in the pressure recorder, thus avoiding the necessity of compensating for ordinary changes of temperature in the room where the recorder is located.

No correction is required for barometric changes, as only high ranges of pressure are employed.

This thermometer is being manufactured and placed on the market by The Bristol Co., of Waterbury, Conn. At 121 Liberty street, the New York branch of the company, one of the instruments may be seen in operation recording the outside temperature. The recorder is placed in the show window where it may be observed from the sidewalk.

THE BY-PRODUCTS OF COKE.

Their Value and the Importance of Saving and Utilizing Them.

The following extracts, of interest to every producer of a coking coal, are from statements made before the committee on manufactures of the Massachusetts Legislature by Messrs. Henry M. Whitney and Joseph D. Weeks, on March 3rd and 4th, and published in full as a supplement to *The American Manufacturer*, of which Mr. Weeks is editor:—

There is one product of these by-product coke retorts which is exceedingly valuable to our agricultural industries, and I will take the liberty, Mr. Chairman, of reading here from Mr. Fulton's book an extract of what he says is a valuable paper by Dr. Bruno Terne, which was read before the chemical section of the Franklin Institute in Philadelphia, Pa., Oct. 20th, 1891:—

"The consumption of ammonia in its various forms has grown enormously in the last 20 years, and the manufacture of illuminating gas is not longer sufficient to supply the increasing demand for ammoniacal liquors. On the other hand, the inroad which electrical plants for illumination have been making yearly on the production of illuminating gas has already been felt, and will be more so from year to year. The production of water gas and oil gas are other factors that are cutting down the amount of ammoniacal liquors produced.

"But there is another source for tar and ammonia which, so far as my knowledge goes, has, with a single exception, not been worked in our country.

"Rich as are our resources, we are not rich enough to waste continually. It seems strange, and, nevertheless, it is a fact, with all the ingenuity of the American people in the advancement of the purely mechanical part of the technical industries, we have been and are yet slow in the development of the chemical industries.

"The acid manufacturer of Europe, especially of England and Germany, had commenced in the beginning of this century to make himself independent of the sulphur mines of Sicily by using the sulphurous ores of his immediate neighborhood, and to utilize the pyrites for making his sulphuric acid. It has only been within the last 20 years that our people have commenced to use the ores that have been lying under their feet, and to-day, even, the United States consumes more sulphur for the manufacture of sulphuric acid than any other nation.

"It is the same with productions of tar and ammonia as a by-product of the manufacture of coke.

"If you will visit the coal regions to-day you will find the nightly sky illuminated from the fires of the coke ovens, and every one of the brilliant fires bears testimony that we are wasting the richness of our land in order to pay the wiser European coke manufacturer, who saves his ammonia and sends it to us in the form of sulphate of ammonia, and who also saves his tar, which, after passing through the complex processes of modern organic chemistry, reaches our shores in the form of aniline dyes, saccharin, nitro-benzol, etc."

Let me, before I enter upon the subject of gas, refer to the importance of ammonia. Everybody who is familiar with agriculture knows that the three essential elements of plant food are nitrogen, phosphoric acid and potash. Now, we have, fortunately for this State, an agricultural experiment station at Amherst, which keeps in close touch with the value of commercial fertilizers, of which the land of this State and of New England is in such great need. A few days ago I visited Amherst and spent an evening with Prof. Groessmann, who has charge of this station. I felt certain that while the theoretical value of barnyard manures was a certain quantity, yet that there was a certain amount of waste from the time that it was dropped until it reached the field, and I was anxious to find what proportion of the theoretical whole was preserved. I found that the experiment station had made tests (66 I think in all) of manures in various parts of this State to determine exactly what the manurial value in nitrogen, potash and phosphorus was as it is put upon the ground. These are Prof. Groessmann's conclusions:

Nitrogen, 4-10 of 1 per cent. equals 8 lbs. at 12c. per lb.; total value	.96
Phosphoric acid, 2-10 of 1 per cent. or 4 lbs. at 5c. per lb.; total value	.20
Potash, 3-10 of 1 per cent. or 6 lbs. at 4½c. per lb.; total value	.27
Total value of one ton of manure	$1.43

Therefore, if you were to buy commercial fertilizers containing the same amount of plant food that is found in a ton of manure, you would pay for it $1.43. I do not undertake to say, Mr. Chairman and Gentlemen, that there are not some other elements in the manure that are of value to the soil, but I do undertake to say that, so far as the experiments of the agricultural station made with exceeding care have gone, you can purchase with $1.43 the same amount of nitrogen and potash and phosphoric acid as you will find in a ton of manure. Very well. Now, then, how many tons of manure do you get from an animal a year? Prof. Groessman says that it is fair to assume that an animal will eat 25 pounds of food a day, and that amounts in round numbers, to 9,000 pounds a year. You can reckon the excrements at about half of the food, or two tons and a quarter. That is, the manurial value of an animal for one year is two and a quarter times $1.43, and that is $3.22.

The professor tells me that, in order to produce good crops, there should be the equivalent of four or five tons of manure, or, better still, six tons to every acre. The importance of this matter to which I am calling your attention is this, that in every ton of bituminous coal burned to-day there is the equivalent of 25 pounds of ammonia, which is the equivalent of five pounds of nitrogen, and, at the same value at which it is reckoned here as manure, there is a money value of 60 cents. The waste of fertilizer in every six tons of bituminous coal which is burned throughout New England, is equivalent to the manurial value of an animal for a year. Now, what does it mean with reference to the agricultural industry of Massachusetts, if all this nitrogen could be saved and placed upon your soil? It means that in this 6,000,000 tons of coal that are burned throughout New England to-day there is a manurial value of a million of cattle. I know of nothing more hopeful for the agriculture of this State, nor of New England, nor of the whole of this broad land, than that capitalists are turning their attention to-day to the preservation of this great amount of nitrogen which is needed for your exhausted soils. What does it mean? Am I mistaken in thinking that this is an enterprise which this State can properly encourage? It means, of course that throwing such a large amount of nitrogen upon the market will cheapen its cost, and that is the advantage of it. I should welcome the time for New England when nitrogen would sell for a quarter of its cost to-day. From 1882 to 1894, 12 years, sulphate of ammonia ranged in price from $90 a ton. The lowest price was about $60. Today, I am happy to say, it is selling for $60 a ton to farmers, and the people in Johnstown told me that they were receiving $52 a ton. Mr. Chairman and Gentlemen, every man who is familiar with the necessities of agriculture at this day, and understands what the cheapening of nitrogen means, understands what a great benefit the saving of these by-products will be to these people. Prof. Groessmann told me that, in his judgment, the problem of the times was how to increase the supply of nitrogen, and anybody who had any scheme calculated to increase and cheapen it was doing a public service.

Mr. Jos. D. Weeks of Pittsburg, Pa., stated, in answer to questions by counsel, that he was editor of the *American Manufacturer and Iron World*, of Pittsburg, Pa.; that he had been interested in the study of coke and coking for twenty-four years, having published in that time quite a number of monographs on this subject; that he had had charge at both the Tenth and Eleventh Censuses, (1880 and 1890), of the United States of the reports on coke, petroleum and natural gas; that he had been for 12 years expert of the United States Geological Survey on these subjects, and as such had visited England, Belgium, Germany and France in 1894 and 1895, charged to examine and report upon coking in by-product coke-ovens; that he had seen at least 2,000 of these coke ovens in operation; that he had been secretary of the board of judges, department of mines, mining and metallurgy at the World's Columbian Exposition, and that he had just completed a term as president of the American Institute of Mining Engineers.

Mr. McLaughlin of counsel, having asked Mr. Weeks to state what was meant by coke, how it was made and how it differed from anthracite and bituminous coal, as well as any other facts and information material to the question at issue, replied:

Mr. Chairman and Gentlemen of the Committee: I think it best for a clearer understanding of this question that certain facts regarding coal, as well as the differences between varieties of coke should be stated. Without entering into a discussion of all the varieties of coal, it is sufficient for my purpose to state that there are two kinds of coal, anthracite and bituminous, or, as they are commonly named, hard coal and soft coal. The differences in these coals are chiefly two:

First.—In the amount of volatile matter contained in them, that is, the amount or percentage of volatile substances that can be driven off from these coals by heat, and

Second.—Differences in physical structure.

Anthracite coal contains from 5 per cent. to 10 per cent. of volatile matter; bituminous coking coal, 15 per cent. to 36 per cent., while coke, which is made from bituminous coal by processes that I will describe later, contains from one-half to 1 per cent. The other constituents of all of these fuels are carbon and ash. Analyses of each of these coals and coke are as follows:

ANALYSES OF ANTHRACITE AND BITUMINOUS COAL AND COKE.

	Anthracite.		Bituminous.	Coking.	Coke.	
	I.	II.	I.	II.	I.	II.
Volatile matter (including water)	5.582	11.100	32.60	21.970	0.490	1.104
Fixed Carbon	83.672	78.891	60.92	73.728	89.556	92.590
Ash	10.746	10.009	6.48	4.672	9.954	6.306
	100.000	100.000	100.000	100.000	100.000	100.000

These coals, that is, the anthracite and bituminous, though they differ now greatly in chemical constitution and physical structure, were originally the same. Pittsburg gas coal, Connellsville coking coal, Cumberland "Big Vein" steam coal and certain Pennsylvania anthracites are all the Pittsburg bed of the upper coal measures. Here, for example, is a piece of anthracite coal, here is a piece of bituminous coal and here is a piece of coke made from Pittsburg bituminous gas coal in a by-product oven (showing the samples to the committee). These coals as well as this coke were at one time in their history the same. The anthracite was at one time a bituminous coal. The volatile matter contained in them has been driven out of it by the earth forces and heat, by the pressure of the earth's strata above it, and by the heat of the earth that has been generated possibly by the earth movements that threw up the Appalachian mountains. In this respect the only difference as compared with bituminous coal between an anthracite coal and coke is that in the anthracite coal the volatile matter has been driven off by natural causes while in the coke the volatile matter has been driven off in ovens in an artificial manner by heat.

Now which of these fuels is the best? Practically a solid fuel with more carbon and less volatile matter is a better fuel than one that has less carbon and more volatile matter. So that pound for pound anthracite is a better fuel than bituminous coal, and coke better than anthracite, as bituminous coals contain say but 61 to 73½ per cent. of carbon, anthracite 78½ to 83¾ per cent., and coke 89½ to 92½. The coke is the better.

You will notice, Mr. Chairman, from an inspection of these samples that the anthracite is perfectly solid while the coke is porous, it is filled with little cells. It is this porosity, this cell space, that makes coke a more vigorous fuel than anthracite, that is, it will burn more rapidly, just the same as a pound of shavings will burn more rapidly than a pound of solid wood. There is the same amount of heat in the same weight of each, but the one burns much more freely, much more rapidly, is a much more vigorous fuel.

It is this porosity of coke, combined with its toughness and hardness, that in a large measure gives coke its value as a blast furnace fuel, much superior to anthracite. A modern blast furnace say 18 feet in diameter at the boshes using anthracite coal will do good work if it makes 400 tons a week. A furnace of the same size using coke will make four times this amount, and a furnace is being built at Pittsburg to use coke as fuel that will make at least 500 tons a day, a feat that would be utterly impossible with anthracite as a fuel. In our United States practice the value of a blast furnace fuel depends largely upon the rapidity with which it will do its work. It is the same in many operations. We must do our work quickly, and to do this where heat is used we need a quick acting vigorous fuel. This gives a porous fuel like coke its great value. I could make a fuel in a coke oven very like anthracite, provided I did my coking under pressure; but I would destroy one of the most valuable features of the coke as a fuel, namely, its "porosity."

This porosity must be kept within proper limits. Coking is simply the driving off from bituminous coals, by the action of heat, of the volatile matter they contain. No matter how coking is performed, whether it be in an illuminating gas works, for the manufacture of illuminating gas is from one point of view a coking process, or in a bee hive or a by-product coke oven, what takes place is always the same. As the heat is applied the coal begins to swell, becomes pasty and sticky, and throws off bubbles of gas. In a word the coal melts, loses all traces not only of its original form but of its appearance and structure as well and the particles freed from volatile substances unite in a coherent mass or as it is termed "cake" or "coke." As this melted coal solidifies or "cakes," it encloses small bubbles of gas, which makes the cells like those in this piece of blast furnace coke if the gassing process has not been pushed too rapidly. But these pores, these cells, can be made large or small. If the operation is with a small body of coal and the "gassing" is pushed, you get the weak coke with large cells known as gashouse coke, that will hardly bear its own weight. But if the coking is done under proper conditions, you get a hard, strong coke that will bear the burden of the blast furnace. This piece of coke that I show you will bear the burden of a blast furnace 125 feet high, without crushing.

Liebig some years ago laid down four propositions regarding fertilization. First that in order to preserve the fertility of a soil there must be kept in that soil the elements necessary for plant life; second, every crop takes out a portion of these elements. Part of that taken out is added again from the atmosphere, but a part of it never is restored unless it is put there by human means; third, the fertility of a soil remains unchanged if all of the elements of fertility are restored to it; and fourth, the manurial product of a farm never can restore all the elements of fertility to the soil. That is, it makes no difference how valuable is the barn yard manure produced on a farm it never can restore to the soil all the elements taken out of it, and therefore, fertilizers must be added to maintain its fertility. As shown yesterday by Mr. Whitney, the most important elements necessary to be added to maintain this fertility are nitrogen, phosphorus and potassium, or nitrogen, phosphoric acid and potash. The most valuable as well as the rarest of these is nitrogen. There are three chief sources of nitrogen: Chili nitrates, ammonia, and the manures either of the barn yard or the green manures. The chief source of ammonia, which is the most important of these, is coal, distilled either in the gas house or in coke ovens. By the use of the water gas instead of the coal gas process the amount of ammonia produced in the United States in gas works has been very greatly reduced, because in the water gas process no ammonia is produced. It is only in the illuminating coal gas process that it is produced. Mr. Whitney showed you yesterday that in a ton of barn yard manure there was about four-tenths of 1 per cent. of ammonia, or eight pounds. In a ton of coal, coked in these ovens there are 25 pounds sulphate of ammonia, and all of this is being wasted into the air.

As near as I am able to ascertain the consumption of commercial fertilizers in the United States in 1894 was 1,550,000 tons in which is included some 31,000 tons of ammonia. If the ammonia from all the coal coked in the United States in 1894 was saved it would amount to about 150,000 tons sulphate, and this would yield over 1,000,000 tons mixed fertilizers, containing 3 per cent. of nitrogen. Regarding the probability of an increased consumption a large dealer in fertilizer writes me:

"If the price was lowered the consumption of it would vastly increase. The question then would be, Can they afford to do without it in agriculture? not whether they could afford to use it."

From Mr. Groessman, of the Massachusetts Agricultural Experiment Station, to whom Mr. Whitney referred yesterday, I have this letter:

"The use of ammonium sulphate as a source of nitrogen for plant food is limited merely by its high market cost. Its high agricultural value is not questioned any more; and its consumption, it may be confidently assumed, would increase in the same ratio as its market price will be lowered."

As to gas: What is the relation between the gas produced in these ovens and the gas produced in retorts in the manufacture of illuminating gas? There are three gases used for commercial purposes: first, the illuminating gas made from coal; second, water gas, which is also in part a coal gas made by the well-known water gas processes, and third, a producer gas, that is, a gas that is made by burning all the combustible parts of coal with a mixture of air into gas. This is used in large quantities in rolling mills. Coke-oven gas is practically the same gas as illuminating gas made from coal, and therefore belongs to the first class.

As to the feasibility of enriching coke-oven gas for illuminating purposes at the point of consumption. Look at the analysis of this gas and tell me what in the world is there to prevent enriching it. What obstacle is there to enriching a gas which contains 25 per cent. of marsh gas and 61 per cent. of hydrogen up to almost any point desirable? And it is a great deal better to do it at the point of consumption than at the point of origin, because the difficulties that come from attempting to convey under pressure the illuminants, which are condensable, are avoided. There are many methods of enrichment in a small way that are feasible and not expensive.

I now come to a most important practical question, viz: Can this coke-oven gas be used economically for heat and power? I have shown that in heat units and chemical composition coke-oven gas does not differ materially from illuminating coal gas, so that for all purposes of heat and power it may be assumed that the two gases are the same. There is no purpose for which coal or coke can be used that gas will not serve, except where a burden is to be carried, as in the smelting of iron in the blast furnace and in the melting of iron in the foundry cupola. In these cases the iron must be kept apart and the fuel has to bear a burden and consequently, in a blast furnace or a foundry cupola, gas cannot be used. Do not understand me that gas cannot be used to make wrought iron from the iron ore or that gas cannot be used to melt pig iron for foundry purposes, because gas can be employed in reducing iron ore, by the direct process, so called and iron is melted for foundry purposes every day by the use of gas in what is known as the air furnace. For all heating purposes in the large mills in Pittsburg, gas is used almost exclusively. Where natural gas is not burned, producer gas, which has not one-third of the heat units per cubic foot which this coke-oven gas has, is used very largely.

VENTILATION OF FIERY MINES.

A Discussion and Criticism of the Separate Ventilation Theory.

Mr. J. J. Mayer, a prominent Austrian mining engineer, very intelligently discusses the separate ventilation theory for fiery mines, in a recent Austrian government publication. Our British contemporary, *The Colliery Guardian*, publishes a translation of his article, and we herewith publish it, with the metrical measurements given in their equivalents in American terms:—

The object of separate ventilation—by which term is understood the independent ventilation of preliminary headings and workings lying out of the direct line of the main air supply—is to reduce the depression of the main current, *i. e.*, to lower the resistance, which the diversion of the main current into all the branch workings by means of valves and splittings would tend to increase. It is therefore intended to assist and supply the deficiencies of a main ventilator, which, by reason of the extension of the workings, the insufficient diameter of the ways, or from other causes producing high resistance, is incapable of supplying the whole of the air needed throughout the pit, and where, from motives of economy, it is not expedient to replace the installation by a more powerful one. This is the sole *raison d'être* of the separate system, and the extension lately advocated and partly carried out in the Saarbruck district cannot be looked on as justifiable.

If the only point to be considered were the supply of a certain quantity of air to the workings in a given time, then it would be immaterial how this air were introduced—whether by the aid of compressed air, hydraulic pressure, ventilating fan, etc.—but it is found that the composition of the air employed is a far more important factor than mere quantity. For instance, air taken from a current already fouled with gas cannot serve as a means of purifying to the fullest extent the workings into which it is diverted or forced; and in fact, attempts made in this direction failed, even when the draught was so strong as to interfere with the working, simply because the air used was impure, the small amount of pure air derived from the motive power working the fan being insufficient to work any beneficial effect. Of course, where the fans are worked by hydraulic pressure the results will be even more unfavorable.

Objection has of late been taken by Uthemann to ventilation by parallels, on account of the great expense of constructing and maintaining the double workings, the liability of the cross-drivings to harbor fire-damp, and the increased quantity of gas bleeding from the larger surface of coal exposed by this method, and he has advocated the abolition of this system in working seams, proposing in substitution the adoption of single headings ventilated separately. This plan is pursued in the Reden and Konig pit at Saarbruck, and it is asserted that the alteration resulted in a saving of wages alone amounting to some $7,300 in one year. The ventilators used are small, not exceeding 4.1 ft. in size, and are therefore got into the pit without difficulty. The latest compressed air fan used at Reden is of the Ser model with arms 20″ in diameter, and driven by belting. These ventilators have also been used with hydraulic power, worked by a Pelton wheel giving 1,700 revolutions per minute, the fans themselves having a speed of from 600 to 1,000 turns per minute. The air supply is conducted through plain cylindrical troughs of galvanized iron, 11.8″ to 19.7″ in diameter, which are found to act better than corrugated pipes and deliver double the quantity of air under identical conditions. The troughs are connected by socket, or more frequently with flange joints, and the percentage of waste air is 25 per cent. in lengths of 328 ft., 50 per cent. in 656 ft., and 76 per cent. in 1,640 feet, the actual figures obtained from a 11.8 trough supplied by a Pinette fan being as follows:—

Length of trough. Feet.	Revolutions of fan.	Effluent air per minute. Cubic feet.	Loss per cent.
328	798	1,118.4	27
	1,063	1,398.9	25
656	762	737	50.5
	950	927.7	50
1,315	698	362	74.5
	928	441.4	74.5
1,672	685	347.5	75
	907	407.9	77

At present there are eighteen fans working by compressed air, supplying twenty-three workings at the Reden pit, and at the Konig pit fourteen worked by hydraulic power, together with twelve by running water, and supplying thirty workings.

So far as the reduction of the working expenses is concerned this system answers its purpose, but when the question of safety is approached matters wear a different aspect, for if it be considered that in ordinary workings strong brattices and bricked airways are always erected as a precautionary measure for obviating the risk of the interruption of ventilation in case of an explosion, and that only where the drivings are short are metal troughs used, what can be the security of the miners working in headings of considerable length when the only air supply is conveyed by these slender troughs which a slight shock would be sufficient to split, and thus render useless, especially in view of the great danger existing in headings driven along seams? As a matter of fact, their position is a very critical one, and the prospects of rescuing any who may be in the workings at the occurrence of even a local explosion of gas would be extremely remote, if not impossible, the only means of communication being through the single way, some 100 yards in length, in which a fall might easily occur. Uthemann puts forth another argument in favor of the single heading system, viz., that an explosion will be more localized, as the gases will remain *in situ*, but this means that the men actually on the spot will certainly lose their lives that the others may escape, an axiom that is surely not justifiable. Besides, the localization of an explosion—say in the case of coal dust, as shown by the experiments of the English committee—is improbable, but the danger remains that the men in other workings may have no way of escape, while with parallels there is always a better chance for them, apart from the additional security afforded by the more substantial separation of the airway right up to the working face.

In the Karwin district, where separate ventilation is employed, the Steindel (exhaust) compressed air system is more generally adopted, as being safer than the fragile fans, the breaking of one of which would leave a whole section of a pit without an adequate supply of air. In a ventilating test made at the Heinrich shaft of the k. k. priv. Kaiser-Ferdinands-Nordbahn, a Capell fan, driven at a speed of 1,100 turns per minute, supplied the necessary air to a 1,821 ft. length of troughing, but at this high speed the wearing parts of the machinery were soon worn out, and it was found expedient to resort to the compressed air exhaust with 0.12″ jet, since the cost of maintenance was thereby reduced 20 per cent., although a much greater quantity of air was used up. As safety is the chief consideration in fiery workings, the exhaust method is preferable to any other method of separate ventilation; but the very best plan is to ventilate direct from the main current, keeping, of course, a sufficient amount of reserve power for emergencies and developments.

EASY LESSONS ON MINING.

This Department contains articles to assist ambitious Miners to educate themselves, and obtain Certificates of Competency as Mine Foremen, or to become Mine Superintendents.

The articles are written to be understood by the unlearned and the learned alike. Plain language is used, no obscure terms are employed, and each subject treated, is made as clear and easy to understand as possible.

Further: The Questions asked at the different Examinations for Mine Foremen and Mine Inspectors, are printed and answered.

The Series of Articles "Geology of Coal," "Chemistry of Mining," "Mining Methods" and "Mining Machinery" was commenced in the issue of March, 1894. Back numbers can be obtained at twenty-five cents per single copy, $1.00 for six copies, and $2.00 for twelve copies.

MINING METHODS.

The Resistance Due to Air—The Different Velocities of Falling Bodies—The Effects of Different Suspension Surfaces—The Unit for the Velocity of Dust Particles—What Should be the Limiting Sizes of Dust Particles—Recapitulation of Facts and Principles.

94. **The Resistance Due to Air.**—All bodies are subject to resistance during their passage through air, and by observing the conditions of surface extension and mass that affect it, we are soon able to classify its modes, and determine the amounts of retardation that are peculiar to each of its phases. As for example, we can throw a pound weight of lead much further than a pound of wood, or a pound of cork, because the matter in the wood has a greater surface of suspension than that of the lead, and presents to the fluid through which it passes a larger area of end surface in the ratio of 5 to 1. From this, then, we see that the distance a body will travel in air is not only a question of velocity but also one of density. Again, a cylinder of wood moving endways through air, is subject to less resistance than a cube or sphere of the same substance, and the same is true of masses of any other kind of matter, and to illustrate this fact Fig. 134 is introduced. For example, at *C* we have the muzzle of an old-fashioned smooth bore cannon for throwing spherical shot, as *B*. Now, if the shot *B* contains the same mass in the same volume as *A*, we can see that the cylinder will meet with less resistance from the air than the sphere, because the extension of the surface of the cylinder across the line of its motion will be much less than that of the sphere, for let us observe that the transverse section of the cylinder, being less than that of the sphere, the displacement at the front of *A*, as *f*, and the closing in at the rear, as *r*, will result in a smaller volume of exchange than at *f* and *r* in the front and rear of *B*; on the principle that a sheet, one yard square, that is extended or spread out in a plane at a right angle with the line of its motion, will push from its front side as great a volume of air as a cube, all of the sides of which are one square yard in area, and the vacuum in the rear of the sheet will be as complete as it would be on the rear side of a cube. The object of the rifled gun *G* is to give a twirling or rotary motion to the shot around its long axis, on the principle of a rotating top that continues to revolve persistently in the same plane; in the same way the shot is made to keep the plane of its axial rotation at a right angle with the line in which it moves *en masse;* that is to say, the long axis of *A* after leaving the gun, continues to move along its path or trajectory *t t* until its journey ends, with its ends *f* and *r* in front and rear; and the result is the shot, continuing to move end on, is subject to much less resistance from the air than the sphere, and this is illustrated in the figure. A shot may be thrown at the highest velocity attainable with the most powerful gun in use, but whether the shot be large or small, swift or slow, the moment it emerges from the muzzle of the gun it begins to fall, and that, too, at the ordinary rate of 16 feet the first second, and 64 feet in two seconds, and so on, and it is on this account that we know that the sphere suffers a greater resistance, because if *G* and *C* are fired at the same elevation, *B* reaches the ground long before *A*, and this is indicated by the curvature of the trajectory of *B*. By the direction of the arrows in front of the sphere the shot is seen to push the air out of its course, and by the direction of the arrows in the rear, the air is seen to rush into a partial vacuum.

95. **The Different Velocities of Falling Bodies.**—Fig. 135 is introduced to illustrate how the velocities of falling bodies are affected by their densities and the transverse extension of their surfaces. First, then, we have three cubes of coal, *C*, *c* and *s*, and a cube and a cylinder of wood, *W* and *w*; a sphere of lead *L*, and a long and a short cylinder of iron, *I* and *i*. Now, if all

FIG. 134.

these masses are let fall down a vertical mine shaft at the same moment of time, they will soon be found to be moving with different velocities, as for example, the little cube of coal *s* will present, for its weight, a greater suspension surface to the resisting fluid than the cube *c*, and the latter will present a greater suspension surface, for its weight, than the cube *C*, with the result that the velocities of the cubes in falling, will be in the inverse order of the square roots of the ratios of their suspension surfaces, as will be more clearly shown further on. Again, if the suspension surface of the cylinder of wood *w*, be taken as the area of one end, and if there is as much weight of wood in *w* as in *W*, then the cylinder will fall quicker than the cube, and this is graphically shown at *C' c' s' W'* and *w'*. The sphere of lead, although it is a sphere, will fall quickly, because its suspension surface is small in relation to its weight, and we can therefore see that a cylinder of lead might be made to fall with an accelerating velocity, nearly equal to a body falling in a vacuum. The next is an interesting example, for here we have two cylinders of iron *I* and *i*. Now the actual end surface of *i* is the same as that of *I*, and yet as far as the quantity of matter in the two bodies is concerned, the *suspension* surface of *i* is greater than that of *I*, and the result is *I* soon attains a higher velocity in falling than *i*. All this will be still more clear after we explain what is meant by the suspension surface with the help of Fig. 136.

96. **The Effects of Different Suspension Surfaces.**—Here *C* is a large cube of coal that we may consider to be a cubic foot or cubic inch, just as may be required for explanation, and to sustain what we are aiming at, namely, to find what coal dust really is, let us watch the conduct of this cube of coal falling down a mine shaft, and let us first consider it a cubic foot, and second, a cubic inch. It is clear that when the resistance of the

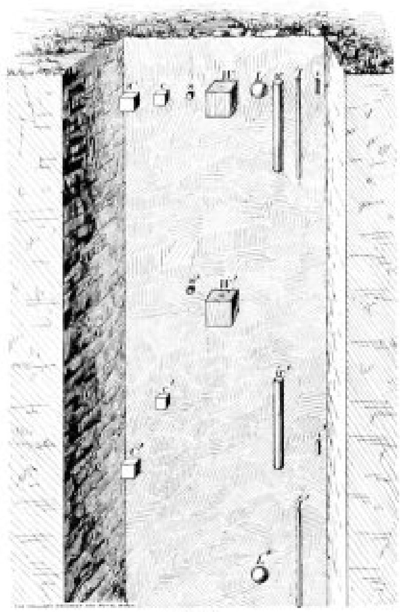

FIG. 135.

air in pounds per square foot is equal to the weight of the cubic foot of coal, the falling cube will cease to accelerate its velocity. Let us, then, take the cubic foot of coal to weigh 80 pounds, the pressure of the atmosphere in pounds per square foot at 2,120, and the *square* of the velocity of air rushing into a vacuum at 1,800,000, then it follows that $\sqrt{\frac{1{,}800{,}000 \times 80}{2{,}120}} = 260.623$, equal to the velocity in feet per second at which the falling cubic foot of coal will cease to accelerate. Next let us try to obtain some idea of what is meant by the surface of suspension, and to make that clear, let our cube of coal this time be a cubic inch, instead of a cubic foot; then a cubic inch will weigh $\frac{1 \times 80}{1{,}728} = .046296$ of a pound. Again, the face of one of the sides of the cube is one square inch instead of one square foot, or 144 square inches; and the pressure at which acceleration will cease must be reckoned per square inch, as $\frac{2{,}120}{144} = 14.72$ pounds,

$$\text{or, } \sqrt{\frac{1{,}800{,}000 \times \frac{80}{1{,}728}}{\frac{2{,}120}{144}}} = \sqrt{\frac{1{,}800{,}000 \times .046296}{14.72}} = 75.24,$$

the velocity in feet per second at which a cubic inch of coal will cease to accelerate in falling through air. Now the cubic foot ceased to accelerate at 260.623 feet per second, and the cubic inch of the same mineral ceased to accelerate its velocity at 75.24 feet per second, and therefore, we observe that $\frac{260.623}{75.24} = 3.33$, that is, the velocity of a cubic foot of coal is 3.33 times greater than that of a cubic inch, when it ceases to accelerate; and further, for the same mineral, these velocities vary as the fourth roots of the surfaces of suspension, as $\sqrt[4]{\frac{144}{1}} = 3.33$ as before. Referring to the last figure, again observe the

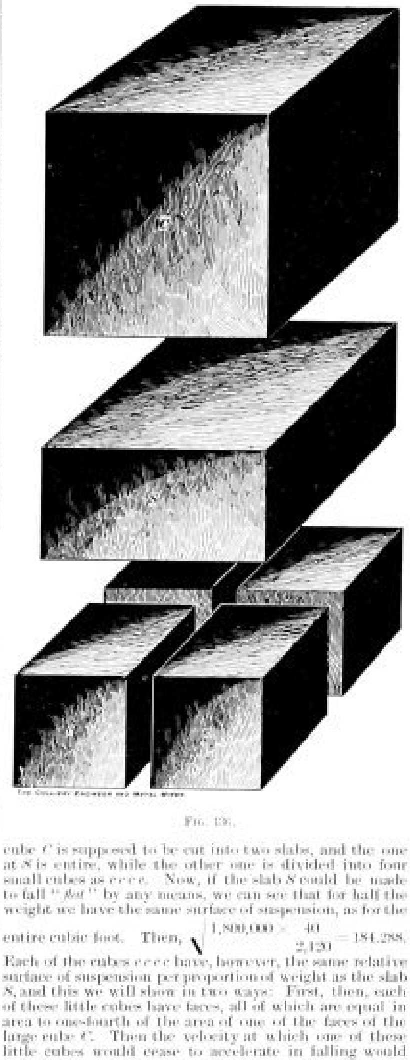

FIG. 136.

cube *C* is supposed to be cut into two slabs, and the one at *S* is entire, while the other one is divided into four small cubes as *c c c c*. Now, if the slab *S* could be made to fall "*flat*" by any means, we can see that for half the weight we have the same surface of suspension, as for the entire cubic foot. Then, $\sqrt{\frac{1{,}800{,}000 \times 40}{2{,}120}} = 184.288$. Each of the cubes *c c c c* have, however, the same relative surface of suspension per proportion of weight as the slab *S*, and this we will show in two ways: First, then, each of these little cubes have faces, all of which are equal in area to one-fourth of the area of one of the faces of the large cube *C*. Then the velocity at which one of these little cubes would cease to accelerate in falling would be $\sqrt[4]{\frac{1}{4}} \times 260.623 = 183.86$ feet per second.

97. **The Unit for the Velocity of Dust Particles.**—From what has been done, we have made good progress in finding out that the velocities at which falling bodies cease to accelerate vary as the fourth root of the areas of their surfaces of suspension. We found that a cubic inch of coal ceased to accelerate when its velocity in falling was equal to 75.24 feet per second; now at *A*, Fig. 137, a cubic inch has first been split into four slabs, and each of these slabs has been cut up again into 16 little cubes, or to put the matter very plainly, a cubic inch has been cut up into 64 little cubes. Now if a cubic inch has a limiting velocity of 75.24, one of these little cubes whose length, breadth, and depth are each one quarter inch will have a limiting velocity of $\sqrt[4]{\frac{1}{16}} \times 75.24 = 37.62$. That is, a piece of coal the $\frac{1}{64}$th of a cubic inch would cease to accelerate in falling when the velocity was 37.62 feet per second, or in other words, 37.62 feet per second is the limiting velocity of these small cubes. Again at *C*, a cubic inch of coal is divided into 13 cakes or slabs and the cake is seen to be divided into 13 × 13 = 169 little cubes, or the cubic inch is divided into 2,197 cubes. Then the limiting velocity will be $\sqrt[4]{\frac{1}{169}} \times 75.24 = 20.86$ feet per second. The cube at *C* is intended to explain what we mean by slabs or cakes, and the numbers are indices of fractional divisions.

98. **What Should be the Limiting Sizes of Dust Particles.**—This brings us immediately face to face with the aim and intention of this lesson, and now let us ask ourselves what dust is, and I think I hear all our readers respond, by dust we mean a cloud of particles that are raised by a wind, whose velocity is greater than

the limiting velocity of these particles when falling; and we know this to be true, because *some* of the particles continue in suspension long after the breeze has subsided. Good! Good!! But you said *some* of the particles, and I suppose you mean the smallest, and this suggests that the particles of different sizes and different specific gravities fall through a height of, say, 10 feet in different times; just so, you reply; and you are correct in your conclusion, say we; and all this having been admitted, we are forced to the conclusion that the particles might be classified by their limiting velocities; for we have seen that the moment the velocity of the wind exceeds the limit of the velocity at which a falling dust grain ceases to accelerate, at that same moment the little body will be raised and join in the company of millions of such particles that go to

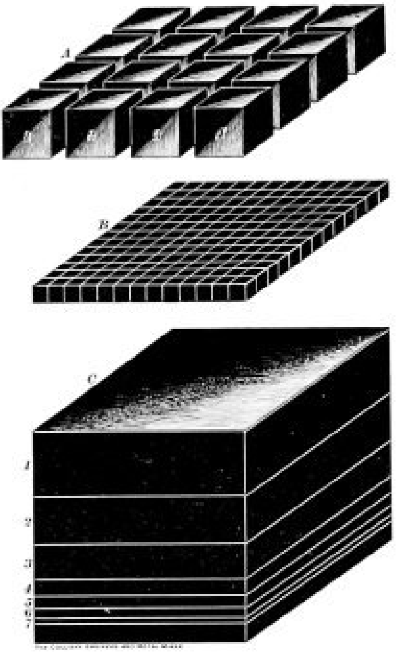

FIG. 137.

make a dust cloud. The subject under investigation, namely, the classification of dust particles, will increase in interest as the manifest importance of the question develops, and therefore, let us recapitulate, with questions and answers, the facts of importance in this lesson, and thus secure a tight hold of the principles to be mastered.

99. Recapitulation of Facts and Principles.—QUES. 1. Does the speed of a body accelerate as much when falling through air, as it does when falling in a vacuum? And if not, why not?

ANS. A body does not accelerate as much in feet per second, when falling through air as it does when falling in a vacuum, because air in common with all matter has weight, and therefore work has to be done in overcoming its inertia in displacing it, and as time is required for the inert air to close in on the rear side of the falling body therefore such a body is subject to a greater resistance on its rear than on its bottom side, and this resistance retards the bodies motion by neutralizing a portion of the earth's attraction. A body falling in a vacuum, is not subject to a greater resistance on its rear than on its front side consequently it is subject to the whole of the earth's attraction, and accelerates at the rate of 32.16 feet per second.

QUES. 2. How does it happen that in calculating the resistance due to a body falling through air, $2g$ instead of g is used, or 64.32, instead of 32.16, for the acceleration in feet per second?

ANS. The constant g, or 32.16, is the equivalent of the earth's acceleration during the period when a body is falling, and to find the energy *stored* in a moving mass, the expression $\frac{v^2 w}{g}$ supplies it, but this is the equivalent of what is called the *vis viva* or the total energy stored in a mass moving with a given velocity.

The *vis viva* is not even the equivalent of pressure, for the moment the moving mass begins to overcome resistance or do work, then the *vis viva* is converted into executive or kinetic energy, having the mean value of $\frac{v^2 w}{2g}$ foot pounds. *Vis viva* is the equivalent of inertia and is therefore more closely allied to momentum than kinetic energy; for example, let a small hammer weigh half a pound, and suppose a man to bring it down on the head of a nail with a velocity of 100 feet per second, and further suppose the nail to advance $\frac{1}{8}$ of an inch with the blow, then the pressure through the distance of an eighth of an inch will be 96 times, that exerted through the space of one foot, or $\frac{100 \times 100 \times .5 \times 96}{64.32} = 7{,}462$ pounds. Or, one blow of the hammer does 7,462 *one-eighth of inch* pounds. We see, then, if work is done through even such a short distance, the *vis viva* energy becomes kinetic.

QUES. 3. What is meant by the "surface of suspension?"

ANS. The surface of suspension is the end surface of a falling body, and the upper surface is the real suspender, because the resistance due to the vacuum over the upper end is much greater than the resistance due to the compression under the bottom end. The extension of the surface of suspension varies for the same weight, inversely as the specific gravity of the substances that fall, and it is greater for spheres and cubes than for bars and cylinders.

QUES. 4. How do you find the velocity at which a falling body will cease to accelerate?

ANS. The velocity at which a falling body will cease to accelerate is the one that will develop a resistance on the surface of suspension equal to the weight of the body that is falling, and the required velocity is found as follows: Let the weight of a cubic foot of coal be 80 pounds, the surface of suspension one square foot, the pressure of atmosphere 2,120 pounds per square foot, and let the square of the velocity of air rushing into a vacuum be 1,800,000, then we find that $\sqrt{\frac{1{,}800{,}000 \times 80}{2{,}120}} = 260.623$ is the velocity at which a cubic foot of coal would cease to accelerate.

QUES. 5. Are the surfaces of suspension in the same proportion to the weights of large and small cubes of the same material, and if not, how do they differ?

ANS. For the same material of any kind, the surfaces of suspension of cubes vary as the cube roots of the contents or inversely as the weights of the cubes. For example, cut up a cubic foot of coal into eight cubes, then the proportion of the surface of suspension to the weight will be for the little cube $\sqrt[3]{8} = 2$; that is, the proportion of the surface of suspension to the weight in the little cube is twice that of the large one.

QUES. 6. Is there any relationship with regard to the limiting velocities of cubes or spheres of different contents or weights?

ANS. Yes; there is such a relationship when the cubes or spheres are of the same material; and that is, the limiting velocities are directly as the cube roots of the weights or contents. For example, the limiting velocity of a cubic inch of coal is 75.24 feet per second, and a little cube of coal has a content equal to the $\frac{1}{425{,}938}$ of a cubic inch; or, the weight of this little cube is $\frac{1}{425{,}938}$ of the weight of a cubic inch of coal; then the limiting velocity of the little cube is $75.24 \times \sqrt[3]{\frac{1}{425{,}938}} = 1$; that is, the limiting velocity is 1 foot per second.

MINING MACHINERY.

The Hydraulic Main or Delivery Pipe of a Pump—The Connection of the Intermittent Flow—Rod and Plunger Pumps—Recapitulation of Facts.

113. The Hydraulic Main or Delivery Pipe of a Pump.—It is possible to fix a larger pump for the discharge of a greater volume of water, and find when it is done, and tried, that its pumping efficiency is not equal to that of the old one. Now it is true that many causes might be assigned for this failure, but in this case, there is only one to be found; for the total steam pressure in the piston is sufficient for a greater output, the intake and discharge valves are in good order, and the waterways through them are quite sufficient to prevent constriction, and stranger still, the modulus of mechanical effect is equal to that of the best pumps in use; but the one cause of failure in pumping efficiency is found to be this, the diameter of the delivery pipe is too small, and therefore, instead of the pump piston making twenty strokes a minute, it is only making ten. The meaning of all this can be understood with the help of Fig. 147. Here a large pump piston is seen at *P*, whose diameter is three times that of the delivery pipe *H*, and in consequence of this disparity in size the velocity of the flow through the delivery pipe is nine times that of the speed of the pump piston, and when we consider the friction due to such a rapid flow and the resistance due to the acceleration out of the pump cylinder into the delivery pipe, we discover the true cause of the small pumping efficiency of the pump under notice.

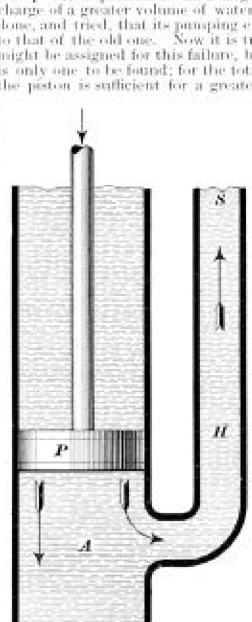

FIG. 147.

For as the steam pressure is constant, and the water head of delivery is constant, and the resistance due to the flow, a variable that increases as the squares of the velocities of flow, it is clear that the variable resistance of the flow will act the part of a regulating governor, restricting the speed of the pump piston to a velocity it can never exceed without an increase in the pressure of the steam. It might be suggested to increase the steam pressure, but to double the pumping efficiency, the total pressure on the steam piston would have to be much increased, and such a mode of proceeding means a large reduction of the modulus, or a small working efficiency of the plant. We see then that the diameter of the pump piston cannot be taken alone to determine the volume of water a pump will lift and discharge in a minute, unless the hydraulic main or delivery pipe is sufficiently large in diameter to run off the flow at a relatively low velocity.

All this, however, is simply a statement that may be on the one hand the writer's *opinion*, but, mere opinions in practical mechanics are not worth the paper they are written on, unless they are the conclusions and deductions from *actual* observations wherein the operations of mechanical law decided the results, for then the statements are based on facts that command respect and attention, and this is the case we claim. There are two factors in the application of steam power that require our closest attention, and these are the *mean effective pressure* throughout the stroke in pounds per square *foot*, and the total volume of the steam in cubic feet per minute after it has expanded; for by the use of these factors the power and also the balance required for the water head plus the resistance due to the flow can be determined. To make this clear let us suppose the mean effective pressure is equal to 30 pounds per square inch, then that would be equal to $144 \times 30 = 4{,}320$ pounds per square foot. Again, let us suppose the volume of expanded steam to be equal to 764 cubic feet, then the horse-power will be equal to $\frac{Q\,P}{33{,}000}$ = the horse-power, or, $\frac{764 \times 4{,}320}{33{,}000} = 100$. Again, $\frac{33{,}000 \times \text{horse-power}}{Q} = P$, and $\frac{33{,}000 \times \text{horse-power}}{P} = Q$.

From these equations we can detect that a steam engine cannot do more work than that due to the volume of steam supplied at a given pressure, and that the boiler cannot generate more steam than that due to the heating surface of the boiler, when the heat supply is normal; further, as the pressure of the steam is stationary, it cannot overcome a resistance greater than that of the balance of the total pressure on the piston. Again, the work done is directly proportionate to the volume of the steam consumed. This being the case, let us carefully notice what follows. First, then, the total steam pressure on the engine piston cannot overcome a resistance that makes the load greater than the pressure, and as the pressure is stationary, so must the resistance remain stationary, for should the latter increase, then the engine would stop, being overpowered by increased resistance. As the resistances due to the movements of fluids vary as the squares of the velocities, then it follows that when the delivery pipe of a pump is too small, a relatively low velocity of the pump piston, by the rapid flow of the column, will develop a resistance, which added to the head, will balance the pressure of the steam on the engine piston; and under these circumstances a small volume of steam will be consumed and a small volume of water will be pumped; for the pump piston could not be run at a much higher speed without a *very great* increase in the pressure of the steam, for in this case to increase the pumping efficiency you must increase not only the volume of disposable steam, but also its pressure. From these facts we learn then that the modulus of a pump, with a delivery pipe of small diameter, may be as high as that of a pump with a delivery column of large diameter; and we must confess that this singular circumstance is misleading, yet we know that the *pumping* efficiency of the pump with the suction and the delivery pipes sufficiently large, is much greater than when they are too small.

114. The Connection of the Intermittent Flow.—When a pump is single and even double-acting, the flow through the column of pipes is always variable in its velocity, and it is claimed that some energy is lost as the result of the force required to set the inert column in motion, but during the period when the stroke is ending, the *vis viva* of the moving water is converted into kinetic energy that assists the pump piston on to the top of its stroke. Apart from this, however, there is a loss due to the acceleration of the column during the stroke, for as the friction varies as the squares of the velocities, it is easy to see that a uniform flow for the discharge of the same volume of water must be subject to a smaller frictional resistance than an intermittent one, and therefore, to secure a uniform flow when the pump piston or pistons are variable in their motion, an air vessel is introduced to equalize, by the elasticity of an air cushion, the pressure of flow; and such an instrument, typical of the forms in use, is seen in vertical section in Fig. 148. To understand its mode of action, we must first consider that, ac-

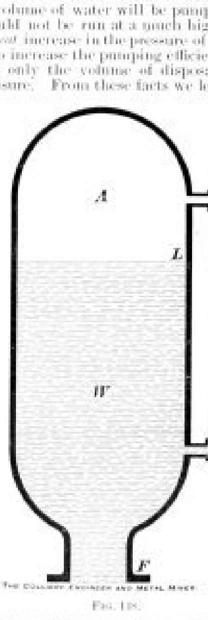

FIG. 148.

cording to Boyle's law, the volume of the air at *A* will be inversely as the pressure; and the result is, if the pump is started with the air vessel empty of water, when the column reaches the elevation of overflow, the air that filled the vessel will be compressed into a small volume; and so much is this the case that if the air vessel was a cylinder of uniform diameter, and the head of column, measured from the level *L*, in the air vessel, to the level of overflow, was 476 feet, then the air would be compressed to the $\frac{1}{15}$th of its former volume, for $\frac{476}{34} = 14$ atmospheres, and as there was in the air at first a pressure equal to 1 atmosphere, $14 + 1 = 15$. Then, suppose the air cylinder to be 8 feet in height, it will now be seen that $\frac{8}{15} = .533$ feet, the depth of air in the cylinder, or it would be equal to $\frac{8 \times 12}{15} = 6.4$ inches. In the figure, *A* is the air space, and *W* is the water space. For two reasons, a useful air vessel is furnished with an air replenisher, and that is a pump to force as much air into the vessel as will make it act as a spring of *long range*, for we must admit that 6 inches is so small that it is not likely to have a cushion range of more than an inch, whereas, if the vessel is half full of compressed air, it may and does attain a range of 8 or 10 inches. Another reason for the use of the replenisher is this: *Compressed air* is soluble to a greater extent in water; than air at atmospheric pressure, and, therefore, when the replenisher pump is not used, the air is soon dissolved out, and then the air vessel is said to become solid. When a replenisher is used, a gauge glass is fixed to one side of the air vessel, as *G T*, and then the level in the gauge at *l* always coincides with the water level *L* within the vessel.

115. Rod and Plunger Pumps.—The rod, plunger and lift pumps are fast passing out of use, and with them, no doubt, will pass away the old Cornish pumping engine. However, they are still in use and the mining engineer cannot therefore disregard them yet. In shallow shafts where great volumes of water had to be lifted, two lift pumps with alternate action were made to do the work, and where the shafts were deep a lifting pump was fixed for the bottom range and then followed in succession the plunger or forcing "sets"; and set in recesses in the shaft side were balance bobs, for relieving the engine of the weight of the heavy wooden rods. What, however, is interesting to us just here, is what is called the H piece *D X Y*, Fig. 149, that is, a single piece of cast iron called the *H* piece, from its resemblance to that letter. The plunger *P*, works through a stuffing box and gland, and is here shown on the up stroke, and the suction water is seen passing up the suction pipe *S*, and on through the suction valve *V*. The *door* at which the suction valve is changed when out of order, for another in order, is seen at *d*. The delivery valve *V*, is seen to be shut, for it only opens during the period of the downstroke of the plunger. At *D* is the door for changing the "check" or "keep" valve. *T* shows the wooden buntons for for supporting the delivery column *H*. In Fig. 150, we have an illustration of what is called the plunger and lift pump. The object of this arrangement is to maintain a continuous flow in the delivery pipe *H*, and to so balance the motor steam engine, and pump rods, that no more work is done on the downstroke than on the upstroke, and this is secured as follows: First then if there were no pump rods to balance, on the upstroke, the displacement of the plunger would be made to be equal to half the water lifted, and therefore on the downstroke, when the pump piston was lifting no water, the plunger would, as shown in the figure, displace the other half of the water lifted on the upstroke, but where the rods have to be balanced the plunger is made larger in diameter, as for example, take the first case and suppose the diameter of the pump piston to be 24 inches; then the diameter of the plunger should be $\sqrt{\frac{24^2}{2}} = 17$ inches, nearly. By this arrangement the piston displaces on the upstroke with an area of 288 circular inches, that is $\frac{24^2}{2} = 288$ and the plunger displaces on the downstroke with an area of 288 circular inches, so that the flow is the same on the up and down strokes. But let us suppose that the displacement of the plunger has to be such that it will balance the pump rods weighing 10 tons, or $10 \times 2{,}240 = 22{,}400$ pounds.

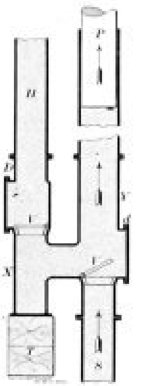

Fig. 149.

The pressure of the head per circular inch will be, when the head is, as in this case, 250 feet; $250 \times .341 = 85.25$ pounds, and therefore the piston or end area of the plunger, to balance the rods, must be equal to $\frac{22{,}400}{85.25} = 262.76$ circular inches. On the down stroke the weight of the rods assists the steam, and on the up stroke the steam has to lift them; the result is, the engine can exert 20 tons more pumping pressure on the down stroke than on the up stroke, and therefore $\frac{2{,}240 \times 20}{85.25} = 525.51$ circular inches must be provided for in piston area for balance alone, and as the area of the pump piston is 576 circular inches, there must be pumped or delivered on the up and down strokes a volume in the proportion of $\frac{(576 - 525.5)}{2} = 25.25$ circular inches. The total area, then, of the end of the plunger must be $525.5 + 25.25 = 550.75$ circular inches, and therefore the diameter of the plunger will be $\sqrt{550.75} = 23.46$ inches.

In pumps of this character, the piston is joined to the plunger with a sword, or toothed joint, *S*, and the two sides of sword are locked securely by the clasp *C*. The door for changing the piston and suction valve is seen at *D*, the plunger is shown at *P*, and the delivery pipe at *H*.

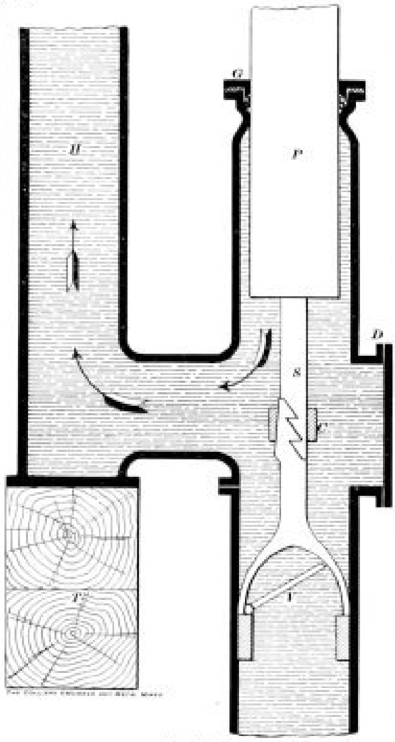

Fig. 150.

116. Recapitulation of Facts.—Ques. 1.—What forces fix the limit of the velocity of a pump piston?

Ans.—There are two forces that control the velocity of the pump piston. The first one is the pressure of the steam, or of any other prime mover; and the second is the resistance of the flow; for after a portion of the pressure balances the water head, the remaining portion can only overcome the resistance of a fixed velocity of flow.

Ques. 2.—How should the diameter of the delivery pipe be proportioned to the diameter of the pump piston?

Ans.—The diameter of the delivery pipe should never be less than the diameter of the pump piston, for if it is so, one of two things must happen. First, the pumping efficiency will be reduced; or, second, the resistance and the pressure of the steam will be very much increased and the pump will have a small modulus of useful work.

Ques. 3.—If the delivery pipe has too small a diameter, and the pressure of the steam is not increased, what will occur?

Ans.—The consumption of steam will be reduced and the pumping efficiency will be reduced in the same proportion as the volume of the steam is reduced.

(To be Continued.)

CHEMISTRY OF MINING.

The Vertical Parallelism or Flames—Forms of Lamp Glasses—The Volume in Relation to the Surfaces of Gauze Cylinders—Commendable Improvements in Lamps—Recapitulation of the Principal Facts.

100. The Vertical Parallelism of Flames.—The flame of a candle or lamp is really a stream of white hot gas, produced by the heat resulting from its own combustion. The gas from fats and oils is generated at the portion of the wick that is situated within the flame, and as the gas escapes from an extended surface, it never attains a velocity into the flame, equal to that of coal gas ejected through a narrow slit in a burner; the result is, the flame of a candle or lamp is always vertical, while the longer axis of the flame from a gas burner may lie nearly horizontal, as the result of the swiftly ejected gas having become ignited before its momentum is expended. The gases that constitute the flame of a lamp, while in a state of incandescence, are much lighter than the cold air in which they float, and the result is, you may cant the candle or lamp, but you cannot cant the flame, and as this is so, it does not require much mental effort to find that the radius of a lamp glass must be so proportioned that the flame can never lick the inside surface of the glass enclosure, for if it is allowed to do so, two things must occur: the glass will be blackened with the sooty smoke of the flame, and as glass is a bad conductor of heat, it will be cracked by the uneven expansion due to the flame heating excessively one point in the shell.

We see then, that when the lamp is held in a truly vertical or normal position the flame is parallel to the axis of the lamp, but if by some accident, ever liable to occur, the lamp should fall on its side, then the flame will be parallel to the vertical radius of the lamp glass, and if the radius of the glass should be too short for the flame, or the flame should be too long for the radius, then the glass would be blackened and cracked even at

Fig. 139.

an angle of inclination of 45° from the vertical, and it is to explain this fact that Fig. 139 is introduced. It will be seen that at *A* the flame fails to reach the glass when the lamp is canted through 45°, and at *B* it just touches, while at *C* both the effects are sure to follow that attention has been drawn to.

101. Forms of Lamp Glasses.—After this we discover that it is no easy matter to determine the form and dimensions of a good lamp glass, and yet we cannot fail to see that little attention has hitherto been given to the matter. Before proceeding further with the investigation let us renotice the principles already treated on. First, then, we found that we should have a maximum length and minimum diameter for the glass, to secure the greatest possible diffusion of light on the roof and floor. Second, a thick glass aided diffusion by increasing the refraction of the light. Third, that a thick glass, or one with an extended surface, offered a greater resistance to the passage of light than a thin glass, or one with a relatively small surface; and now the fourth principle is before us, and it involves the relationship of the radius of the glass to the length of the flame. Now, keeping in view the fact that the glass with the minimum radius secures at once the greatest amount of diffusion, and the least resistance to the passage of light, we should try to find a glass with a minimum top and bottom diameter, and yet to have its sides sufficiently out of the range of the tongue of flame, in the event of the lamp being canted, and to clearly show what is here meant, Fig. 140 is introduced. At *D* a spheroidal glass is shown with the required small top and bottom diameters, and should the lamp from any cause be turned on its side, the tip of the flame *c* during the act of turning would sweep through the arc *c a d*, and when the tip reached *d* it would not touch the inside surface of the glass; had, however, the glass been cylindrical its side would have coincided with the dotted line *e f*, and in that case after the lamp had turned through about 40°, the tongue of the flame would have touched the glass at the point of intersection *a*. At *E* we have a glass that only bulges in the neighborhood of the flame, and it certainly looks more retiring and appears to be more like a befitment for the conditions. Here the tip of the flame would describe the arc *h g l*, and had the glass been a cylinder, its inside surface would have been continued along the dotted

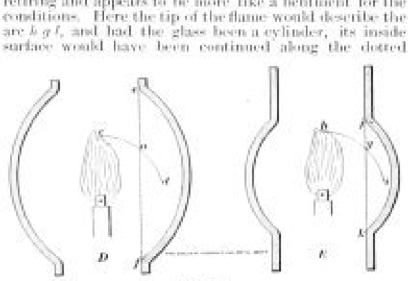

Fig. 140.

line *j k*, and the tip of the flame, after turning through an angle of 40°, would have touched the glass at the point *g*; but it will be seen that in this, as in the other case, the tip of the flame could not touch the glass even if the lamp was turned on its side. These spheroidal glasses look very well in theory, and especially when disassociated with the fact that glasses having large surface areas are great wasters of light; but in practice they would be very disappointing unless some one could guarantee a special make of glass that had a toughness and an elasticity such as no glass was ever known to have before. Glasses of these peculiar shapes are more subject to unequal heating, and consequent unequal expansion, than cylindrical ones. This can be seen by observation and consideration, for let us notice that the spheroidal or belly portion of the glass is cooler under normal conditions than the cylindrical ends, and especially the upper one, through which passes the heated gases from the flame, for here the area is so constricted that the higher temperature causes end expansion, and the frequent rupture of the glass. We see, then, that the safety of the glass shell becomes a matter of serious thought and cannot be overlooked in this investigation.

102. The Volume in Relation to the Surfaces of Gauze Cylinders.—The volume of the gas and air space within a lamp is a matter of serious consideration, for if it is too large, then the oxygen of the entering air is only partially consumed, and, therefore, when the air is charged with marsh gas, and highly heated, the mixture explodes. This has been proved by painful experience, where large Davy lamps have been used. In some cases the writer has seen the gauze of a Davy lamp no less than 3½ inches in diameter and 9 inches in length, and such were the dimensions of the Blantire lamps in Scotland, at the period when the last explosion occurred in that mine. Now, when one of these lamps was placed in a still, or motionless explosive mixture, it fired instantly, and, as we might expect, when a smaller Davy with a gauze $1\frac{1}{2}$ inches in diameter and 6 inches in length was tested under the same conditions, it remained in the mixture from 2 to 3 minutes before it fired, and some Davy lamps withstood the test for a longer time. Let us just compare the two volumes under notice, and to make the matter easy, we will take the relative and not the actual volumes, as

Blantire Davy $= 3.5 \times 3.5 \times 9 = 110.25$.
Improved Davy $= 1.5 \times 1.5 \times 6 = 13.50$.

That is, the contents of the Blantire are 110.25, and those of the improved Davy, 13.5 cylindrical inches, or, the contents of the Blantire gauze were 8 times those of the improved Davy. There are two reasons why the large gauze is dangerous. First, every square inch of gauze is subject to a higher temperature in the large than in the small gauze cylinder, and this can be proved by dividing the contents by the surface of the gauze in each of the two cases, as

$$\text{Blantire} = \frac{3.5 \times 3.5 \times .7854 \times 9}{3.5 \times 3.1416 \times 9} = .875.$$

$$\text{Improved} = \frac{1.5 \times 1.5 \times .7854 \times 6}{1.5 \times 3.1416 \times 6} = .375.$$

We thus see that the heat produced in the large gauze is $2\frac{1}{3}$ times greater per square inch of surface than in the small gauze, for $\frac{.875}{.375} = 2\frac{1}{3}$. Second, in the event of an explosion within the gauze, the flame will not only pass easier through the meshes of the large gauze, but the volume of the flame ejected will be 8 times greater than that of the small one.

103. Commendable Improvements in Lamps.—We cannot but commend real improvements in lamps, and especially departures in the right direction, and here is one of them, that gives a distinctive character to a modified Mueseler lamp, Fig. 141. In it the air to support the combustion of the oil is made to pass down short poles outside of the glass cylinder, and we may rest assured that by this arrangement one good result will be secured, and that is, a better motive column to aid combustion and improve the light. In the old Mueseler, the air to feed the flame first passed through the meshes of the lower end of the gauze cylinder, and then continued on its course through the sheet ring of gauze, called "the diaphragm," and down the glass cylinder to the flame, being impeded all the way with the object of securing the complete isolation of flame. In the Mueseler lamp, however, as in some others, safety was secured by the sacrifice of a good light, and therefore, we admire the improvement here introduced.

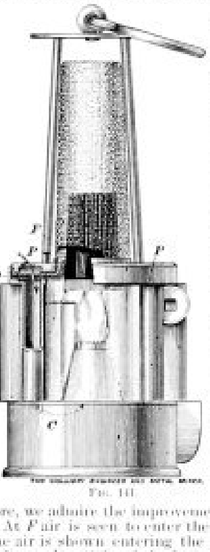

Fig. 141.

At F air is seen to enter the old way, and at P and P the air is shown entering the top ends of the tubular poles, and at C the air is shown leaving the bottom ends of the poles, and, as in the line of the arrow C, we observe it entering a hollow cone, whose top restricts the air stream, and projects it directly onto the flame.

Fig. 142 is a combination of the Gray and the Marsaut lamps, but instead of the air being conducted down the main poles of the lamp frame, a special funnel P is provided, so that when gas testing is required P can be turned up, and a sample of the stratum of air floating under the roof can be conducted right onto the flame. The funnel turns in a vertical plane on the axis H. W is the gauze within the bonnet. O O are ports for the entry of air when the funnel is out of use. This lamp, too, is suggestive of future improvements.

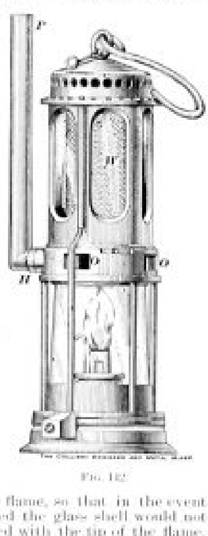

Fig. 142.

All the witnesses on the trial of the lamp glasses are not yet examined, therefore the trial is again postponed.

104. Recapitulation of the Principal Facts.—Ques. 1.—In what way does the flame in a safety lamp affect the length of the radius of the glass shell?

Ans.—As the axis of the flame in a safety lamp is always vertical, the radius of the glass should be longer than the axis of the flame, so that in the event of the lamp being overturned the glass shell would not be cracked by being touched with the tip of the flame.

Ques. 2.—What are the advantages and disadvantages of bulging or spheroidal glasses?

Ans.—The advantages of bulging glasses are that they can be so contracted in their top and bottom diameters as to greatly assist in the diffusion of the light; and their disadvantages are, they reduce the intensity of the light by an over extended surface, and they are liable to crack as the result of their tendency to unequal expansion.

GEOLOGY OF COAL.

The Miner's Interests in Geology—The Origin of Metallic Ores in Veins—The Nature of the Contents of Veins.

60. The Miner's Interests in Geology.—The miner who has push and enterprise in his make-up has a better chance of securing a competency than a man in almost any other profession, for with "Aladdin's" wonderful lamp of knowledge in his hand he can discover the hiding places of nature's boundless treasures.

Not long ago courage and endurance were the prime factors that made successful men, but now such a man requires, in addition to the qualities named, to be learned in the cunning revelations of science, for it is through these that the light shines that dispels the darkness that conceals the rich productions in nature's laboratory. It is strange, and nevertheless true, that notwithstanding the great value and importance of geological knowledge, few men can be persuaded to obtain it. We do not doubt that the cause of the neglect is to be found in the lack of a good, and useful, and interesting literature, especially adapted to the miner's wants, but let him make the best use he can of the supplies of knowledge within his reach and then he cannot fail to reap a handsome reward.

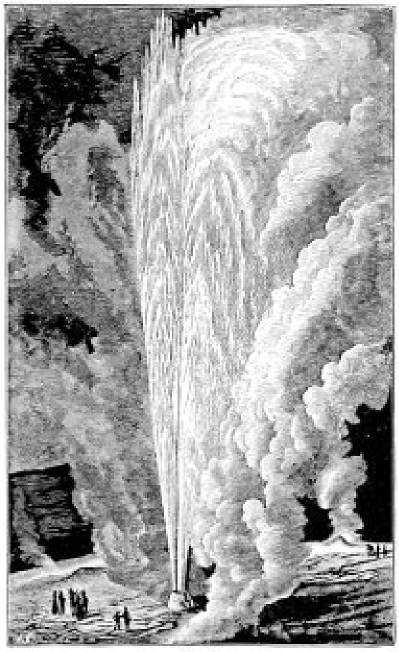

Fig. 98.

61. The Origin of Metallic Ores in Veins.—The science of chemistry, aided by observation, is rapidly removing the veil that concealed the origin of the storage of metallic ores in veins, and in the interstices of certain rocks. We cannot, however, think about the matter even in a cursory way, without coming to the conclusion that the special localization of the ores in veins and in the joints of rocks to which they were peculiar, was not accidental but entirely the result of the operation of forces that may be investigated. The ores, then, have only been deposited where suitable conditions existed for their selection, collection and deposition, and therefore let us here try to find the origin of the conditions under notice; and to assist in the investigation of the matter, let us proceed with the help of Fig. 98. Here we have a natural fountain of boiling water that springs up through a vent whose mouth is surrounded by a hive-like incrustation of silica.

We cannot look at this geyser without feeling a desire to find the answers to some questions its appearance and phenomena suggest, such as: What is the required pressure of the steam that ejects with such force this mighty jet of water? From whence comes the supply of water for the outflow? What kind of chemical and solvent action will boiling water have? What produced the silica hive at the mouth of the vent? And will this incrustation be the result of the same mode of action as the quartz found crystallized on the cheeks of veins?

The pressure of the steam that throws the jet of the geyser to such a great height cannot be measured by the vertical length of this water column, because the resistance of the air, and the expansion of the associated steam, break up the liquid stream into such finely divided particles that the vastly increased surface exposed to atmospheric resistance is enormous, and therefore the height of the jet is far short of that of a solid vertical stream, that would equal the initial pressure of the steam as it was generated in one of the earth's hot rock caldrons, situated far beneath the depths of the deepest stratified rocks. If we claim that the pressure of the steam that tossed up the geyser was considerable, then we must admit that the temperature of the steam at the moment of its production must also have been far higher than any of the sensible temperatures of the steam artificially made, for it is now well known that all temperatures have their corresponding pressures.

If the pressure, and consequently the temperature, of the steam, as generated in the deep hot caverns of the earth, was very great, and we cannot doubt the conclusion, then we can see how silica, lime and the chlorides of the metals and other mineral compounds, have been carried up by the hot solvent waters from the depths of the nether rocks. Again, we can see without an effort of the imagination, that the minerals in solution would crystallize out as they became insoluble through the falling temperature of the water that contained them.

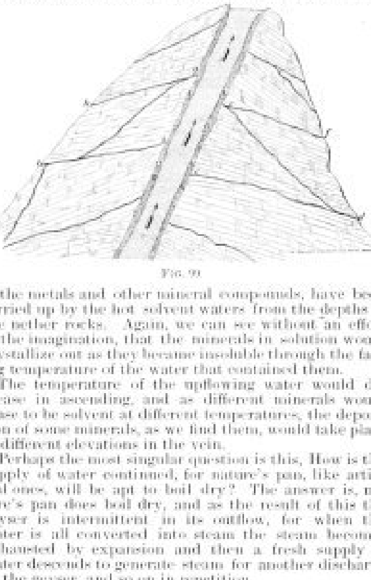

Fig. 99.

The temperature of the upflowing water would decrease in ascending, and as different minerals would cease to be solvent at different temperatures, the deposition of some minerals, as we find them, would take place at different elevations in the vein.

Perhaps the most singular question is this, How is the supply of water continued, for nature's pan, like artificial ones, will be apt to boil dry? The answer is, nature's pan does boil dry, and as the result of this the geyser is intermittent in its outflow, for when the water is all converted into steam the steam becomes exhausted by expansion and then a fresh supply of water descends to generate steam for another discharge of the geyser, and so on in repetition.

We can now see what produced the silica hive-like incrustation around the vent of the geyser, for this is a portion of the silica that was soluble in the very hot waters of the jet, and has become insoluble and crystalized as these waters cooled, and we now learn that the earth's heat has been the principal agent in the selection and deposition of the metallic ores in veins, and to further sustain this conclusion Fig. 99 is introduced.

62. The Nature of the Contents of Veins.—The funnel of a geyser is one thing and the fissure of a vein is another, and therefore we do not expect to find a vein pouring out a great vertical sheet of water, as a geyser throws up a column; but one thing remains common to both, and that is that they alike are channels for the upward passage of hot waters containing mineral matters in solution.

The vein, however, could only be once filled with water, and if a still further upflow continued it would overflow, unless channels were provided for the escape of the excess; and such channels actually exist, for it is the universal experience that the most productive veins are now, or have been at the time of filling, above the drainage level of the region, and the escape or outflow arteries of the containing rocks are such as *h g*, *j i*, *e f*, *c d* and *c d*. The upflow of hot water at the time of the filling of the vein is shown by the arrows, and the crystalization proceeding in the sides of the vein is shown at *a a*, *b b*, etc.

(To be Continued.)

Pipe For Mining Purposes.

The Michigan Pipe Co. of Bay City Mich., the largest manufacturers of Wyckoff (wood shell) pipe in this country, or for that matter, in the world, make their first appearance as advertisers in this issue of THE COLLIERY ENGINEER AND METAL MINER.

The pipe manufactured by this company has had the test of years of service to prove its durability and strength in conducting sulphurous and mineral waters in places where metallic pipe would stand the action of such waters but a few months. Besides water pipe, they make steam pipe casing, bored from solid logs, which is adapted for covering steam pipes in mines and underground work. They furnished the steam pipe casing for the steam heating plant in this city (Scranton), and for all the other steam heating plants built by the American District Steam Company of Lockport, N. Y.

The Michigan Pipe Company has a creosoting plant and manufactures and treats with dead oil of coal tar, conduits for underground electrical wires which are in use in the large cities where wires are buried.

An Injunction Granted.

Judge Dallas, of the United States Circuit Court, filed an opinion on the 6th ult. granting the Ewart Manufacturing Co. a preliminary injunction against James H. Mitchell, restraining the defendant from the manufacture of an infringement of the plaintiff company's patented chain, which is known as the Dodge chain, and which is legally manufactured by the Link-Belt Engineering Co. of Philadelphia and the Link-Belt Machinery Co. of Chicago.

Hose.

The Boston Belting Co., has just issued handsome and convenient little catalogues of superior hose for fire purposes at mines, as well as for municipal fire departments. As a hose for use at coke works, the Boston Belting Co.'s brands stand unsurpassed for durability.

MISCELLANEOUS.

MEXICO'S FLOATING GARDENS.

Tourists who come to Mexico always go to see the floating gardens. But they never see them. The whitest-haired old man now living, if he remembers them at all, recalls them faintly, for this century has seen few of them. Still the floating gardens or "chinampas" in the musical language of the Aztec, are a never-ending attraction to the sightseers, who visit this ancient capital, although, contrary to popular belief, the floating gardens at Santa Anita and Ixtacalco do not float.

Many years since, however, in fact, before the conquest of Mexico by the Spaniards, the name was appropriate, for real floating gardens were then common on the lakes in the valley of Mexico, especially in the immediate vicinity of the city. But when Humboldt visited Mexico (then called New Spain) in 1803, and Abbe Francisco Clavigero, a missionary among the Indians, a few years later, these peculiar possessions of the Mexicans were rapidly diminishing in number, and in 1826, Captain G. F. Lyon informs us that "the little gardens constructed on bushes or wooden rafts no longer exist in the immediate vicinity of Mexico (the city); but I learned that some may yet be seen at Hochimilco." As late as 1888 two or three floating islands still existed in Lake Chalco, and can probably be seen there today. There are no others known now.

Abbe Francisco Clavigero describes the true floating gardens as follows:

"They plait and twist willows and roots of many plants or other materials, together, which are light, but capable of supporting the earth of the garden firmly united. Upon this foundation they lie the light bushes, which float on the lake, and over all, the mud and dirt, which they draw from the bottom of the same lake." The common form was a quadrangle, and the average size about 12 by 40 feet, although some of the largest were 100 feet in extent. Many of the latter contained a small hut, in which the cultivator sometimes lived. One or more trees were also growing in the centre of these largest plots. The earth used was extremely rich, and this being kept in a moist state by its proximity to the water and capillary attraction, (the elevation above it being not over a foot), the gardens were productive of the choicest vegetables and flowers, including also maize.

The gardens of the present day are very different affairs. They do not float, but, on the contrary, are composed of strips of solid ground, usually about 15 by 30 feet in extent, although some are larger.

These plots are intersected by small canals, through which visitors are propelled in canoes. They are constructed by heaping up the earth about two feet above the water. Willows and sometimes poplars and silver maples, also a species of cane, are often growing along their banks to keep them from washing down.

The nearest gardens to the City of Mexico are along La Viga Canal, a public waterway, about forty feet in width and of varying depth. Its source is in Lake Hochimilco, two and a half miles south of the city, whence it flows through the town and by a circuitous route to Lake Texcoco. The gardens are located where the ground is naturally low or swampy.

All produce the choicest vegetables, flowers, and not infrequently fruits in great abundance, embracing nearly every variety grown in the United States, and others unknown there. Even in the ditches or little canals beautiful water lilies often line the way, while many of the plots are one mass of vari-colored flowers, the most common ones being roses, pinks, geraniums, poppies and fuchsias. The great variety of shades and the enormous size of many kinds astonish and delight the visitor from more northern latitudes.

The poppies are more attractive than the finest Northern peonies. On certain feast days every one wears a wreath made exclusively from these showy flowers.

The quick and luxuriant growth of the products is mainly due to the daily application of water, which is dipped up in gourds attached to long swinging and pivoted poles, and deftly thrown about.

Little is certainly known regarding the origin of these famous places. Abbe Clavigero says that when the Mexicans were driven from their native country, ages in the past, they were forced to occupy small islands in Lake Texcoco, where "they ceased for some years to cultivate the land, because they had none, until necessity and industry together taught them to form movable fields and gardens, which floated on the waters of the lake. These were the first fields which the Mexicans owned after the foundation of Mexico." The custom may have originated as above stated, but the following view, founded on a careful examination of some of the oldest works on Mexico, is advanced as the more probable, especially since the Mexicans still retained and cultivated the watery plots after their independence was again established.

For long ages the valley of Mexico was subjected to devastating inundations. The valley is about sixty miles in width, and is surrounded by a continuous wall of hills and mountains. The waters collected on these flow into six principal lakes. The Plaza Mayor, or great square in the City of Mexico, is elevated a few feet only above the nearest lake—Texcoco. In former times a prolonged rainy season caused the surplus waters in the other lakes, which have an elevation of from three to thirteen feet above the Plaza Mayor, to burst their banks and flow into Lake Texcoco, which, in turn, overflowed and flooded the valley. In June, 1629, the date of the last great flood, the city was covered with water to a depth of three feet, and it remained in that state for five years.

The regular fields were, of course, ruined whenever a freshet traversed the valley, and necessity finally compelled the people to depend upon floating gardens for a supply of produce at all seasons and to prevent a famine. These were moored in places where the rise and fall of the lake waters would not affect them. During the period when floods were looked for at any time these floating patches were very common, but when the city and valley were partially protected by a gigantic canal in 1789 (commenced in 1607), by which the main overflow was carried off in safety, they gradually disappeared, until at the present time nothing but the pretty name and stationary plots surrounded by water remain to perpetuate an ancient custom.

WHY THE WINDS OF MARCH GIVE PLACE TO SHOWERS.

The weather conditions prevailing in April indicate a transitional state between the winter and summer seasons, with the winter types, on the whole, more vigorous. The contrast between March and April may therefore be mentioned, in order to explain the modification in the weather now setting in. The most prominent feature on the whole, is the drifting of the Rocky Mountain area of high barometric pressure to the northeastward, nearly into the Lake Region, and the supplying its place by the more permanent area of low pressure that enters the region from the southwest, intruding northward from the Gulf of California. The result of this change is to transfer the discharge of cold air from the interior of the continent, where it still lingers near the Hudson Bay, from the western to the eastern side of the lakes. Hence sudden outflows of cold winds occasionally advance over the Middle States and New England, by which one is reminded that winter has not yet gone from those districts.

In contrast with these cold northwest winds of the east, it is found that strong warm winds prevail in the southern and the Rocky Mountain districts. They are often of great velocity and carry immense quantities of sand and dust over the plains to the northward. These may be called "southers," in distinction from the "northers" of winter, which prevail in Texas and Arkansas. An attendant feature of the south wind is to carry the lines of equal temperature, the isotherms, rapidly to the northeast, from Texas to the lakes, causing hot weather in the Mississippi and the Missouri Valleys, often in unseasonable severity. This process may go so far as to make conditions for severe local storms, thunderstorms and tornadoes in Missouri, Iowa, Illinois, and would no doubt do so more frequently if the air were sufficiently charged with moisture, which does not always happen at this time in the spring.

At any rate, such a marked interchange of cold and warm winds in the Central Valleys is an important part of the April weather, and it is shown by rapid and wide oscillations of the barometer in those regions. There frequently occur great depressions of the barometer over the entire mountain plateau and slope, sometimes with high wind velocities, sometimes without them, even though steep gradients exist, in which there may be but little precipitation. This is probably due to the fact that in the increase of the general heat of the atmosphere in the middle latitudes the capacity of the air for greater quantities of moisture is increased, while there is also a corresponding diminution in the size of the cold masses that must be projected into the warm masses in order to produce a fall of rain. Hence strong gradients and wind do not necessarily imply much rain, and such storms may move to the Atlantic coast and go over, as it were, very dry, with only an occasional shower.

The showers of April may be simply understood. Instead of the atmosphere being collected into great sheets of cold and warm air which, as in winter, move eastward over the United States in a succession of waves, the cold and the warm masses become broken up into smaller portions or patches, which lie interspersed among each other in an irregular way. The contact of such masses of air, in smaller bodies, tends to cause local showers, and this condition lasts for a month or two, till the entire northern cap becomes warmed up, and then the summer conditions are fully established.

It may be not uninteresting to note the three ways that exist in the atmosphere of condensing the moisture, suspended in the form of aqueous vapor, into rain. The first consists in the cooling of the air by expansion when it rises from the lower to the higher strata, by which the cumulus and the cumulo-nimbus and nimbus clouds of summer are chiefly produced, and from whose bases the rain sometimes falls. The second is the intimate mixture of two masses of air having different quantities of vapor in them, but it has been shown that only small amounts of rain can in this way be produced, although very extensive fogs may be formed. The third is by far the most important, although in some respects a complex process, and it may be called direct cooling by contact.

One of the most important physical properties of air at different temperatures is a reluctance to mingle. Such masses will rather flow alongside in distinct strata, like oil and water, with contact on the surface. The effect of this is seen in many of the cloud forms that spread over the sky, showing exactly where the currents of different temperature touch each other. In the cyclonic circulation of the atmosphere which is to be referred primarily to the counterflow of currents from two adjacent high areas there is a powerful force that tends to compel a breaking up of the currents into shreds of air, warm and cold in quick alternation, in the interflow especially in the southeastern section of lows. Here the direct contact in the air of masses having moisture in suspension with the cold masses that are partially dry tends to form a rapid condensation, and hence rainfall. No doubt all these three processes are at work more or less simultaneously, but it is clear that direct cooling is the most efficient of all in producing ordinarily rainfall.—*The Philadelphia Press.*

SOME FACTS ABOUT BULLETS.

The first bullet used was probably a stone. Iron and lead bullets were not long in following. The latter were round, and were, of course, used in smooth-bore weapons. The calibre of all firearms was formerly much greater than now. The calibre of the first musket used was such that eight bullets weighed a pound. In consequence, the piece was so heavy that it had to be fired from a forked stick inserted in the ground.

Rifling was introduced while round bullets were still the only ones used. The grooves were straight, and were not intended to give greater accuracy to the projectile. They were merely to diminish the friction when it was rammed home.

By accident it was discovered that spiral grooves gave greater accuracy to the flight of the projectile, but the science of the day was unable to assign a reason for such superiority. In consequence, the form, number, and twist of the grooves depended upon the caprice of individual gunmakers. Now the cause has been explained, and the result of any alteration in the grooves can be foretold with certainty.

In 1729 it was found that good results could be obtained by using oblong projectiles. The great difficulty of loading the rifle, however, which was accomplished by the blows of a mallet upon the stout iron ramrod, prevented it from being regularly used in warfare. This difficulty was later overcome by using a bullet which fitted the barrel with only a moderate degree of tightness, but which was made to take the grooves by the expansive action of the powder upon a hollow base. The celebrated Minie bullet, used extensively during the civil war, was made on this principle. A sheet-iron cup was inserted in the hollow base for strength. The Minie bullet possessed great range and accuracy, but it had certain defects which prevented it from being extensively used in military service. It was compound in structure, and the iron cup was sometimes forced in obliquely, thus producing unequal expansion.

The bullet used by our army at the close of the war was in one piece, and, therefore, an improvement on the Minie. It was .58 in. calibre, and weighed 500 grains. The bullet of the Springfield rifle, which was adopted in 1869, and has just been superseded, is .45 in. calibre, and weighs 500 grains. The bullet of the new magazine rifle weighs but 220 grains, and has a calibre of .30. The new navy rifle has a calibre of .236. So from the first use of firearms we see a steady reduction of calibre and weight of bullet, which have been accompanied by increased velocity, range, and accuracy. It is impossible to predict whether the limit has been reached, but it is believed that it has been.

Our new bullet is a radical departure from any other type heretofore used. It is a cylindrical bolt with a rounded head, nearly four diameters in length. It is made of nickel steel, with a jacket of German silver.

There has been a deal of discussion and experiment to find out the destructive effect of the small calibre bullets now used as compared with those of twenty years ago. The result seems to be that at short and long ranges the effect upon bones is explosive, while at mid ranges a clean perforation is made. Should the bullet not encounter a bone, however, the wound is cleaner and the shock less than with the old projectile. What the effect of all this will be upon battles of the future cannot be foretold with certainty.

Prof. Hebler, the greatest authority in Europe on rifles and rifle shooting, has just invented a tubular bullet, which he claims to be a success. The object of such a bullet is to reduce the surface exposed to the air in front, and thereby increase velocity and range. Hebler's bullet is curved inward at both ends, with its channel widening funnel like. The conical rear end is fitted into a pasteboard shoe, which has a prominence projecting into the channel of the metal. The shoe acts as a guide, centring the bullet in its passage to the muzzle. It then drops to the ground. Prof. Hebler is very enthusiastic about his new bullet, with which he has been experimenting for twenty years.

Patched bullets are extensively used by marksmen, though never in war. They are made smooth, without grooves, and from three to six thousandths of an inch smaller than the bore of the rifle. The diameter is increased to the required size by rolling a thin paper patch about the bullet. There is a difference of opinion about the relative merits of patched and unpatched bullets. For hunting the latter are preferable, however, for they cannot be injured by moisture. In target practice some wonderful scores have been made with patched bullets, and many expert marksmen will use nothing else.

The common idea of an express bullet is one having an explosive at the point. This, however, is the exception rather than the rule. Properly speaking, the express bullet is made like any other, except that the point is deeply hollowed. The object of this is to make the bullet flatten out, or "mushroom," when it strikes, thereby increasing the shock, making a larger and more freely bleeding wound, and preventing escape. The hole may be strengthened by a copper tube, or simply filled with wax. Heavy charges of powder are used to increase the effect. The range of the express bullet is small, for it will not travel long "point on." It is a formidable affair, however, and is much used in hunting large game. For obvious reasons its use in war is prohibited by the law of nations.—*From the New York Sun.*

RUBBER SHOES SIXTY YEARS AGO.

To make a satisfactory purchase of a pair of rubber shoes sixty or more years ago, was an undertaking requiring the accredited keenness of a "Philadelphia lawyer." Boston, Mass., was then headquarters of the rubber trade, the largest importers being found there, where, besides supplying the regular trade, the commission merchants held rubber auctions at stated seasons. Notices sent abroad secured a full attendance of boot and shoe dealers from the large cities.

Most of the rubber, and the best, came then, as now, from Para, South America, or along the Amazon river, where natives procured it by tapping the trees. Clay and wooden lasts of various sizes were dipped in the cream-like liquid, the coating being dried by a dense smoke exactly as is done today. When the several dippings were over, the shoes were stamped on the toes in fancy designs, more or less elaborate, taken off the lasts and stuffed full of rice hulls and hay; the tops were then sewed together with twine or coarse thread.

Two of about the same size were tied together, and these ill-assorted pairs were packed in wooden boxes of all sizes and shapes, mostly sugar boxes, and shipped to foreign ports. A boot and shoe dealer receiving a box would immediately consign it to the cellar of his store, where on being opened, the stitches would be cut, the hulls and grass emptied out, together with a few scorpions and other live stock such as frequently took passage in the shoes. The shoes were then turned wrong side out and after a thorough washing inside and out to free them of all adhering clay and dirt, were left to dry.

Then followed the tedious process of trimming and shaping them. Each shoe was turned over a wooden last—the one that seemed to be about the right size. If it was not sufficiently large, another would take its place. If too large, the shoe was heated and by extra exertion was often made to work down to the required capacity. Then with sharp scissors the edge was neatly trimmed and after being sponged with Japan blacking the shoe was ready for sale. Only about enough for one or two days' sales were made ready at one time.

Repairing and resoling rubbers was a very nice operation, requiring great skill and cleverness. The shoe was again put on a last, when the sole or part to be mended was shaved with a sharp knife until it was all fresh and adhesive, and then a similarly prepared piece of rubber was put over it, the fresh surfaces pounded together and then trimmed neatly around. The shoes being soft and easily injured, had to be frequently mended. They tore readily; stones and sticks penetrated the soles, heat softened them, cold stiffened them, and the sun discolored them; but notwithstanding all that, every woman and child, and many a man, was obliged to wear them through the muddy, slushy, and snowy seasons; so the sales were proportionally great.

Here and there may occasionally be found a man whose hand even now bears the marks of trimmings done on "gums" during the days of his youth, but there are comparatively few people living who remember the old time rubber shoes with their stamped toes—which were considered a valuable improvement over wool socks and Indian moccasins. —*Boot and Shoe Recorder.*

THE TYRANNY OF THE MOON.

Some notable cases of so-called moonblink, or moon blindness, were reported recently, the victims being sailors on board the ship *El Capitan*, which had just returned to New York after a long cruise in Chinese and Japanese waters. These men, we are told, were in the habit of lying on the deck at night, with their faces turned upward, and as a result were stricken with temporary blindness. During the day time they could see well enough, but at night they could see nothing. This singular affliction beset them as long as they remained in the warm countries.

As to the cause or exact nature of this disease no explanation is to be found in medical works. Sailors themselves believe that it is caused directly by the moon, and many who have looked into this subject of lunar influence agree with them. One thing is certain—moon blindness was recognized as a curious malady many years ago, and by one, who evidently wrote after careful consideration, was attributed directly to lunar influence. Martin in his "History of the British Colonies," a book published many years ago, says:

"I have seen in Africa newly littered young perish in a few hours at the mother's side, if exposed to the rays of the full moon; fish become rapidly putrid, and meat, if left exposed, incurable or unpreservable by salt; the mariner, heedlessly sleeping on the deck, becomes afflicted with nyctalopia, or night blindness; at times the face is hideously swollen if exposed during sleep to the moon's rays; the maniac's paroxysms are renewed with fearful vigor at the full and change, and the cold chill of the ague supervenes on the ascendancy of this apparently mild yet powerful luminary. Let her influence over the earth be studied; it is more powerful than is generally known."

The author italicizes this last sentence, showing how important he deemed it. And this man, be it noted, was not a fortune teller, nor the seventh son of a seventh daughter, but a sober-minded historian and traveller, who gives us the results of his own experience.

Why he calls moon blindness "nyctologia" is not clear. The word is not to be found in standard dictionaries, and the only explanation is that it is a misprint, for "nyctalopia," which is correctly derived from the Greek, and signifies damage to the eyes at night time.

That the moon and sun have a boundless influence on the health of all persons born in this world cannot be denied. Indeed, it is claimed by those who have spent years in studying the subject that it is impossible for any person to die unless the sun or moon is afflicted by some malignant planet. The moon, afflicted in the sign of the Ram, invariably affects the eyesight. There are certain fixed stars, also, which threaten the eyesight. A person born when the moon is in conjunction with the Pleiades, Proserpine, or Antares will very probably either be born blind or will receive some injury to the eyes at some time in life. This will especially be the case if either Saturn or Mars, both of which are malignant planets, be at the same time in conjunction with Regulus.

That the moon, whose zodiacal sign, by the way, is the tropic of Cancer has an extraordinary influence over animal and vegetable matter in tropical countries has been pointed out by more than one observant traveller. Thus in Demarara, we are told, "there are certainly thirteen springs and thirteen autumns in the year, for so many times does the sap of trees ascend to the branches and descend to the roots. For example, wallaba, a resinous tree, common in the Demarara woods, somewhat resembling mahogany, if cut down in the dark a few days before the new moon is one of the most durable woods in the world for house building, posts, &c. In that state, attempt to split it, and with the utmost difficulty it would be riven in the most jagged and unequal manner that can be imagined. Cut down another wallaba, that grew within a few yards of the former, at full moon and the tree can be easily split into the finest smooth shingles of any desired thickness or into staves for making casks, but in this state applied to house-building purposes it steadily decays. Again, bamboos as thick as a man's arm are sometimes used for paling, &c. If cut at the dark moon they will invariably endure for ten or twelve years; if at full moon they will be rotten in two or three years. Thus it is with most, if not all, forest trees."

The English language bears testimony to a belief in lunar influence. How else can we account for the words lunatic and moon-struck?"—*From the Boston Herald.*

A WORD WITH THE DOCTOR.

That longevity is promoted by friction there can be little doubt. The declining energy and decay from age appear to arise, or, at all events, are accomplished and accelerated by the gradually decreasing energy of the circulation, and the use of the flesh brush restores energy to the parts. It is, therefore, recommended as a panacea for premature decay and all the diseases depending on it. It takes but a few minutes to give a vigorous rubbing to the entire body on jumping out of bed in the morning, and the beneficial results will amply repay the time and trouble.

Sulphonal is a good remedy for insomnia.—Take fifteen grains in hot milk or water at bed time and repeat the dose in an hour or two, if necessary. This remedy is a harmless one, and can be used without fear of acquiring a habit detrimental to health.

Experiments with toasted coffee prove it to be a powerful means of rendering harmless and destroying animal and vegetable effluvia. If a room needs a disinfectant, simply carry a coffee roaster, in which a pound of coffee has been newly-roasted, through it. But the best mode of using the coffee is to dry the raw bean, pound it in a mortar, and then roast the powder on a moderately heated oven or tin plate, until it becomes a dark brown color. Then sprinkle it in sinks and cesspools, or expose it on a plate in the room.

One part acetic acid to seven parts water, rub well into the scalp once a day, will induce a new growth of hair.

For canker sore mouth, one tablespoonful of salt, one of alum, half teaspoonful of borax, and as much blue vitriol, two tablespoonfuls of honey and a pint of strong cider vinegar. Simmer over a slow fire in an earthen vessel, then put into bottles. Use this frequently with a swab.

Great are the achievements of contemporary science in the department of therapeutics. No one who has undertaken to raise a family can fail, or at least should fail, to be thankful for antitoxine. It has really annihilated the worst terrors of diphtheria, and grateful voices rejoice in it wherever it has been used. Its success revives hope that the wise men will presently learn to deal effectually with the bacilli of consumption, and of cancer, too, if it should turn out, as begins to be suspected, that cancer is a communicable disease.

When the thumping sensation begins in the head take equal quantities of pure cayenne pepper and flour; mix them up with water to form a smooth paste thick enough to spread like a salve. Put this upon a piece of soft paper and apply it to the back of the neck just below the edge of the hair. In warm weather it is best to wash the neck with a cloth wet with soap and water, as the oily perspiration may interfere with the action of the plaster. One great advantage of cayenne pepper plaster over mustard is that while the latter frequently blisters, the former never does so, no matter how strong it is applied. In the use of mustard, if the skin is broken, all treatment must cease until it heals, but with pepper when the plaster loses its effect another may be applied without unpleasant consequences.

For earaches, that are so common to children just now, put a few drops of vaseline in a teaspoon and hold it over the gas to heat. Hold the spoon in the hollow of your palm for a second, and when it ceases to burn you, pour it in the child's ear, making it lie on the other ear, so that the oil will be retained for a moment or two. Then put some cotton in the ear. It will give almost instant relief, for the heat is excellent and the vaseline loosens up the dry wax in the ear.

An English surgeon claims to have relieved ninety-eight patients out of one hundred in cases of rheumatism by making a liniment of equal parts of wintergreen and olive oil. He applies it to the part, keeping it covered with oiled silk and flannel. He says the pain is relieved in from four to six hours. We advise any one who is afflicted with rheumatism to give this remedy a trial. We feel that it will be efficacious.—*From The American.*

SOME REMARKABLE RIVERS.

It is a recognized fact in science that very few great rivers have been thoroughly explored by going up stream. For nearly 2000 years travelers and explorers endeavored to discover the sources of the Nile by ascending that wonderful river. But by the time they had reached the difficult part of the stream their supplies and energy were exhausted, and they could go no further. It is only by seeking the sources of rivers by overland routes that explorers meet with success. It was in this manner that Henry M. Stanley traced the route of the Congo, in Africa. In this way of procedure Frederick Schwatka was enabled to float down to Yukon, and Speke found the secret of the river Nile.

One of the most curious rivers that has come to the knowledge of men is the Webbe Shebeyli, of Eastern Africa, a deep and rapid stream. Although it flows for hundreds of miles through fertile lands the immense volume of water never reaches the sea. A short distance north of the equator the river is lost in a desert region, a few miles from the Indian Ocean.

Some of the more recent explorers of Alaska and British America claim that the Mississippi can no longer be regarded as the largest river on the North American continent. This distinction is claimed for the great Yukon river. According to Ivan Petroff, who spent over two years in Alaska, collecting materials for the last census, the Yukon empties into Norton Sound about one-third more water than the Mississippi pours into the Gulf of Mexico. The Yukon basin comprises the largest part of Northern Alaska, and 600 miles from its mouth the river is a mile wide. The Yukon river is over 2,000 miles in length.

Travelers report that in Algeria there exists a small stream which the chemistry of nature has turned into ink. It is formed by the union of two rivulets, one of which is very strongly impregnated with iron, while the other, meandering through a peat marsh, imbibes large quantities of gallic acid. Letters have been written with the natural compound of iron and gallic acid, which forms this small yet wonderful stream.

The Rio de Vinagre, in Colombia, is a stream the waters of which, by admixture with sulphuric acid, become so sour that the river has been appropriately named the Rio de Vinagre, or Vinegar river.

The Orange or Gariep river, in Southern Africa, rises in the mountains which separate Natal from the Orange Free State. The length of this stream is 1,000 miles. Its banks abound in various valuable woods, and around it are found rich copper ores. In this stream are many varieties of fish which are found until the river passes through a rocky region containing copper, below which the water is said to be poisonous, almost instantly killing the fish that venture near it.

"China's Sorrow," a curious name for a river, is the title bestowed upon the great Hoang Ho, which rises in the mountains of Thibet, and follows a wonderfully circuitous channel for 2,500 miles to the Yellow Sea. The waywardness of this mighty volume of water makes the river a constant source of anxiety and danger to the 170,000,000 of people inhabiting the central plain of Asia. It is known to have suddenly changed its course nine times. It has moved its mouth four degrees of latitude each time, emptying its vast floods in different directions, and finding a new channel for itself, where scores of towns and villages have stood.

Another remarkable river is the Indus, a great stream in Hindustan. It rises in Thibet, and its course is a wonderful one. On reaching Sussi, its most northern point, it turns southward, loses itself in the hills and reappears at Takot, in Kohistan. The Indus is 1,700 miles in length. After receiving the waters of many tributaries its channel grows narrow, and here it divides into many channels, some of which never returned to the parent stream.

That classical river the Ganges is erratic in its course, like the Hoang Ho. It is prominent both in the religion and the geography of India. It varies not only from season to season, but from year to year, and frequently exchanges old passages for new ones. It has been said that the Ganges delivers into the sea every year 534,000,000 tons of mud, sand and other solid matter.

PRESIDENT AND CABINET.

"In all important matters the President is consulted by all the secretaries. He is responsible for all executive action, and everything that is out of the routine receives his attention. Every important foreign complication is usually discussed with him, and the diplomatic note receives his approval. The same thing is true of each of the departments. Routine matters proceed without the knowledge or interference of the President; but, if any matter of major importance arises the Secretary presents it for the consideration and advice of the President. Only matters of great and general importance affecting the general policy of the administration are discussed in the Cabinet meetings—according to my experience—and votes are of rare occurrence. Any Secretary desiring to have an expression upon any question in his department expresses it, and it is discussed; but usually questions are settled in a conference between the President and the head of the particular department. There is a yielding of views, now on one side, now on the other; but it must, of course, follow that when the President has views that he feels he cannot yield, those views must prevail, for the responsibility is his, both in a constitutional and popular sense. My habit was to give an afternoon to each Cabinet officer, on a fixed day of the week. These meetings were chiefly given up to the consideration of appointments, but if any other matters were pending, and deemed by the Secretary of sufficient importance, they were presented and discussed. The labors of a Cabinet officer are incessant and full of responsibility. His time is largely taken up with calls, and, like the President, he must, out of such fragments of time as he can secure, manage to study and decide the important questions that are daily presented to him. Certain appointments, chiefly of a clerical character, are by law given to the heads of the departments, and with these the President usually refuses to interfere, though often urged to do so. It was my practice to refuse to send any card of recommendation to a Secretary, though I spent many a weary hour explaining to friends why I could not do so."—*Ex-President Harrison in March "Ladies' Home Journal."*

THE PROBABLE ORIGIN OF A WELL-KNOWN SEA STORY.

The atmosphere in the vicinity of the Cape of Good Hope has that peculiar power of unequal refraction which produces the spectral mirages so well known to the early settlers on the great plains and to all travellers and explorers in desert regions. This unequal blending of the rays of the light gives rise to what are known as "spectral loomings," by which is meant the apparent suspension of ships and other objects in midair. The peculiar properties of the atmosphere over that portion of the ocean mentioned have been known since men first "rounded the Cape" in their voyages from western Europe to the Indies, and the regular appearance of the mirage at that point is responsible for the legend of the "Death Ship," otherwise known as the "Flying Dutchman."

According to the story, a Dutch Captain, homeward bound from the East Indies, met with long-continued bad weather while trying to "round the Cape." This series of squalls was coupled with other circumstances which made "turning the Cape" next to impossible. The wind was "dead ahead" and the weather was dark and foggy. At the time when the brave little Dutch Captain was making a final effort to get off in a northwesterly direction, and was about to make a failure of it, the mate and the sailors advised him to turn back and seek shelter in a neighboring harbor until the gale was over. But this he refused to do, swearing that he intended to "turn the Cape" if he had to beat back and forth along that shore until the day of judgment. For this burst of profanity, so the tradition says, he was doomed to steer against the blustery winds forever. The sails of his ship, so those who believe in the legend say, have become bleached with age, and its sides and bottom worm-eaten and decayed in the long struggle which has ever since been kept up between the cursed vessel and the elements. The little Dutch Captain and his crew, like all persons living under a spell, continue to exist, knowing their condition but unable to help themselves. Ship captains, who have sighted the doomed vessel time and again during the past century and a half, report that the crew of the cursed Dutch vessel appear to be living skeletons. Yet they continue to live under the blighting effects of what was brought on by their master's rashness. They cannot lower a boat they are so weak. Yet they occasionally hail passing vessels, imploring to be rescued from their awful fate.

Such is the story of the "Flying Dutchman," which no doubt, originated through ignorant, superstitious sailors viewing the mirage in awe-stricken terror.—*From the St. Louis Republic.*

EMERY.

Emery is one of the few valuable rocks not yet produced in important quantities in America. Large amounts are yearly brought from Turkey and the Greek Islands, where it has been quarried since history began. Its wonderful properties were no secrets to the ancients, who used it for cutting and polishing; but their methods of working are not certainly known. Curiously, modern methods of mining this substance have made no progress, and to this day ledges of emery have been heated by huge fires and the hot rock cracked by douches of cold water.

During the middle ages, and for many years afterward, the properties of emery, while not forgotten, could not be utilized. The old art of working was lost and ingenuity was unable to give useful forms to this intractable substance. It long defied every effort. Slowly, however, emery again came into use, first as a polishing and cutting powder, and later, in the form of small grains, was attached to fabrics like a sandpaper. Means were afterward found to cement and mould its small particles into wheels. Emery wheels soon came into use, their remarkable cutting properties proving at once the great industrial importance of the invention.

Years elapsed, however, before the emery millstone could be made; but, at length, this too was accomplished, and a practical emery stone was brought out in England. Later, Yankee ingenuity improved upon this and produced the present successful rock emery millstone, which is built up of large blocks of emery set in strong metal.

These millstones grind fast because the emery face is always sharp, and as they are not damaged by heat, they can be run at high speed.

Many new uses will doubtless be found for emery; but probably it can take no more important place than that of the emery wheel and the emery millstone, the one cutting and polishing in the shops the hardest surfaces and the other grinding the surface to any degree of fineness.—*Scientific American.*

SPARROWS' SAGACITY.

A bevy of sparrows, evidently the advance guard of an extensive foraging party, flitted into the quiet precincts of Carondelet street in New Orleans recently. Some men were cutting the fresh spring grass from the banquette, and the sparrows were eager for a raid on the upturned soil. There must have been nearly thirty birds in all. Perhaps a half-dozen or so who were the leaders of the party, settled on the ground at once and began investigating the find. The rest, twenty-five plump little fellows, stopped up above to await orders from the leader, stringing themselves out in a row on a telephone wire, chattering and chirping most gleefully.

Suddenly a woful thing happened. The innocent-looking wire became surcharged with electricity, and like a veritable thread of destruction, sent the merry little birds to their death without a warning. Quicker than it has taken to tell it, the little tragedy was enacted, and twenty-five plump little sparrows lay dead in the gutter. The birds on the banquette looked on aghast. Finally, amid much chirping and fluttering, having satisfied themselves that their fellows were indeed dead, they evidently settled upon a plan to save from destruction the rest of the party that was already appearing in installments up and down the street.

One little fellow, with a noticeably shrill voice and general fussiness, seated himself on top of the wire post, well out of harm's way, and called out a note of warning to the birds as they drew near. The rest of the leaders divided up, one going up, another down the street, and so on, challenging every fresh arrival in the block and spreading the news of the tragedy.

This was evident, for during the whole day, though innumerable sparrows feasted on the upturned bugs and worms on the banquette, not another one was seen to rest on the electric wires overhead.—*From the Philadelphia Times.*

THE CARE OF THE AGED.

When a man or woman passes seventy years of age, great care should be given to the conditions surrounding him or her for the prolonging of life. The vital forces are greatly enfeebled at that period of life, and the powers of resistance in consequence of age are the weakest. A man of three score years and ten, and over, is like an old machine that by proper care given to its condition has been kept running many years, and is still able to do work, but its wheels and axles and pinions are much worn and are rickety, and if it should be pushed, even to a small extent, in excess of its diminished powers, it breaks down and cannot be repaired, for every part of it is shattered. But if worked carefully and intelligently by a person who understands its condition and knows its capabilities, it can be kept in action a much longer time than would be possible if a careless engineer controlled it. In these fast times, however, it is generally not profitable to husband the resources of an old machine. But this is not true as regards our old men and women. It is desirable to hold on to them as long as possible, and if we can succeed in prolonging their lives five or ten years, or more, it will greatly enhance our happiness.—*Medical Review.*

NEW INVENTIONS.

PNEUMATIC PUMPING.

No. 555,785. Michael Mish and William Foster, Brooklyn, N. Y. *Patented March 3rd, 1896.* Fig. 1 exhibits the form of the apparatus employed for ordinary low lifts, and Fig. 2 shows the arrangement designed for high lifts. The water is raised by means of compressed air, which is forced by a compressor *C* through a pipe b^2 and jet b' into a deflecting cup *b*. The part of the pump containing the jet and deflector is submerged as shown. The jet of air is spread out into a thin sheet and turned upward, and as it passes over the edge of the deflector it engages the surrounding water and drives it upward, after the manner of an ejector. The tendency of the air to escape in bubbles from the bottom of the pipe is thus overcome, and the depth to which the pump must be submerged is consequently much less than in other forms of pneumatic or "air lift" pumps. In Fig. 2 the lifting action is enhanced to any desired extent by means of the ejector *Z*. The compressed air, which is also supplied to the annular space *e*, escapes through the narrow passage *g* in a thin sheet, and drives the water *f* upward with great force. The ejector *Z* and deflector *b*, working together, are able to operate lifts of considerable height, with a very moderate depth of sump.

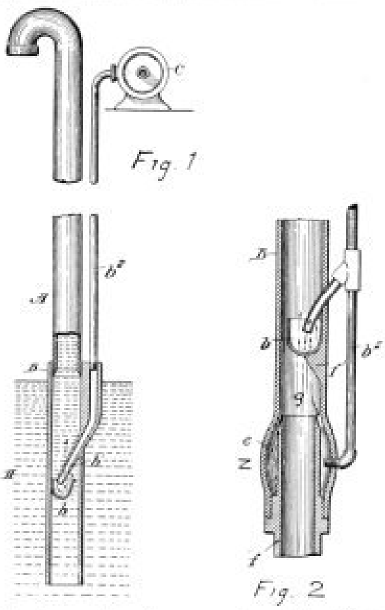

Fig. 1 Fig. 2

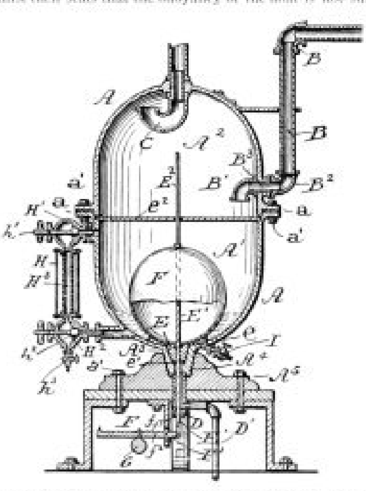
STEAM TRAP.

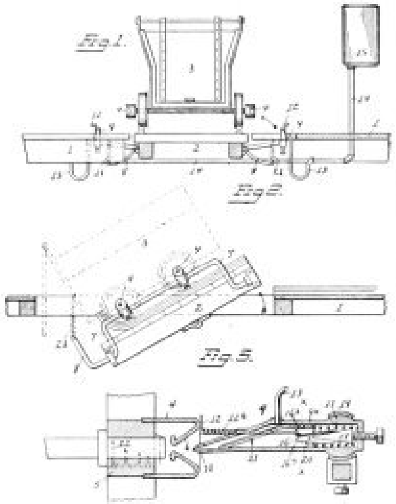
No. 555,708. Felix T. Howell, Birmingham, Ala. *Patented March 3rd, 1896.* The steam pipe enters the receiver *A* at *B*, and delivers the wet steam in a downward direction. As the steam turns to go out by the pipe *C*, the entrained water is thrown down to the bottom of the receiver. The escape valve is controlled by a float *F*. It is a common defect of float valves, that high steam pressure forces them so firmly against their seats that the buoyancy of the float is not sufficient to lift them; and if they are adjusted to work properly at a given pressure, they will fail to operate under a higher pressure. This defect is overcome by means of a lever *F*, and balance weight *G*, which serve to lift the valve and float. The valve stem passes down through the water outlet *D*, and through a suitable stuffing box, and rests upon the short end of the lever. The buoyancy of the float can be quickly adjusted to any steam pressure by shifting the weight *G*; or the trap may be drained at any time by moving the lever *F*.



LUBRICATOR FOR MINE CARS.

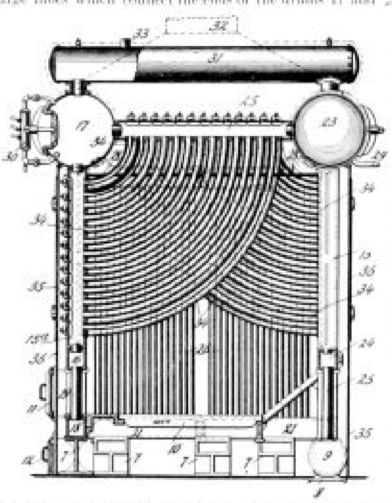
No. 553,484. George Maurer, Hilldale, Penn'a. *Patented Jan. 28th, 1896.* Fig. 1 is an end view of the apparatus; Fig. 2 is a side view, and Fig. 3 is a section on a larger scale of the oiling nozzle.

This apparatus is designed to oil the car wheels while the car is being dumped. Each side of the dump is fitted with a bent bar or rock shaft 7, which has an arm 8, attached by a spring 21 to a convenient stud in the floor. Each rock shaft carries two automatic oil feeders, which enter the caps 4 on the ends of the wheel hubs 5, and squirt in a small amount of oil every time the dump is turned down to empty a car. Each oil feeder is connected by a rubber tube to an oil pipe which extends to the tank 15. When the dump is level, the oilers lay down, as in Fig. 1. The oiling nozzle is pointed as shown, and the oil valve 11 is held shut by a spring 17. A rod 12 touches the end of the cap 4 and opens the oil valve, and its inner end is provided with a latch, which is regulated by the conical screw 18, so that it will let go the oil valve, and will hold it open but a moment, thus avoiding an excess of oil, in case the car remains in an inclined position for an unusual time.



STEAM BOILER.

No. 553,700. Robert R. and Harry L. Zell, Baltimore, Md. *Patented Jan. 28th, 1896.* The view given is a vertical section of the boiler, from front to back. The boiler is built up on a square frame or base, which is composed of a front header 18, two side headers 21, a rear header 24, and a mud drum 9. The corners of the structure are composed of four large tubes which connect the ends of the drums 17 and 23 with the base frame. These tubes are cooler than any of the others, and the water travels downward within them. The sides of the combustion chamber are composed of vertical tubes 26, set in double rows very close together. The upper part of the combustion chamber is occupied by curved water tubes 34, which connect alternately the front vertical headers 13*a*, and the rear headers 13, to the horizontal top headers 25. These top headers adjoin and close the top of the combustion chamber. The front and rear headers 13*a* and 13 have spaces between them, which are fitted with removable doors, for cleaning purposes. The water is carried at the middle of the drums 17 and 23, and the steam is dried in the top drum 31. The boiler is encased with plates which are lined with non-conducting material. All joints of tubes and headers are made by expanding the tubes or nipples into bored holes.



DEVELOPING POWER FROM STEAM.

No. 554,073. James M. Miller, and W. L. Collins, Vacaville, Cal. *Patented Feb. 4th, 1896.* Steam from an ordinary boiler is applied by the pipe *B* to the injector *C*, which is supplied with water from any convenient source by the pipe *E*.

The water which is delivered by the injector is passed through the large pipe *D*, which runs through the cooling tank *I*. Here all steam which is mingled with the water is condensed, and the body of water is made solid and free from bubbles. The upper part of the pipe *d* is an air chamber. The water is delivered through a jet *K* upon a water wheel of the Pelton type *F*, to which it imparts its momentum. The jet *K* is made double, as shown in Fig. 2, for the purpose of securing a solid, unbroken stream of water upon the wheel.

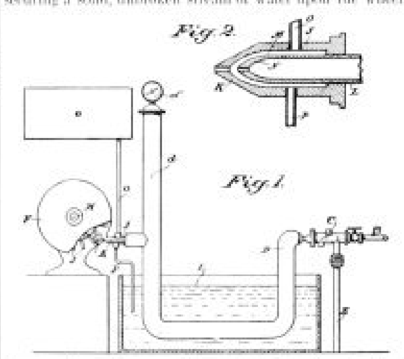


Fig. 2. Fig. 1.

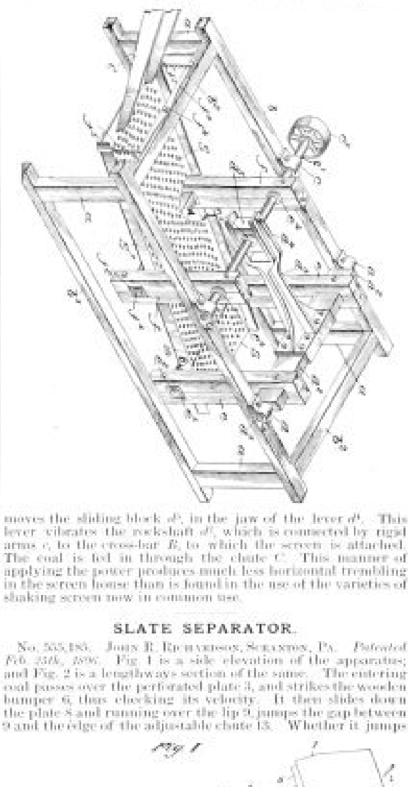
The pipe *O* supplies a small amount of water from the tank overhead, and the surplus runs into the condensing tank, through the pipe *P*. It is claimed that the energy of the steam, at the injector, is converted into static pressure of water in *D*, to such an extent that notwithstanding the loss of power at the wheel, this mode of applying steam power is reasonably effective.

SHAKING SCREEN.

No. 555,262. David E. Phillips, Mahanoy City, Pa. *Patented Feb. 25th, 1896.* The screen is shaken vertically and horizontally at the same time. The vertical movement is imparted by the eccentrics c^2, pitmen *f*, and the cross-bar *A*. The horizontal motion is imparted by the eccentric c^3, which



moves the sliding block d^2, in the jaw of the lever d^1. This lever vibrates the rockshaft d^3, which is connected by rigid arms *e*, to the cross-bar *B*, to which the screen is attached. The coal is fed in through the chute *C*. This manner of applying the power produces much less horizontal trembling in the screen house than is found in the use of the varieties of shaking screen now in common use.

SLATE SEPARATOR.

No. 555,185. John R. Richardson, Scranton, Pa. *Patented Feb. 25th, 1896.* Fig. 1 is a side elevation of the apparatus; and Fig. 2 is a lengthways section of the same. The entering coal passes over the perforated plate 3, and strikes the wooden bumper 6, thus checking its velocity. It then slides down the plate 8 and running over the lip 9, jumps the gap between 9 and the edge of the adjustable chute 13. Whether it jumps

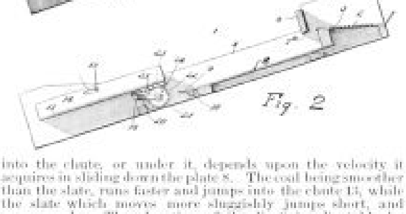


Fig. 1 Fig. 2

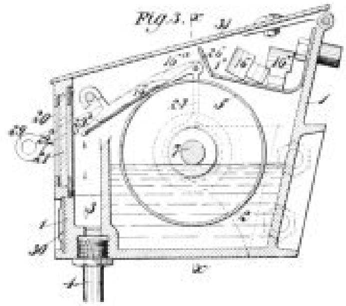
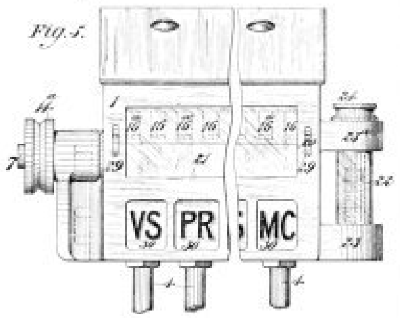
into the chute, or under it, depends upon the velocity it acquires in sliding down the plate 8. The coal being smoother than the slate, runs faster and jumps into the chute 13, while the slate which moves more sluggishly jumps short, and passes under. The elevation of the lip 9 is adjustable by means of the locking handle 12. The chute 13 may be moved forward or back by means of the pinion 24 and rack 25, and is held in place by the lock handle 26. The handle 17 is attached to a bent bar or crank 16, which serves to elevate or depress the upper end of the chute 13. All of these parts may be adjusted readily, while in operation.

LUBRICATOR.

No. 554,891. John I. Thornycroft, London, Eng. *Patented Feb. 18th, 1896.* Fig. 3 is a cross section of the apparatus, and Fig. 5 is a broken front view of the same. This device is designed to feed oil regularly, and by positive means, to a large number of bearings at the same time. The oil is picked up by a smooth drum 5, which rotates in the oil in the chamber 2. The oil is taken off the drum and delivered in drops into the end of separate oil ducts 3, by means of blocks 16 and 16². These blocks are quite narrow, and are provided with grooves in their edges as shown. They are suspended by hooks *a*, from a rod 6, and they rest lightly upon the revolving drum. The blocks 16² are longer than those marked 16, and may be thrown out of service by lifting

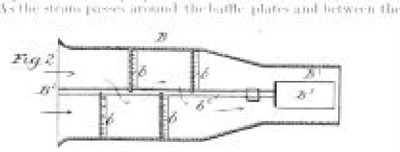


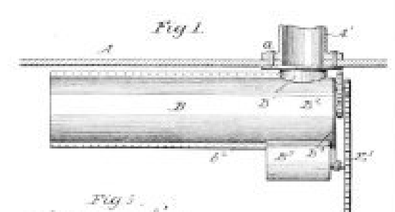


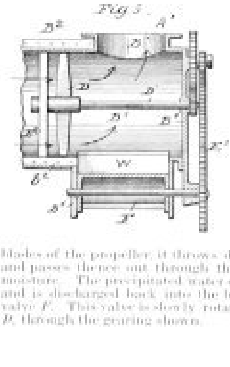
them clear of the drum, by means of the rod 26 and handle 29. These extra blocks are used only for heavy bearings that are liable, at times, to require an unusual amount of oil. The drum is rotated by means of the pulley 14, and the amount of oil in the case is shown by the glass tube 22. Each duct is provided with a tablet or label at 30, which shows the destination of the oil.

STEAM SEPARATOR.

No. 554,892. Charles W. Baker, Montclair, N. J. *Patented Feb. 4th, 1896.* Fig. 1 is a side elevation of a separator in position for work; Fig. 2 is a horizontal section along the center of the main drum *B*; Fig. 5 is a vertical section through the outlet end of the separator, on a larger scale; and Fig. 6 is a cross section of the valve chamber. This separator is placed inside of the boiler, and is designed to separate the entrained water from the steam before it passes out from the boiler. The body *B*, is oval in section, and is made with several baffle plates *b*. The part *B'*, is circular in section, and is provided with a propeller wheel *D*, and a draining valve *F*. As the steam passes around the baffle plates and between the



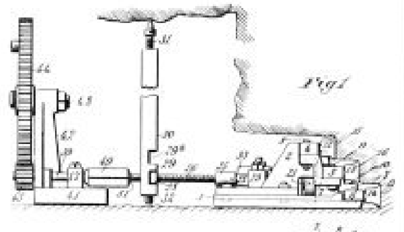


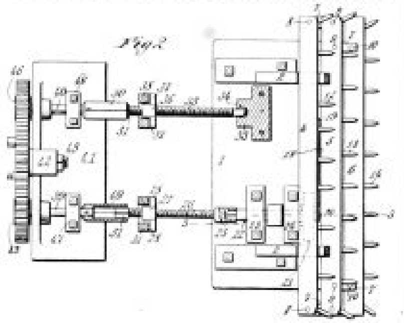


blades of the propeller, it throws down the entrained water, and passes thence out through the discharge *A'*, freed from moisture. The precipitated water collects in the chamber *W*, and is discharged back into the boiler, at intervals, by the valve *F*. This valve is slowly rotated by the propeller wheel *D*, through the gearing shown.

MINING MACHINE.

No. 555,218. George W. Lutes, Lisbon, Ohio. *Patented Jan. 21st, 1896.* Fig. 1 is a side view of the machine, and Fig. 2 is a top view of the same. The cutters 12, 13 and 14 are attached to three parallel bars 4, 5 and 6, which are fixed at different levels, as shown. The cutter bars are fastened together, so that they operate as one, and they are reciprocated lengthways, while pressed against the coal. The cutters operate by scraping. The main frame 1, upon which the

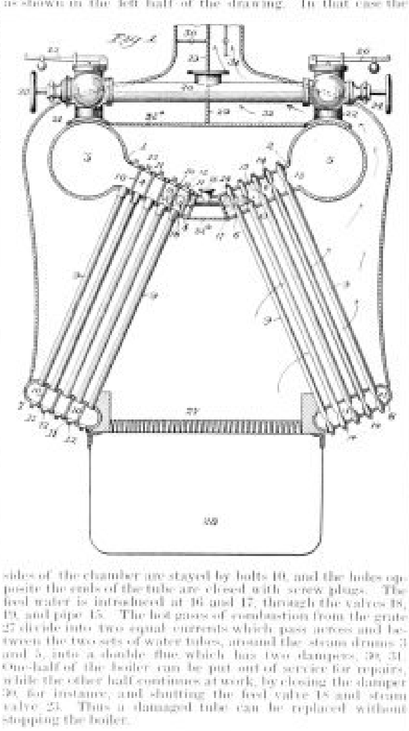




center bars are mounted, is pushed forward by means of two screws 35 and 26. The latter screw is used as a shaft to transmit motion to the crank 21, which reciprocates the cutter bars by means of the pitman 18. The thrust of the screw is resisted by the jacks 30. Power is applied to the screws through the gear 44 and pinions 45 and 46. The wheel 44 may be turned by hand, or may be driven by some convenient motor. The under cut made by this machine is quite high, and is stepped, as shown, to facilitate the breaking down of the overhanging coal.

WATER TUBE BOILER.

No. 556,108. Horace See, New York, N. Y. *Patented March 10th, 1896.* The figure is a vertical cross section of the boiler. The tubes are arranged in two sets, one on each side of the furnace. The tubes 9 extend from the base boxes 7 and 8 to the steam chambers 4 and 6, which connect with the steam drums 3 and 5. The tubes may be expanded into both plates of the base boxes, as shown on the right half of the drawing; or they may be expanded only in the single plates as shown in the left half of the drawing. In that case the



sides of the chamber are stayed by bolts 10, and the holes opposite the ends of the tube are closed with screw plugs. The feed water is introduced at 16 and 17, through the valves 18, 19, and pipe 15. The hot gases of combustion from the grate 27 divide into two equal currents which pass across and between the two sets of water tubes, around the steam drums 3 and 5, into a double flue which has two dampers, 30, 31. One-half of the boiler can be put out of service for repairs, while the other half continues at work, by closing the damper 30, for instance, and shutting the feed valve 18 and steam valve 23. Thus a damaged tube can be replaced without stopping the boiler.

COAL TIPPLE.

No. 555,365. Thompson B. DeArmit, Turtle Creek, Pa. *Patented Feb. 25th, 1896.* Fig. 1 shows the general arrangement of the screening and weighing apparatus; and Fig. 3 shows the mode of shutting off the screens so that the coal may pass over them without being separated. The coal is dumped into the upper end of chute 3. The bottom of this chute 3' is composed of a screen of 1¼ inch mesh. The miners are paid only for the coal which passes over this screen, that which passes through being reckoned as waste. The screened coal passes onward into the screen box 4, where it is further separated by the screen 15, the egg coal passing into the

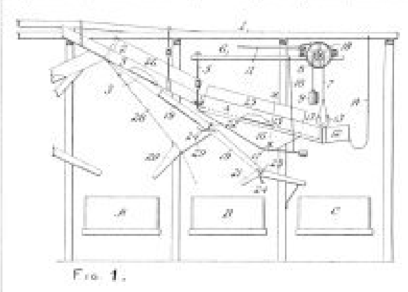


Fig. 1.

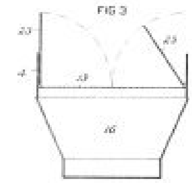
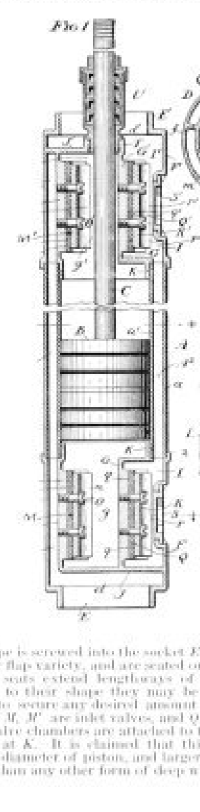
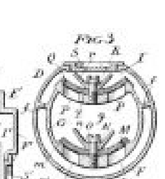


hopper 16. This screen box and hopper are suspended by rods 5, from a scale beam 6, and by chains 7 from the pulley 8 and counterweight 9. The screen box is closed at the lower end by a hinged section 12, and the coal is released from it by raising the brake lever 11, and allowing the end to sink until the chain 14 tightens and pulls the part 12 upward, thus opening the joint between it and the screen box. At the same time the chain 18 opens the gate 17 and releases the egg coal from the hopper 16. The stuff which passes through the screen 3' passes over another screen 19, which takes out the nut coal; the slack drops into the hopper 28, and may be delivered into the car *A* or *B* as desired. By means of the gates 22 and 23, the nut coal may be delivered into *A*, *B* or *C*. The screens 3' and 15 may be thrown out of use by turning down the hinged plates 25, 26. The run of mine may then be shipped by car *C*. When it is desired to ship run of mine, while still paying the miners on the basis of 1¼ inch screened coal, the plates 26 are raised, and the gates 22, 23 are set so as to deliver all the screenings, except the slack, into the car *C*.

PUMPS.

No. 555,200. William D. Hooker, Chicago, Ill. *Patented Feb. 25th, 1896.* Fig. 1 is a vertical section of the pump; Fig. 3 is a cross section through the valve chamber; and Fig. 5 is a plan of the valve seat. This pump is designed for pumping bored wells. The main barrel is double; the space *A²* between the working cylinder and the outer shell is divided by partitions *f*, into two parts or passage ways. The





tail pipe is screwed into the socket *E*. The valves are of the rubber flap variety, and are seated on concave seats as shown. These seats extend lengthways of the pump barrel, and owing to their shape they may be made of any length, in order to secure any desired amount of valve opening. The valves *M*, *M'* are inlet valves, and *Q*, *Q'* are discharge valves. The valve chambers are attached to the main barrel by screw joints at *K*. It is claimed that this construction affords a larger diameter of piston, and larger passage ways and valve areas than any other form of deep well pump.

The Colliery Engineer

AND

METAL MINER.

VOL. XVI.—NO. 11. SCRANTON, PA., JUNE, 1896. With Which is Combined THE MINING HERALD.

THE OQUIRRH MOUNTAINS

OR THE MERCUR MINING DISTRICT, UTAH.

An Epitome of the Geological Survey's Report of the Region by Messrs. Emmons and Spurr. With Notes and Comments by Prof. Arthur Lakes.

Written for THE COLLIERY ENGINEER AND METAL MINER by Prof. Arthur Lakes.

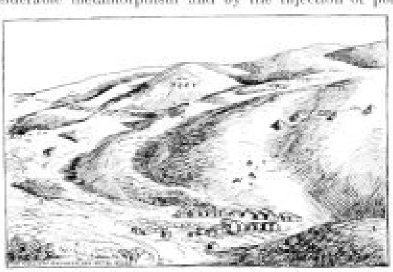
From the base of the Wahsatch mountains on the east, to the Sierra Nevada on the west, stretches an arid region called the Great Basin, so named because it has no external drainage to the ocean. This region was once occupied by two large distinct freshwater seas, which have gradually disappeared by evaporation, until at the present day only small salt lakes remain. The basin consists of broad level valleys, 4,000 to 6,000 feet above the sea, intersected by mountain ridges trending north and south, called the Basin ranges.

The Oquirrh range, in which is situated the Mercur mining district, is the first of these Basin ranges west of the Wahsatch mountains, and about thirteen miles distant from them. The character of the great basin is a sage brush and desert. A few small streams occur in the Oquirrh range, but insufficient for mining purposes. The range is thirty miles long and culminates in Lewiston Peak (10,628 feet) near its extreme end.

Utah has long been celebrated for its silver rather than its gold products. Hence the interest attached to the little gold mining district of Mercur.

Some of the most noted mining districts of Utah are the Bingham canyon, where placer as well as silver mining was carried on, but principally silver and copper. Ophir and Stocton, Camp Floyd and Tintic, have all been noted for their silver products more than those of gold.

The Oquirrh mountains are composed mainly of Carboniferous limestones and quartzites, which the forces of contraction acting in either direction have compressed into a series of complicated folds, accompanied by considerable metamorphism and by the injection of por-



MERCUR BASIN, LOOKING SOUTH; MERCUR HILL ON RIGHT.

phyry dykes, together with subsequent mineralization in the more disturbed districts. The Lower Carboniferous limestones of Lewiston canyon constitute the ore-bearing horizon of the Mercur district. Associated with these are beds of clay shales. On the north side of Ophir canyon a peculiar arch of Cambrian quartzite has been uplifted by a fault.

There are no large exposures of eruptive rocks, such as result from surface outflows, but rather dykes and irregular intrusive bodies. In Bingham canyon the ore is found only in the vicinity of one of the bodies of porphyry that occur there. In the Mercur district the igneous rocks are mainly in thin sheets parallel to the stratification and immediately beneath these sheets the principal ore deposits occur.

According to Mr. Spurr there have been two distinct periods of mineralization in this district. During the first the silver ledge was formed, during the second the minerals of the gold ledge were deposited. In each period the minerals constituting the ore were deposited mainly along the lower contact of a porphyry sheet,

where a porous or brecciated zone had been formed by the intrusions of the igneous material which the mineralizing solutions reached through fractures or fissures extending downward from the respective sheets.

The principal vein materials of the silver ledge are silica, barium, antimony, copper and silver, brought up by ascending hot solutions, the metals in the form of sulphides, the barium as sulphates. They were mostly deposited in the contact zone below the lowest of the thin porphyry sheets and to a limited extent above this sheet. The limestone throughout this zone is replaced by silica. The fissures through which the mineral solutions ascended have since been filled with calcite. There are two varieties of quartz porphyry. One, called Eagle Hill porphyry, is very like the Leadville white porphyry, the other, or birdseye porphyry, is like the gray Leadville porphyry.

Two ore-bearing beds about 100 feet apart exist near the middle of a great series of limestone strata. The lower of these two beds consists of quartzite, or dark silicified limestone, brecciated and porous, carrying silver and antimony and copper, but no gold, and is called the silver ledge. The upper, known as the gold ledge, is a zone of decomposed bleached red or yellow limestone and shale, containing realgar and cinnabar, with a low but uniform percentage of gold. The silver ledge was easily traceable, owing to the hardness of the rock, causing it to protrude as a ledge, but the gold ledge was more difficult to follow, being marked at the outcrop only by a slight ocherous appearance in the rock, the gold never being visible. The Geological Survey discovered that certain seams or beds of shale-like matter in the mines, forming the roof of the ore bodies, are highly altered sheets of a white porphyry, called, from the name of the hill, Eagle Hill porphyry. Three of these sheets, one above the other, were traced in the ore-bearing zone, an important point bearing upon the oft-observed connection of igneous rock with ores.

The vein materials of the gold ledge are realgar cinnabar and pyrite with gold, and with these are associated barite and calcite and gypsum. The deposits are formed at the intersection of zones of north-east fracture, with the lower contact of the middle of the three porphyry sheets, reaching a thickness of 20 feet and thinning out away from the fracture fissures. Some of the principal fissures are still open, and show no evidence of filling or erosion by circulating waters. These fractures cut across the silver ledge, and as a rule do not extend above the gold ledge.

The average section of the mining area of the rocks of the Mercur Basin are in ascending order:

1. Blue-gray, Lower Carboniferous limestone occupying the bottom of the canyons, 200 feet of which are exposed.

2. Above this a series of interbedded limestones and calcareous sandstones, 600 feet thick.

3. A very thick blue-gray limestone, 5,000 feet thick. This limestone contains in its beds narrow strata of shale at intervals, which furnish the water supply of the district; also in its lower portion it carries the ore horizons.

4. Above this another series of interbedded limestones and sandstones, like the lower series, 5,000 feet thick. Altogether in the Mercur Basin a total thickness of 12,000 feet of strata.

The two porphyries found in this region are very dissimilar in appearance. The Eagle Hill porphyry is nearly pure white, with a pinkish tinge, showing small crystals of quartz and mica in its fine grained feldspathic ground mass.

The porphyry is generally much decomposed, the weathered rocks are stained various shades of red and yellow. It occurs in two principal sheets in Eagle Hill parallel to the bedding of the limestone and overlying the ore bodies. As the hills around Mercur are not covered by drift, it is easy for the prospector to trace continuously the line of contact of the eruptive with the sedimentary rock. If the actual boundary cannot be seen, it can generally be identified by fragments lying on the surface which correspond pretty closely with the solid rock below. In the weathered

MERCUR BASIN, LOOKING NORTH; MARION HILL IN LEFT FOREGROUND.

rock the limestone chips are of the typical dark blue color while those of prophyry are cream yellow, brown or green, and on a bare hillside the line separating the two can be rapidly traced. If the hill is steep a talus may hide the contact.

The birdseye porphyry forms two eminences called Porphyry Hill and Porphyry Knob. Its color is grey with distinct light grey feldspar crystals, mica and quartz crystals speckled all over it and forming the greater part of its bulk. In decomposing, the ground mass becomes deep olive green color. The Eagle porphyry weathers into small sharp fragments but the Birdseye decomposes gradually in place. A large part of the rocks in the Mercur basin contain traces of gold showing a very slight but widespread mineralization. Of the rocks analyzed by Mr. Spurr, the great blue limestone showed a trace of gold; black shale, a trace of gold; altered weathered limestone, small quantities of gold. The two porphyries showed the largest traces of gold, about 0.01 oz. to ton.

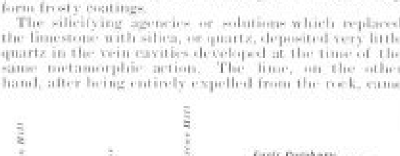
The pure white crystalline calcite veins, although in no way connected with the chief mineralization, showed small quantities of gold 0.025 oz. to ton. This shows a slight general mineralization of the rocks of the basin. In certain localities, the mineralization has been so great as to furnish ores of gold and silver which have been profitably worked. In all cases these localities are at the contact of porphyry sheets with inclosing limestone. The exact line of contact, however, is not always profitably mineralized. In localities only is it rich forming ore bodies. In these contact ore bodies are two groups. In the first the lime is hardened at contact with the porphyry and is called by miners "black quartz." It shows chloride of silver, antimony, copper, carbonate and barite.

In the second group, lime and porphyry are both decomposed and changed into a soft rock called "shale" by the miners. It is nearly black but oxidizes to light yellow. The first group contains only very small quantities of gold with silver; the second no silver, but enough gold to be valuable. This latter ore carries much arsenic and mercury sulphide. The silver ledge is a zone of highly silicified rock at the contact of the lowest of the three minor sheets of Eagle Hill porphyry. The outcrop of this zone is very prominent throughout the basin, having been fashioned by erosion into a steep cliff conspicuous from a distance. The rock at the contact is much brecciated, the fragments, composed of cherts and silicified limestone, are enclosed in cement of white calcspar and barite. The contact of the ledge with the porphyry is very distinct, greater erosion of the porphyry leaving a shelf 20 feet wide. In the limestone below the silver ledge are numerous narrow vertical calcite veins which do not appear in the broken rock above or in the porphyry, showing that the formation of fissures and cracks since filled with calcite was not later than the intrusion of the porphyry. The breccia of the silver ledge was formed by the friction of the intrusion of the porphyry sheet against the limestone walls, and the filling up of the spaces between the fragments with crystalline calcite followed closely. The fissures in the limestone below may have been opened up at the time of the intrusion of the porphyry and have been filled by calcite at the same time as the breccias of the silver ledge. A noticeable hardening and darkening of the limestone is found at this upper contact for 5 feet. Three sheets of porphyry are developed on this hill, one 20 feet thick associated with the silver ledge is the lowest. Above this a smaller sheet much decomposed associated with the gold ledge; and above this a third sheet which does not seem mineralized.

In the Silver Cloud mine the silver ledge outcrops as a broken, flinty zone with irregular veins of barite. The drift at the bottom of the shaft shows a strongly fractured zone. The fractures are open and large, without vein filling, and indicate the action of faulting. These fissures contain no ore, and were later in origin than the vein filling of the silver ledge. The rock cut by these planes is much metamorphosed. It is an altered, cherty, broken limestone, dotted with small blotches of calcite or barite, and is cut by veins of calcite in a network. Large geode cavities occur, lined with crystals of dogtooth spar. Barite is common in bunches or pockets, veins or geodes. Malachite and copper stains occur. In some of the crevices a good deal of kaolin clay occurs. The open fissures were later in formation than the calcite veins and geodes, as they cut abruptly through these. The softer and decomposed porphyry is actively prospected for gold.

The mineral which accompanies the ore is a flinty, impure quartz called black quartz by the miners. Complete silicification, or changing of rock into a quartz-like condition, was one of the first stages of metamorphic action. The quartz is always in this massive amorphous condition; crystals are rare. The quartz which occurs in cavities has been produced by dissolving agencies. On the walls of cavities and in irregular cracks, it may form frosty coatings.

The silicifying agencies or solutions which replaced the limestone with silica, or quartz, deposited very little quartz in the vein cavities developed at the time of the same metamorphic action. The lime, on the other hand, after being entirely expelled from the rock, came



Geological Section of Mercur Basin.

in and crystalized as pure white calcite in numerous fissures and cavities opened by the silicifying solutions, forming veins several inches wide, lining walls of large cavities with beautiful crystals of dogtooth spar. These veins are found everywhere and are indicative of considerable mineralization, more than is contained in the silicified limestone alone.

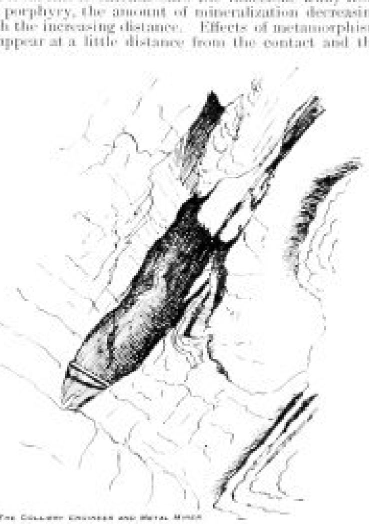
This does not show, however, any close connection in deposition between the limespar and the ores. It is the honeycombed condition of the rock which is significant of the intensity of the action accompanying or inducing mineralization, and the calcite, coming later, filled by a slower process the cracks and cavities formed by the eating away action of the mineralized solutions. The calcite veins are not intimately associated with ore; usually they are barren. (In the volcanic region west of Cripple Creek, Colo., we have observed many large calcite veins in the lava, but have not as yet heard of them being productive.)

Barite, or heavy spar, on the other hand, is closely associated with the ores. It occupies irregular spaces in the rocks. At the contact of barite with chert, or flint, there is a zone of transition from one to the other, suggesting that barite may have replaced the limestone at the time of silicification, and that barite and silica were introduced at the same time. This mineral is a sure sign of considerable mineralization (a fact which we have observed in many of the mines of Colorado also). The barite is often the gangue in which the metallic sulphides that furnish the ore are imbedded.

Antimony occurs in thin radiating crystals and bunches. Films of various forms of copper occur, closely associated with silver. In the neighboring Tintic district copper forms a conspicuous part of the ore and an important product. Arsenic occurs in the gold ledge in the form of the sulphide realgar. Chinese talc, or gouge, as the miners variously term it, occurs as at Leadville, a white or rusty clay resulting from the decomposition of the feldspars of the porphyry. It is a silicate with a varying amount of sulphate of alumina. It is compact, semi-translucent, white and soft, and hardens and becomes opaque on exposure to the air.

The silver ores in the silver ledge, all carry small quantities of gold. The silver ore is small films of chloride of silver disseminated through altered silicified limestone.

Mineralization has taken place at the contact between porphyry and limestone. The point of greatest mineralization is in the limestone directly on this contact and from this it extends onto the limestone away from the porphyry, the amount of mineralization decreasing with the increasing distance. Effects of metamorphism disappear at a little distance from the contact and the



Natural Open Fissures in Face of the Drift, Silver Cloud Mine.

limestone below is unaltered. The zone of alteration is from 10 feet thick, to 50 in places of great mineralization. The mineralized zone does not deviate from this line of contact. It does not extend into the porphyry or follow any steeply dipping zone as would be caused by planes of fracture. There are no fractures or water channels in the zone through which the mineral solutions could have come except the minor fractures in the limestone at contact with the porphyry, and they were merely the result of friction caused by the intrusive porphyry.

The mineralizing agents were heated waters, circulating along the contact, containing silica, barium, antimony, copper and silver. The work of these solutions was the removal of lime and deposition of silica by process of gradual replacement, without destroying the original features of the rock. In many places, as here, the effect of these solutions is shown in the alteration of the limestone in the vicinity of the ore-deposits to chert or silica, the derivation of one from the other being quite clear. Quartz in the vicinity of eruptive rocks accumulates in compact crystalline masses or in a jasper or chalcedonic condition. So the silicification of the limestone of the Mercur district at contact with porphyry is only a common result of metamorphic action.

Mr. Spurr gives a very clear explanation of the way in which ore bodies are deposited in connection with igneous rocks and igneous activity, which will apply to Leadville and Cripple Creek, Colorado, and many other igneous localities of ore deposit.

The water which lavas contain is not emitted till the actual moment of solidification, when, by process of crystallization it is separated out and becomes conspicuous by its fluidity. When the solidification takes place at the surface it forms clouds of steam which issue from cooling lavas, but where the rock is forced into a molten state between the strata, so that the water which is separated is still under sufficient pressure to keep it in a liquid state, there results intensely heated solutions capable of a great degree of corrosion. These solutions act most violently at the contact, and become rapidly cooled on penetrating the adjoining rock, and in case of small bodies of igneous rock at a short distance, become incapable of much altering power. Lavas possess a wonderful power of retaining for a very long time and up to the moment of solidification, considerable quantities of water, showing that heat does not exclude the action of water and that the latter has even at high temperature an affinity for the silicates of lavas. The width of the zone of alteration following the contact of an igneous with a sedimentary rock, varies constantly with the nature and size of the intruding mass, and the nature of the sedimentary rock, and other conditions. Along the same contact between the same eruptive and sedimentary rock, are great differences, and at points where the eruptive rock forms reentrant angles the zone of alteration is greater than at projecting angles. All such phenomena are exemplified in the Mercur contact zone.

The phenomena of the silver ledge indicates brief intense action, highly heated waters capable of great metamorphosing influence, as shown by complete replacement of limestone by silver and by great corrosion of the rock. The mass is full of irregular cavities of dissolution, especially where alteration has been gradual. Some of these are several feet in diameter, others are small. Whether the material removed from these spaces was lime or silver such a riddling of the rock indicates very active agents of solution.

The barium found in the silver ledge as heavy spar, was derived from the cooling eruptive mass. Barium is of frequent occurrence in igneous rocks especially in the feldspars of the porphyry, and most of the metals found in veins are present in the minerals composing igneous rocks. On crystallization, a portion of them would be taken up by the forming minerals; and the small amount, left dissolved in the heated waters expelled at the same time, would be carried out and deposited in the enclosing rock when conditions were favorable.

Mr. Spurr considers the ores were deposited as at Steamboat Springs, Nevada, by ascending hot solutions. The solutions, exuding at every point from the cooling porphyry, found in the limestone a zone where the passage of solutions was made relatively easy by the opening of fissures and formation of breccias. These waters heated and under great pressures would move along this broken weakly resisting zone, and whenever possible also in an upward direction. Where the porphyry sheets cut across the strata the waters would rise rapidly. Where circulation was retarded, accumulation and mineralization would be greatest. The greatest mineralization does not attend the greatest sheets of porphyry, but often the contrary, the neighborhood of the smaller sheets being most mineralized.

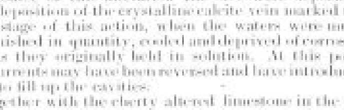
SUMMARY OF SILVER LEDGE GEOLOGY.

Silver ores characterize a zone of altered limestone, following the contact of Eagle Hill porphyry along the lower surface of the lowest sheet of igneous rock. This zone is marked by silicification of the limestone by presence of barite, antimony, copper and silver. The copper is a carbonate, the silver a chloride, associated with sulphide of antimony.

There was great straining and fracture at time of introduction of the eruptive rock. Breccias are common and many fissures cross the altered rock, but do not persist far into the mass of unaltered limestone, and there are cavities formed by the corrosive action of circulating solutions. The walls of these cavities and fissures are covered with calcite, whose large crystals show a slow, quiet period of formation. The calcite was deposited after the main alteration.

Silver and copper and antimony were originally deposited as sulphides. The mineralizing agents were waters which contained silica and barium in solution, with small amounts of antimony, silver and copper. The gelatinous silica was deposited as quartz, the barium as sulphate, the metals as sulphides. The action was intense and brief, the waters highly heated. That the mineralization clings closely to the porphyry shows the waters were either derived from the igneous rock or had a common origin with it. The minerals which the waters deposited are such as would be derived from the porphyry. The water which accompanied the eruption was separated from the lava at the moment of cooling and found its way into the adjoining rock. It exerted a powerful soluble force on the soluble limestone, and in the course of this alteration the ores were deposited. The deposition of the crystalline calcite vein marked the final stage of this action, when the waters were much diminished in quantity, cooled and deprived of corrosive agents they originally held in solution. At this point the currents may have been reversed and have introduced lime to fill up the cavities.

Together with the cherty altered limestone in the ore zone, large veins of barite occur, sometimes in open cavities, into which the crystals of barite extend, and cinnabar coats these crystals. Much of the clay in this zone is altered decomposed porphyry. Faults occur not unfrequently, and the fault crack is filled with mineral,

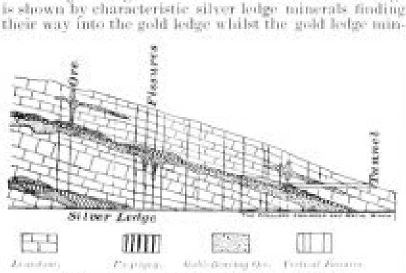


Section Along Geyser Tunnel, Mercur.

which shows that the mineralization, which introduced the gold in some mines, took place after the faults were developed. (The gold may occur in combination with tellurium, as at Cripple Creek, Colo.) There is rarely over one-half an ounce of gold to a ton of ore, and three ounces is very rare. The greatest mineralization in the gold ores is at the lower contact of the thin sheet of porphyry next above the lowest, or silver ledge sheet, with the blue limestone. From the contact the ore descends, as at Leadville, downward into the limestone for a few feet without change, then falls off rapidly, so that the ore gives place irregularly to unaltered and barren limestone, carrying only a trace of gold. The ore is richest where the alteration is greatest.

The porphyry at contact shows many irregularities, rolling up and down along the course of the tunnels and above the limestone. Open fissures occur; also other fissures filled with calcite, belonging to an earlier period than the fissure; these are merely gash veins, whilst the open fissures mark a period of sheeting of the rock after the formation of the calcite veins, and are of greater length than the calcite ones, but often following a calcite vein as a line of least resistance. Mining stops at the lower contact of the altered porphyry, leaving a clear, quite regular wall. Below, the mineralization extends more irregularly and gradually into the limestone. Average thickness of available ore is 7 feet. A convenient distinction between the altered porphyry and altered limestone is the presence of calcite veins in the limestone, which are never found in the porphyry. The limestone in many cases shows profound fracturing and sheeting, and is open fissured. Where fissures are widest there is least mineralization, and where most sheeted and the fissure narrow, most mineralization occurs, ore solutions being detained in the narrow passages, whilst they passed rapidly through the wide ones, leaving no deposit above the contact alteration, and mineralization of the porphyry takes place slowly. The altered porphyry always contains a trace of gold. Where the alteration is least and mineralized zone of limestone narrowest, the ore stops abruptly at the contact with the porphyry. Occasionally the whole porphyry sheet may be sufficiently impregnated with low grade ore to be mined bodily (as in the Little Johnny, Leadville). Shrinkage causes certain planes of weakness to develop in the limestone, causing vertical cracks, so that the rock is divided into blocks, between which the mineralization penetrates inward. The vertical fissures, before alluded to, have been instrumental in opening up the rocks through which they pass to the mineralizing currents. Sometimes (like at Cripple Creek) they are crowded close together, forming a "sheeted zone." Along such zones the pulverized rock crumbles readily and is carried away, leaving the open fissures we have described. The mineralization of the gold ores occurred at a period later than the mineralization of the silver ledge and the formation of the calcite veins which are so abundant in all the rocks.

The vertical fissures existed before the arrival of the gold and were the channels for this mineralization. That the gold ledge was mineralized after the silver ledge is shown by characteristic silver ledge minerals finding their way into the gold ledge whilst the gold ledge min-



GEOLOGICAL SECTION OF PART OF MERCUR MINE.

erals do not transgress into the silver ledge. The porphyry had nearly reached its present state of decomposition before the minerals were deposited. One of the marked signs of alteration of the porphyry is like what is common at Cripple Creek, Colorado, viz., curious patterns and concentric markings of red and yellow oxide of iron on the porphyry ground mass. The limestone in alteration shows the removal of calcite and replacement by silica with a great deal of more or less porous chert, which Hills observes is due to the leeching out of the siliceous element of the limestone and concentrating them in the form of chert nodules.

The realgar, which is a conspicuous mineral in the deposits, is a sulphide of arsenic of a rich reddish brown color altering on oxidation to a brilliant yellow. The impregnation of the limestone with mineral took place by filling cavities from which quartz or calcite may have been leeched out, also by actual metasomatic substitution or replacement, as at Leadville.

The ores of the gold horizon were originally deposited as sulphides, and all stages of the transition from sulphides to oxides can be seen where the ores are exposed.

The agents which brought about the mineralization were ascending, rising from below, till they met the sheet of altered porphyry, when they spread out along the under contact and so produced mineralization. The channels along which they rose were the open vertical fissures. Where these fissures are thickest the mineralization is greatest.

In the case of the silver ledge the agents of mineralization were heated waters derived from the lava at the time of consolidation. In the case of the gold ledge the phenomena being somewhat different; we may suppose that the mineralizing agents were more in a gaseous than liquid condition. The various metals found associated with the gold, such as antimony cinnabar, etc., were just such as would easily pass into the state of vapor and the last also to be deposited. The phenomena of origin and ore deposit seems very much like that going on at the Steamboat Springs, Nevada, which we have before described in THE COLLIERY ENGINEER AND METAL MINER.

After the eruption of the porphyry a disturbance brought about a set of vertical fissures establishing a communication with a body of uncooled igneous rock at an uncertain depth and affording a vent for moist volcanic vapors. The limestone at the lower contact of the porphyry had been partly silicified at the period of the primary mineralization and in the succeeding period had been rendered porous by the leaking out of a large part of the residual lime. Along this porous zone the vapors spread out, and becoming cooled deposited the gold and other minerals and penetrated slightly upward into the altered but less porous porphyry. Lava retains heat an enormous time after eruption. At Jorullo, in Mexico, a bed of lava emitted vapors from fissures 100 years after its eruption. Such would supply both heat and vapor for mineralization. A point worth noticing in cases of mineralization in volanic areas like Cripple Creek, Colorado, and elsewhere, is that "after eruptions a vast body of heated lava may remain beneath the bottom of the crater in which the process of solidification goes on slowly for an indefinite and very long period affording a continuous source of aqueous vapor charged with various mineral substances."

THE GOLD LEDGE.

The gold bearing horizon is about 150 feet above the top of the silver ledge. It follows a sheet of Eagle Hill porphyry of slight thickness and much decomposed and, as is so often observed in mines, the porphyry owing to decomposition is not easily recognized even as an igneous rock, but this material can be traced through various gradations to a distance from the mine where it passes into a true unaltered and undoubted porphyry. The gold is invisible and only gauged by assays. It is associated with arsenic (realgar), cinnabar, iron pyrites, barite, calcite, gypsum, Chinese talc. It is associated too with a zone of broken cherty, silicified limestone and with a sort of black fissile rock resembling a black shale. This is greatly mineralized especially by realgar, iron pyrites and gold averaging half an ounce gold to ton. The ore zone is well defined and 20 feet thick. In some mines the ore is in an oxidized condition and the gold free. In others it is contained in the original sulphide. The occurrence of the gold in a limestone zone is unusual.

Limestones are not as a rule favorite depositories for gold as they are for lead and silver, but the present case is paralleled by that of the Little Johnnie at Leadville, Colo., where in a somewhat similar way the gold is at the contact zone between porphyry and limestone. Doubtless in both cases the poryhyry is more responsible for the gold than the limestone, which is merely a convenient receptacle for any kind of ore by reason of its solubility and cavernous structure. It is the tea cup which holds the tea, but not the teapot which pours it out; or, perhaps a better simile, it is the vessel into which the liquid is poured from the sponge which holds it. The black shale is an alteration of the porphyry sheet. The decomposition and leaching out of the sulphide ores gives a peculiar aspect to the mineralized zone which makes it easy to be followed. The oxidized ores have been the most worked and readily yield up their gold to the influence of cyanide of potassium or the cyanide process. In the sulphide state, however, the ores have to be roasted and the sulphur driven off, a process which entails some loss.

SUMMARY OF THE GOLD LEDGE.

The gold ledge is developed as a mineralized zone on the lower part of Mercur Basin, mainly on Mercur and Marion hills. It consists of an altered limestone, following the under contact of a thin sheet of altered white porphyry. The mineralization of the limestone along the contact of this upper porphyry is not continuous, but varies from 20 feet to nothing. The lines of greatest mineralization coincide in direction with a set of nearly vertical northeast fissures, forming "shoots" or channels. The ores are of two classes, oxidized and sulphides. The former are extracted by the cyanide process, the latter by roasting. In the sulphide zone the ores are soft and shale-like; in the oxidized zone, soft and easily pulverized; both contain much scattered chert. The amount of gold in the ores rarely exceeds three ounces to the ton; silver is absent.

The mineralization of the gold ledge took place after the silver ledge, by gaseous rather than liquid agents, which ascended along open vertical fissures from some uncooled body of igneous rock below, impregnated the zone at the lower contact of the porphyry sheet already made porous from the effects of the mineralization of the earlier silver ledge, with arsenic, mercury and gold.

Coal Fields of China.

The North China *Herald* of January 17, 1896, quotes a writer of "The Situation" in the Peking and Tientsin *Times*, of the 28th ultimo, as saying: "There are symptoms indicating that the Chinese near Peking are awakening to the advantage of employing foreign engineering knowledge and machinery. Considerable coal fields extend over a vast area of the mountains north and west of the capital, at a distance of about 100 li from it. They have hitherto been worked by the stereotyped, irrational, mole fashion, so characteristic of Chinese. When the natives discovered the coal seams on the sides of the mountains, they commenced digging into them, and in some places they have penetrated as far as 8,000 feet, in others only a few hundred feet, when they were stopped by water, with which difficulty they have been entirely unable to cope, and the mines have consequently, in many cases, been abandoned. We are glad, however, to hear that some rich Chinese, stirred by the railway movement, have entered into contracts with a foreign engineer to develop the mining possibilities of the northern districts.

"China's coal fields are exceeded by none but those in America, and in a more distant time they will have equal effect on the commerce and manufactures of the world. The cost of sea freights has been low enough to allow the coal to be carried to distant countries and sold more cheaply than coal from nearer sources; but the construction of railways, the improvement of navigable rivers and other means of transport are, in many countries, entirely altering the conditions of the coal trade, and in Japan, India and Australia the native coal is rapidly superseding the imported coal, and the same change will eventually take place in South Africa and in China when the coal deposits are developed."

Boiler Test.

We have received from Messrs. H. E. Collins & Co. a handsome illustrated pamphlet, which is a report of a comparative test made by the Pittsburg Testing Laboratory, Ltd., for Currie Furnace Co., as to the relative efficiency of Cahall and Babcock & Wilcox boilers. The results of the test show higher efficiency for the former than for the latter boilers.

THE VULCAN EXPLOSION.

A Description of the Mine and the Conditions Existing Therein.

The Work of Rescue and an Investigation of the Probable Cause of the Disaster.

Written for THE COLLIERY ENGINEER AND METAL MINER by David Griffiths, State Mine Inspector.

On Tuesday morning, February 18th, 1896, an explosion occurred at the Vulcan mine operated by the Atchison, Topeka and Santa Fe Coal Company, one and one-half miles southeast of the town of Newcastle, Garfield county, Colo., which resulted in the death of forty-nine men including James Harrison, the mine foreman, John Funke, assistant mine foreman and Thomas Larrigan, fire boss.

The coal bearing strata at this mine pitches about 47½° and the strike of the seam is southeast and northwest. There are several workable seams of coal on the property, the Wheeler and Allen seams having an aggregate thickness of about 70′.

The mine is under the management of Mr. C. J. Devlin, general manager of the Atchison, Topeka and Santa Fe R. R. Co.'s coal properties; Mr. Robert T. Herricke, local superintendent and Mr. Joseph Fletcher the company's mine inspector, who inspects and reports on all the mines owned by the company about every three months. The immediate officials at the mine were the foreman with an assistant and three fire bosses who each worked eight hour shifts.

The accompanying map of the mine on a scale of 400′ to the inch will enable the reader to arrive at a good idea of the conditions existing at the mine and will make clear the statement of my investigations as to the cause of the explosion. The mine is opened by a slope, *A*, driven on a pitch of 5° 43′ for 250′ through the surface wash and the measures underlying the Wheeler seam. At this point the bottom slate of the seam is encountered and the slope is continued in a direct course on the bottom slate diagonally across the pitch. From the point where the slope strikes the bottom slate of the seam the average pitch is about 30°. The air course, *B*, parallel to the slope, is driven on nearly the same pitch as the slope with the exception that near the surface it is driven on about 40° pitch thus shortening the distance for the connection at the crop entry. The total length of the slope and parallel air course is about 840′ from the mouth.

At a point about 460′ from the mouth of the slope, the right, or west entry, *C*, is turned off on a pitch of 27°, forming a very short curve and a steep grade for haulage. Over this entry a wooden air bridge *D*, is constructed for the main slope air course and about 75′ above this air bridge a shaft *X*, is sunk from the top of the seam to the bottom of the parallel air course, and the right entry is driven to the west boundary line. At 250′ from the slope the right entry runs on the strike of the seam and a double parting about 13′ wide and 100′ long is constructed for the purpose of facilitating the haulage. This is shown at the point *E* on map.

At the outside end of the parting close to the point of strike, a cross-cut is driven to the top of the seam and from this point another air course *F*, is driven parallel to the entry and to the west boundary line. The upper and top slate air courses are connected by an air bridge driven through the solid coal across the main right entry at *G*. At 180′ from the outside end of the parting the first room or breast is turned off. In this entry there are eight rooms and sixteen chutes as shown on the map, and the inside room is driven up nearly on the boundary line. The distance from the point where the entry begins to run on the strike of the seam to the face is 710′. At a point 730′ from the mouth of the slope the left or east entry *H*, is turned off on an easy grade and curve. A parallel air course along the top slate is driven through the slope from the main slope air course (see *I*). The main left entry and parallel air course are about 920′ from the slope. In this entry there are eight rooms and sixteen chutes.

The rooms are all turned off the main entry and on the bottom slate of the seam; they are 40′ wide with 40′ pillars between them. There are two chutes to each room thus forming an entry pillar of about 25′ between the chutes. At a point about 30′ up the pitch the chutes are connected by a cross-cut and the face of the room is then formed. The miners take out from 7′ to 8′ of the coal seam and 40′ wide in the breast. There is a manway built on each side of the breast about 3′x 8′, or 24 sq. ft. sectional area for ingress and egress and for ventilation of the face of the workings. The rooms are driven up about 175′ from the entry and then stopped, after which all the cut coal is taken out of the room.

Another operation then takes place. Men selected for the purpose, called "top men," are put to work to cut the seam at right angles to the pitch and up to the top rock, then the whole thickness of the seam, about 45′ of coal, is blasted down and taken away through the chute below, care being taken not to draw out too much, so as to give the men something to stand on and keep them close to their work. On arriving at the top of the room in taking down the top coal, the breast is tapered off so that there will not be any point of it higher than the top cross-cut in the bottom coal. This is necessary because if the top coal was excavated higher than the air current there would be an accumulation of fire-damp. The first operation of working up the room is done by the yard and the top coal men are paid by the day. As soon as the top coal operation is finished all the coal is taken out as rapidly as possible because if left for any length of time it is liable to spontaneous combustion. The coal is loaded by men selected for that purpose who are paid by the day.

At the time of the explosion the mine was ventilated by two fans *K K*, of the compressive type. One was a Guibal fan 12' in diameter with blades 5' 6'' in width and the other was a double Murphy fan 6' in diameter. These fans were capable of producing from 38,000 to 40,000 cubic feet of air per minute separately and from 54,000 to 60,000 cubic feet of air when working together. The interior of the mine was so arranged that if one fan was disabled the one fan would ventilate the whole mine. The right and left entries had separate and distinct currents of fresh air from the outside. Each current was again split in the mine thus giving a separate current for the room workings and the entries. The split currents joined at the face of the entries and returned through the main entries. Air crossings were built or formed in all practical points in order to avoid doors and to keep a continuous air current through the workings. The mode of ventilation and its distribution received great attention and was, in my opinion, well conducted.

The management recognized the danger incident to the presence of coal dust and took the following precautions. Under the brow of the hill and about 50' above the mouth of the mine three large wooden tanks *T*, were constructed, into which water from the Grand river was pumped. The tanks are connected with a 6'' wrought iron pipe and the pipes running into the rooms are connected to 4'' pipe on the entries which are reduced to 2'' in the rooms. Two-inch valves are used on the room connections; some of the rooms have pipes near the face but generally a hose connection is made and the hose is moved to the point of watering. The hose has a reducing nozzle and by the use of it every section of the mine can be reached from the nearest connection. The altitude of the tanks, which are about 330' or more above the entries, yields a pressure of nearly 140 lbs. to the square inch. There was a man engaged for the purpose of extending the pipes and sprinkling. I consider the system as good as can be adopted.

The subject of damping or sprinkling the dust in the mines of Colorado is gaining favor among the mine officials, and there are very few officials who do not recognize the importance of keeping the dust from contaminating the air current. Some of the extensive mines in the southern part of the state are now watering all their haulage ways and the officials state that great benefits have been derived; the quantity of air is increased and improved in quality, and besides there is a perceptible decrease of temperature in the mine. Where explosives are used to mine the coal the dust question is a matter of great importance and should not be neglected at any time, and it should be borne in mind that sprinkling is not sufficient to overcome this dangerous element. In order to be on the safe side the dust must be well watered. The Prussian Fire Damp Commission and other authorities say that the dust must be dampened with 50% of its own weight of water before any degree of efficiency is obtained.

Previous to the explosion I made several inspections of the mine in company with Mr. R. T. Herricke, superintendent, and Mr. Connors, who was then the mining boss, and invariably found the mine in good condition. At the time of one visit we discussed the question of safety lamps and the management informed me that they had decided on the use of the Mueseler lamp to replace the Clanny lamp then in use. I approved of the change, and that was the lamp used by all workmen except the fire bosses at the time of the explosion. On the whole I considered the mine in excellent condition and had no suggestion to make to the management whereby a greater degree of safety could be secured. There were no rooms in operation at the times of my visits, all places being worked in eight hour shifts in order to make speedy developments.

On September 20th, 1895, Mr. John D. Jones, Deputy Inspector, made an examination of every working place in the mine, accompanied by Mr. R. T. Herricke, superintendent, Mr. James Fletcher, inspector of mines in behalf of the A. T. & S. F. Co., Mr. James Harrison, mine foreman, and Mr. John Funke, his assistant. This was Mr. Harrison's initiation to the mine. He was anxious to see every place as to its condition, etc., and he was satisfied that everything was well conducted. Deputy Inspector Jones reported as follows: "Quantity of air entering per minute, 32,500 cu. ft. A current of air is carried through all the working faces, also a supply of water to sprinkle the rooms. The haulage ways are well timbered. A new fan will be put up in the near future which will undoubtedly be of great benefit."

This additional fan was put in operation on the 15th of October, 1895, and the two fans gave a combined volume of 50,000 cu. ft. of air per minute, with neither fan running at full capacity. We were notified of this by the officials and we felt assured that another safeguard had been added to the Vulcan mine. On February 8th, 1896, I made another inspection of the mine in company with Messrs. Herricke, Harrison and Funke. On this day the mine was not working. There were a few company men at work in No. 1 room on the left entry. I inquired of Mr. Herricke as to the condition of the mine previous to entering and he informed me that the mine was in better condition than ever before. We walked down the slope to the left entry and there met Mr. Harrison, and we examined the main and back entry. We then came back and went up to the top coal room where there were five men at work blasting down top coal. Here I found a good current of air and a hose for the purpose of sprinkling the dust. The dust had just been sprinkled at the time and six shots were charged ready to fire. We examined the highest point in the top coal with a Davy safety lamp but found no traces of fire-damp. I inquired if there were any more rooms in the mine working top coal and the answer was in the negative. We then came up the slope and the six shots were fired. By the time we arrived on the knuckle we heard the six shots in the top coal room going off quite distinctly. On leaving Mr. Herricke, Mr. Harrison asked me if I had any suggestions to make and I answered no, but that they had a mine to look after that required great care and attention. I did not visit all the working faces, but was satisfied from what I had seen that the local management was doing everything for the safety of life and property. In many cases where the miners are of the opinion that the officials do not comply with the law regarding coal mining we receive complaints, but in this case we have never received a complaint either by word or letter.

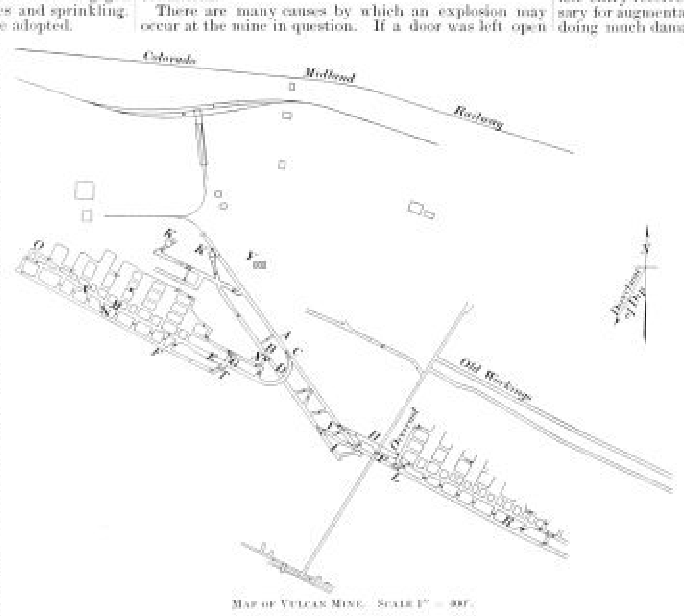
On the 23rd of February I received a communication from Governor McIntire as follows: "I desire to call your attention to the necessity of the most careful and scrutinizing investigation on your part into the causes of the recent terrible disaster at Newcastle so that the responsibility for the awful loss of life may be placed exactly where it belongs. Allow no stone to be left unturned in getting at the exact truth."

I can conscientiously say that I did as the Governor directed me. However, my endeavors were fruitless and I am sorry to say that no definite cause could be found for the disaster. If the exact cause could be found and the blame placed where it belonged we would obtain some satisfaction for the relatives of the ill-fated miners and probably prevent a repetition of a similar accident at this mine or at other mines working under the same conditions.

There are many causes by which an explosion may occur at the mine in question. If a door was left open for a short period an accumulation of gas would be the result and a defective safety lamp would ignite the mixture. Under the same conditions a careless miner might open his lamp and set off the gas, or a blown out shot might cause the disaster; a too heavily charged shot may do the same thing. A sudden outburst of gas may take place and impregnate the ventilating current and form an explosive mixture and the same coming in contact with a naked light or a flame cause the explosion. Other modes could be enumerated by which a disastrous explosion might occur in a gaseous and dusty mine. However, I must form an opinion of the cause from obtainable evidence.

As I previously stated, the mine, in my opinion, was in good and safe condition and there was no accumulation of gas or dust. I will even say more, and that is if the most competent fireboss had examined the mine a minute previous to the explosion he would have proclaimed the mine to be perfectly safe and in a workable condition. By this I mean to say that our present mode of detection of danger is too crude and the danger line is much too high. We are aware that it is impossible to detect less than 2% of fire-damp in the atmosphere of a mine with the common Davy lamp and generally our fire bosses cannot detect less than 4% which in itself is nearly at the explosive point. Experiments prove that even less than 1% is very dangerous in a dusty atmosphere. Some experimenters claim that some kinds of dust, in the absence of any gas, is explosive, others doubt the phenomena. However, all experiments have proved beyond doubt that when both the above ingredients are in the ventilating current (fire-damp being less that 1%) it becomes highly explosive under certain conditions. With these remarks in view, let us consider the conditions existing in the Vulcan mine. Every person that has worked in the mine is well aware that great quantities of gas are constantly transpiring from the strata and that the coal is naturally dusty, and furthermore, explosions have occurred in this field which have been claimed to be due to dust alone. There is no doubt that the dust produced in the Wheeler seam is highly inflammable.

Now the question arises, How could the explosion occur? We admit that gas is emitted freely from the strata in an unknown quantity as to percentage in the air current, but not sufficient to be detected by the Davy lamp, and there must be some small quantity of minute particles of highly inflammable dust in suspension in the air. Such a mixture would be non-explosive in contact with a naked light, but highly explosive if detonated by a blown-out shot, ignition of loose powder, or a small quantity of fire-damp. From the location of the bodies of Mr. Larrigan and Mr. Funke, and the course taken by the force of the explosion, I am of the opinion that the explosion originated in the right or west entry near one of the chutes between No. 7 and No. 10, shown on the map at points *M* and *N*. The timber from this point was evidently forced inwardly and outwardly. The inward force traversed the entry and forced its way to the parallel air course and backward, some of it going up the manways No. 15 and No. 16 at point *O* on map and over the top air course and out through the fan openings. It is evident, however, that in passing through the top air course and rooms, the force was not greatly augmented, because the air course was found in good shape, the only damage done being at the mouth of the fan openings. That the greatest force came through the main right entry is evident by the manner in which the timber was strewn. When the outward force arrived at the air-bridge located across this entry at *D*, a weak point of resistance was found and the force expanded, some of it going up and down the main air-course parallel to the slope and most of it in contact with the return air from the left entry. The force going up and down the main air-course (and intake of the mine) did not get the necessary ingredients to augment its force; it only received a fresh supply of oxygen for the support of combustion. The force on getting in contact with the return air of the left entry received the inflammable ingredients necessary for augmentation and went down the slope without doing much damage to the timber, etc., only one set of which was knocked out, and this at the entrance into the left entry, and five or six more at the double parting. It is evident that the force going down the air-course preceded that going down the slope. This is proven from the fact that the stoppings in the cross-cuts were blown outwardly into the left entry, the most conspicuous being that of the regular stoppings between the left air-course and the double parting at *P*. Evidence of great violence in the force traveling inwardly through the air-course and entry were found, and I am of the opinion that it was aided by explosions of powder which the miners had in readiness for their use. However, we could not find direct evidence to localize this any more than that the augmentation of the explosion was very great. At the face of the left air-course a car was found, the ends and sides of which were smashed into kindling wood. The bodies found near the face of the main entry were badly mutilated. The forces coming in through the air-course and main entry met at about No. 12, or at point *R*. This, I think, caused great commotion at this point. After expending all the elements of energy the reaction took place and volumes of smoke came out leisurely through all the openings.



MAP OF VULCAN MINE. SCALE 1'' = 400'.

I have as yet omitted to explain how I think the explosion originated. Thomas Larrigan was supposed to examine every place in the mine previous to firing any shots. He was also supposed to fire the shots. Now, I have formed an opinion that one of the chutes in the right entry had become blocked, and in order to remove the stoppage it was necessary to put in a little powder to start the same, and in so doing the explosion occurred. I have no doubt that Mr. Larrigan examined the condition of the place and used his judgment as to the amount of powder, etc.; but there may have been a small quantity of fire-damp existing in the chute at a point he could not reach or observe. It is probable that any practical man would have done the same thing he did. Now, assuming the above statement to be correct, I will endeavor to explain how the explosion originated. The explosive used may have been placed on the lump of coal blocking the chute and covered with a small quantity of dust or slack; from this the flame would elongate and set off the small quantity of gas that could not be observed and an explosion on a small scale would be the result, and the compression of the air current due to this would cause the air itself to become explosive, and the agency causing the compression would also ignite the mixture.

On Sunday, March 15th, after all the bodies were recovered, we held a conference in the mine consisting of the following practical miners, all of whom had been aiding in the explorations: M. M. Walsh, mining boss, Blossburg, N. M.; Robert O'Neill, mining boss, Starkville, Colo.; Ed Flynn, superintendent, Rockvale, Colo.; Joseph Fletcher, coal mine inspector, A., T. & S. F.; Robert Herricke, local superintendent; John P. Thomas, mining boss, Rockvale, Colo.; Harry John, fire boss, Rockvale, Colo.; Charles Grant, fire boss, Rockvale, Colo.; George Ward, local fire boss, Rockvale, Colo.; Humphrey Davies, fire boss at Newcastle mine.

Others were invited, but for some reason did not attend. The object of this conference was to try and localize the point of origin of the explosion, but no definite conclusion could be arrived at.

In examining the effect of the explosion, the reason why there were so many different opinions is made manifest. I will here state that my opinion is based upon the most plausible cause from which it could have occurred. Many are under the impression that it originated from a blown-out shot because it was about firing time when the explosion occurred, but there is no evidence of any shots having been fired except the one fired by Mr. Larrigan in a dog-hole near the face of the left entry. There were several lamp keys found on the bodies, but not a single open lamp. Matches were found on some of the bodies, but there was no evidence found that anybody was lighting a lamp or attempting to smoke. On taking everything into consideration I am of the opinion that the principal ingredients causing the disaster were dust and gas, but that the known line of danger was not perceptible, and that the cause or origin is only a matter of supposition at best, and will remain a mystery like many other similar disasters.

The effect of the explosion was so violent that I am of the opinion that every man in the mine died instantly and that not one of them breathed any after-damp. Some or the bodies were burned, but I do not think the burning effects would have resulted in death. The fans located on the surface at *K K* were blown to pieces and the three openings shown on the map were nearly closed. This was caused by the timbers being blown out and the dirt they sustained caving in. Every wooden stopping and door in the mine was broken except one door in the inside haulage cross-cut in the right entry at *S*. This was forced open and nearly off its hinges; the others were shattered like matchwood. Two stone stoppings were blown out, one between the slope and air-course opposite the left entry at *V*, and one between the left main air-course and left main entry on the double parting at *P*. Several stone stoppings between the slope and its parallel air-course stood the severe test and thus aided us greatly in getting air through the workings after the explosion. On the curve coming out of the right entry nearly all the timbor was blown out. Many sets in the inside withstood the violence, not a set being out on the double parting. The slope timbers were undisturbed with the exception of six sets at the mouth and one near the entrance to the left entry. Inside of the parting on the left entry and air-course the force was most violent. Nearly every set of timber was blown out and heavy caves of coal had fallen, which greatly retarded the explorations.

There are some peculiarities in connection with this explosion which caused different opinions as to the ingredients which were predominant in the explosive mixture. It is the opinion of scientists and practical men that if fire-damp predominates at the time of the explosion intense heat is developed, and that traces of this will be left on all material susceptible to fire, and if the dust in suspension in the air current predominates, that caking or coking results will be found in abundance after the explosion. In this case we have no traces of fire on any susceptible material, such as timber, canvas, or brattice cloth. The steam pipes were covered with hay and then wrapped with shredded canvas, which was as dry as tinder and strewn all over, but even on this we could find no trace of fire, and with a very diligent search by myself and others we failed to find any trace of coked dust as a residue. Still, some of the bodies were burned in proximity to some of the susceptible material mentioned above. Such a statement may appear to be absurd, nevertheless it is true. The only way I can account for these phenomena is that the elements in the explosive were not productive of a long-extended flame, but intense heat was created and the explosion passed through all the workings with lightning rapidity. That there was intense heat I have no doubt, but it must have been of very short duration. Some of the bodies were denuded and horribly mutilated, decapitated and disemboweled. Nearly all of them had to be identified by their wearing apparel or other appurtenances.

On the body of one of the men a watch was found that had evidently stopped instantly, owing to the violence of the explosion, at 11:27 a. m., so we concluded this to be the correct time of the explosion. I was notified of the explosion through the courtesy of Mr J. A. Kebler, general manager of the Colorado Fuel and Iron Co., at 12:45 p. m., and at 2:05 p. m. received an official telegram from Mr. Herricke, the local superintendent.

In accordance with section 8, Coal Mines Act, myself and my deputy boarded the first available train and on board the cars we met Mr. Kebler and Mr. Willard, general superintendent of the coal agency of the A. T. & S. F., also Mr. Coughlin and Mr. McGourty, both of whom had sons in the ill-fated mine. We arrived at the scene of the disaster about 12:30 p. m. on the following day. At this time some bodies had been brought out of the mine and a fan was in operation. Great credit is due Mr. Herricke, local superintendent, Mr. Paul Blount, superintendent of the Newcastle mine, and his mechanic, Mr. Jas. Buchanan, for the expedition with which they erected this fan, which had to be transported from the Consolidated mine, engine erected, fan cased, etc., it being in operation in less than twenty-four hours after the explosion. Mr. Choate, the division superintendent of the Rio Grande, sent some carpenters to aid in its construction.

At this time all hopes of rescuing any of the miners alive had been given up and we waited for the fan to clear out the foul atmosphere in the mine. During this time we held a conference as to how we were to proceed. In this conference were Mr. Kebler, Mr. Blount, Mr. Herricke and myself, and we decided to enter the mine at 2:40 p. m. and that from inside observations we could decide on the mode of action. At the appointed time Mr. Herricke, Mr. Kebler, George Ward, John Evans, Humphrey Davies and myself entered the mine. George Ward, John Evans and Humphrey Davies were the heroes of the party. The first obstruction we met was the dilapidated air-bridge across the right entry at *D*. Ward and Davies passed over the obstruction, and penetrated into the right entry about 300 feet. On returning they reported that the narrow entry round the curve was in bad shape, but that the double parting was in good shape and that they had not seen any fire-damp, also that there was a good current of air passing. Evans, owing to an accident (a nail penetrating his foot), returned to the surface, and the remaining five in the party went down the slope as far as the entrance to the left entry. Here we found a set of timber blown out, and about 30' in the left entry fire-damp was found. We then concluded to return to the surface and take immediate steps to remove the fire-damp from the left entry and at the same time have the air-bridge over the right entry at *D*, temporarily erected.

We had all the voluntary help we needed at this time and the first work done was the placing of a temporary stopping on the crop entry; this carried all the air produced by the fan, about 40,000 cubic feet per minute, down to the air-bridge, and returned it through the slope. Then the air-bridge proposition was considered and from the amount of work necessary to erect it and the greater number of bodies being in the left entry, it was decided to build a stopping on the entry and have the air down to the left entry as soon as possible.

During this preliminary work, Mr. Kebler acted as consulting engineer and he coincided with our views and the men under his management were the volunteers. On Wednesday night, February 19th, about midnight, Mr. Joe. Fletcher, Sante Fe mine inspector, and Dan. McLaughlin, superintendent of Starkville, arrived with a reinforcement of men, twenty in number, and some of them were immediately put to work building stoppings, etc. As yet there had been no system adopted as to the hours of work. On Thursday night, February 20th, Mr. C. J. Devlin, general manager of the A. T. & S. F. coal properties, arrived on the scene. All the details then known as to the condition of the mine and mode of procedure were stated to him, and he was satisfied that everything had been done to the best advantage under the circumstances, and that the hours of labor were too long and that in order to expedite the exploration it would be necessary to systematize the work. On the 22nd of Febeuary the following notice appeared, signed by Mr. Devlin and approved by me:

NOTICE TO MINERS.

"In order to push the work with the greatest speed the following rules will govern:

"1. Shift Bosses will each work six hours. Pay in accordance therewith.

"2. Others in mine will work three hours each.

"3. Pay for three hour shifts $2.75. Pay for shift bosses, per shift, $3.00. Each man is requested to do his utmost so as to get the bodies out in the shortest possible time."

Previous to this notice the men had been working six hours at a shift and some dissatisfaction was exhibited, but not enough to delay the exploration work. Messrs. Fletcher, Herricke and myself selected eight shift bosses who were men of practical experience and acquainted with the mode of working, etc. They were George Ward, Henry John, John Evans, J. P. Thomas, Joseph Griffiths, William Doyle, Humphrey Davies and J. W. Smart. Two of these men were in charge of the work every six hours; their duty was to direct the men what to do and to watch the fire damp that we knew existed in the mine. When this system was enforced we found it difficult to obtain men for the work and many of the miners had to work six hours in order to keep the work going. If it had not been for the Colorado Fuel and Iron Co. closing down their mine it would have been impossible to get the required number of men necessary to carry on the work. On the 23d of February Mr. Ed. Flynn arrived with twenty-eight men from Rockvale. On the 25th, Mr. Robert O'Neill, of Starkville, arrived with five men and M. M. Walsh, of Blossburg, N. M., brought seventeen men with him on the same date. We were now well reinforced and everything was done that was necessary to expedite the work. Mr. Devlin left after being there a few days and entrusted Mr. Joseph Fletcher with the management of the exploration with the instructions that he was not to consider expense, but to get the bodies out with all possible haste.

After removing some of the gas in the left entry we were able to explore the double parting up to the haulage cross-cut and did not find much obstruction, only a few sets of timbers being out. At the end of the parting we found that a great quantity of coal had fallen and had to be removed. The slope was cleared and the cars were put in motion to remove the fallen coal. The gas in the two parallel entries was removed by placing a temporary stopping in the cross-cuts as we advanced and all the miners were taken into the intake air course until it was diluted. On the night of the 27th of February the main left entry was all cleaned up and examined. During this time work was also carried on in the back entry, but from the fact that there was more coal to handle, etc., it took a few more days to get cleaned up, but some of the explorers went over the fallen coal and found the body of Robert Steiger, track-layer, in the face of the back entry. During the time of cleaning up the entries we knew that the man-ways, cross-cuts between rooms, and some faces were full of inflammable gas and this was constantly watched by one of the shift bosses in charge. Preparations for a greater supply of air had been made by repairing and erecting the double Murphy fan, and at 12:30 a. m., March 1st the fan was started and the air current turned up the inside rooms. While doing this a three-hour shift was laid off and only five bosses allowed to be in the mine. The quantity of air had now been increased at the outlet from 38,000 cu. ft. to 50,000 cu. ft. per minute, but from the fact that all the stoppings were leaking, the quantity playing on the gas did not exceed 28,000 cu. ft. In removing the great quantity of gas from the rooms great precaution was used in keeping all lights from the return air and also from the mouth of the slope. By the morning of March 5th all the standing gas had been removed from the left side of the workings and all places thoroughly examined.

On Friday morning, March 6th, operations were started on the right entry. While the greatest force of men were working on the left entry, preparations were made for getting into the right in order to be able to split the air current. By doing this the quantity of air in the left entry was greatly reduced. However, enough air was kept there to dilute all the gas that was given off. It is evident that some air had been going through nearly all the workings in the right entry or we would have found more standing gas than we did. The only place where standing gas was found was at the top slate air course and at the top of No. 8 room at O. We found things in a much better condition here than we expected, the worst caved place being around the curve outside of the double parting. On the double parting an accumulation of water had taken place and to remove this it was necessary to have a pump located near it. A pump was already on the ground and in less than forty-eight hours the water was pumped out and the cleaning up of the entry resumed. On Sunday morning, March 15th, the body of Robert Allier was brought to the surface and this completed the number as reported on the official list. During the exploration work some of the shift bosses resigned and other men equally as good were appointed to fill the vacancies; they were Messrs. Thomas Neeson, James Daniels, Charles Grant and George Bunn.

Great credit is due Messrs. Jones, Deputy Inspector, Herricke, Fletcher, McLaughlin, Flynn, O'Neill and Walsh for the general overseeing of the work and to the shift bosses for their diligence. However, the greatest credit is due the miners who were actually doing the work.

To give the details of the exploration would cause this article to be too voluminous. Suffice to say that the work was very perilous and the surroundings unpleasant. We were fortunate not to have any serious accident to any of the explorers.

Before resuming work at the mine with the full force of men I recommended Mr. Herricke, local superintendent, to make the following changes:

Have rock stoppings built in all cross cuts between all parallel entries, and in placing doors on the gangways have them packed or tightened with cement, lime mortar, or some other material not liable to fire. Have a fan or fans capable of producing, say 60,000 cu. ft. of air per minute, to be distributed to the right and left entries in separate currents and in proportion to requirements. Have the air distributed through the working places the same as it was previous to the explosion. I recommended an exhaust fan as giving better results than a compressive or blower fan. In connection with the use of safety lamps I am of the opinion that the Mueseler lamp now in use is as good as any. In relighting the lamps in the mines I recommended that no man be allowed to have a key except the fire boss and that all lamps be opened in the intake air course. I also recommended that the watering system be kept in good order and in shape to sprinkle all the working places, that such timbering as was necessary to put the entries in good order be immediately set, and to allow no blasting except at stated periods when all the men except those actually needed to fire the shots are out of the mines. I also recommended an electric bell or gong in the steam engine house for the purpose of signaling. In case they continued to use steam for pumping purposes, I recommended that the present steam pipe covering be removed, and, if the pipes must be covered to keep down condensation, to have them covered with an asbestos composition. I also suggested the use of compressed air for pumping purposes. I requested Mr. Herricke when ready to resume work and the aforesaid improvements were made to notify me so that I might examine the general condition of the mine.

Our present mode of the detection of gas is too crude and as there is now on the market a reliable and very sensitive mechanical instrument by which small percentages of gas in air may be detected (namely Shaw's Gas Testing Machine) I think the mine inspector should possess one so as to enable him to find the percentage of gas in the air currents of our gaseous mines and have the air currents regulated accordingly. Furthermore, every superintendent of a gaseous mine should have one of these machines so that daily tests can be made of the return air currents and a record thereof be kept in the local office.

In regard to the use of explosives I would recommend the following rules for use in dusty and gaseous mines.

First.—The powder should be of that brand known as the least productive of flame.

Second.—All holes should be drilled under the supervision of a competent person.

Third.—All holes should be charged, tamped and fired by men selected for that purpose. The charge should be in accordance with the burden of the hole, etc., and the tamping should be of material not productive of flame. Before firing the surroundings should be thoroughly examined as to the presence of dust and gas.

Fourth.—No shots to be fired or powder detonated anywhere in the mine except at a specified time and all men to be out of the mine except those actually required for the purpose of firing.

Ruberoid Roofing.

Our attention was recently called to the roofing used at one of the larger anthracite collieries on the breaker, engine house, boiler house and other colliery buildings, by an official of the colliery. It was made from a heavy wool felt thoroughly saturated with a water and acid proof composition. It was strong and very durable, would not run at any temperature, contained no tar, and was simple and economical to lay. Long use had proven it absolutely impervious to moisture, and proof against steam and gases. On the boiler house, where it was subjected to the action of heat, steam and the gases generated from the combustion of coal, it gave remarkably satisfactory results. Besides it makes a fire-proof roof. It is not expensive, and the ease with which it is laid makes it an ideal roofing for mine and mill structures. It is manufactured by The Standard Paint Co. of No. 2 Liberty street, New York, whose reputation as the manufacturers of the well-known "P. & B." paint is sufficient guarantee of its excellence, even if practical use had not demonstrated its superior merits.

METAL MINING.

ARTIFICIAL MEANS OF VENTILATION.

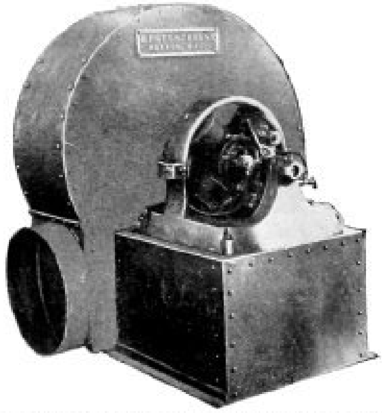
American and Foreign Practice Compared—Fans and Their Different Varieties—Air Pipes for Blowers and Fans—Force and Exhaust Systems Compared.

Written for THE COLLIERY ENGINEER AND METAL MINER by Albert Williams, Jr., E. M.

(Continued from May Number.)

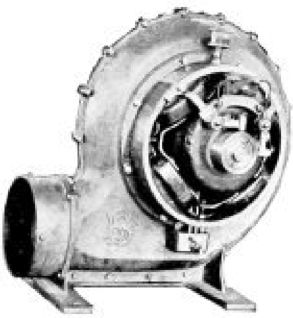
FANS.

American practice in the mechanical ventilation of metal mines varies widely from English and Continental methods. Abroad they adhere to the large, low-pressure centrifugal fans, of which the Guibal is a well-known type. These large fans are well suited to collieries, as they handle great volumes of air at low pressure. They are usually run as exhausts and without



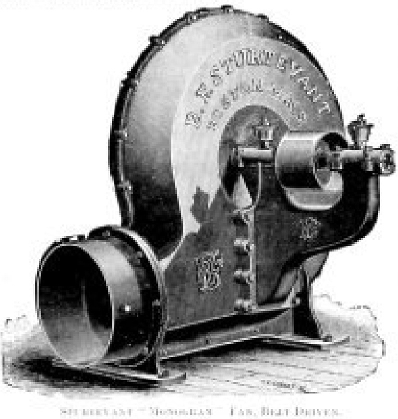
STURTEVANT EXHAUST FAN WITH SLOW MOTION ELECTRIC MOTOR (GENERAL ELECTRIC CO.)

underground air pipes, being placed at the side of a shaft mouth, from which they suck out the air. Some fans of this class are as much as 50 feet in diameter, and the medium sizes would here be regarded as clumsy and



STURTEVANT FAN.

unnecessarily cumbrous. They are run at relatively low speeds. A few are seen in American metal mines. Preference is, however, given to the small, high-speed fans of greater relative power and with better mechanical construction and efficiency.



STURTEVANT "MONOGRAM" FAN, BELT DRIVEN.

Fans are much more frequently used than blowers, and some of them develop pressures or vacua comparable with blowers, so that they are effective for the longest distances reached by mining.

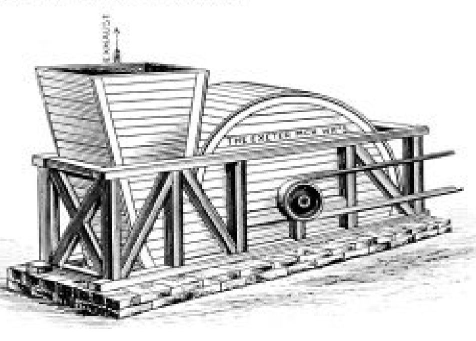
As to mode of action, there are two main divisions of fans—centrifugal and propeller. The former class is much the more important.

A simple apparatus like the paddle wheel of a side-wheel steamboat, on being rapidly rotated, would produce a tangential movement of the air by centrifugal force, the outgoing air being replaced by air drawn in at the center. This principle is taken advantage of by a multitude of devices giving improved efficiency over that obtained by merely beating the air with plain flat radial buckets or floats (as in the paddle-wheel, or blades or vanes as they are called in fans). The propeller class act on the principle of the small ventilators used in buildings, are run open, and drive the air through them.

Mentioning first some of the large centrifugal fans:

The Guibal fan.—In this fan the blades are flat or slightly curved at the tips. They are not set radially, but are inclined backward. There may be 8 or 10 blades. The fan is cased in. Other features are regulating shutters and an expanding exhaust stack which reduces the velocity of the air and consequently the back pressure of the atmosphere. There are many modifications of the original Guibal.

The Capell fan of equal power is smaller than the Guibal and is run at higher speed. It has two concentric shells besides the outer casing. In each are curved vanes, convex side forward. Air enters the inner shell, is forced out through ports into the second outer



EXETER FAN, SHOWING CASING.

shell where it strikes the concave faces of the outer blades, the idea being to return part of the impulse first received and also to discharge the air at low velocity. It has an expanding exhaust flue, and is used as a suction fan.

The Waddle fan is run without a casing. It is narrow and of large diameter. One side is closed; the other has a central opening. It is an exhaust fan.

The Schiele fan has curved blades, and its main peculiarity is that it is set close to the casing at one point only. It is much smaller than the Waddle and the Guibal and is run at a speed comparable with the American fans.

There are many other fans of European invention, but the Guibal and its modifications is probably the most frequently used.

Passing now to American fans.

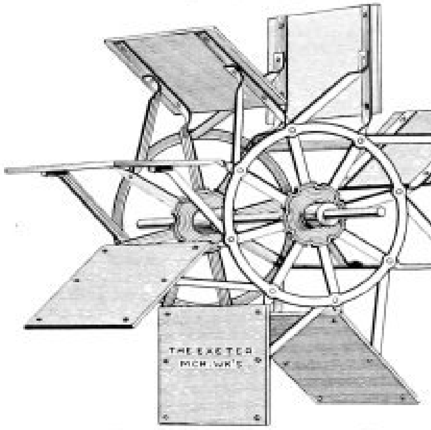
The Sturtevant fan.—This is a strongly built (of steel) compact machine, capable of being run at very high speeds (up to 2,000 revolutions or over per minute), and therefore of large capacity in proportion to its size. It is used to furnish air at high pressure for iron furnaces and for forcing air long distances, as in pneumatic tube delivery systems, and consequently is fitted to meet extreme requirements in large mines, using smaller air pipes, if necessary, than usual. When used at high pressure it is called a "blower." It is made as a forcing fan and also as an exhauster; right-hand or left-hand power; with horizontal or upright discharge; and in ten sizes. It is either driven by belt (in

CHAMPION FAN WHEEL.

which case a large pulley should be used on the counter-shaft, to obtain high speed of fan without too high driving speed), or by electric motor on the fan itself.

A special form of Sturtevant fan, known as the "Monogram," is designed for forcing or exhausting large volumes of air, as in mine use. The castings are very heavy and strong.

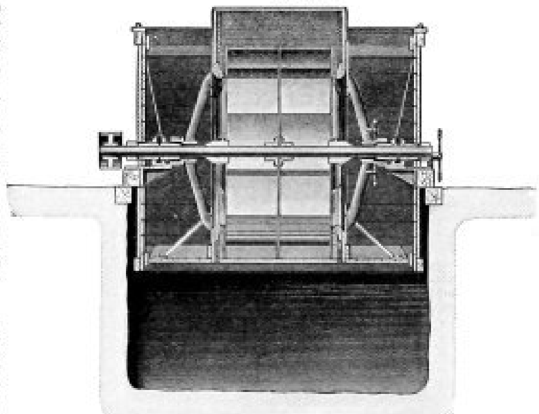
Exeter Fans.—Among other fans, the Exeter Machine Works make exhaust mine fans, the construction of which is clearly shown in the cut. These fans are of rather large size, one style being 5 to 15 feet in diameter,



EXETER FAN, SHOWING ARRANGEMENT OF BLADES.

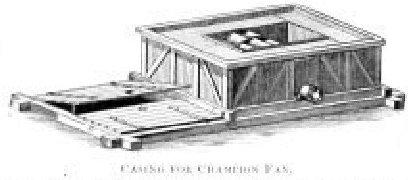
and another 15 to 30 feet in diameter.

The Champion Fan.—This is really two fans joined together by a common center ring, which is a solid plate. The outer rings have unusually large openings. The blades have a curvature designed to propel the air with minimum resistance. The fan is used either to blow air into the mine, or as an exhauster. There is an inner casing (called a hood) and attendant diaphragm which are hung on bearings, so that by revolving the hood around the fan without stopping the latter, the current may be changed at will from blowing to exhausting. The Champion is used without air pipes. It is placed at the side of an air shaft, with which it is connected by an airway, and at a tunnel mine it is located at the side of the tunnel mouth, connecting with the tunnel by a similar side airway. The fans are made in six sizes, running from 4 to 14 feet in diameter.



CHAMPION FAN, CROSS-SECTION.

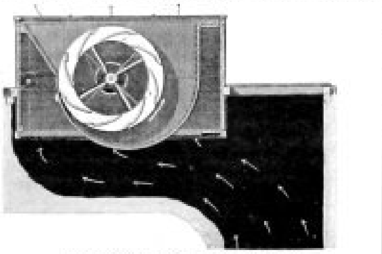
The Smith Fan.—The essential feature of this fan (or blower, as it is usually called) is the double discharge. To secure this the case is extended on the rear end and a second outlet is provided, which is led around and under the first one, to the front, where the two outlets unite in one discharge. The theory of this construction is that a vane of a fan wheel becomes loaded with air



CASING FOR CHAMPION FAN.

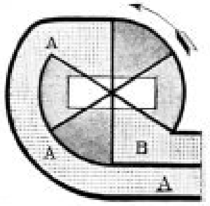
long before it completes a revolution (at one-third revolution, it is claimed), which air cannot be discharged until carried around, against the back pressure, till it reaches the outlet.

The same result (as effected by the double outlet) cannot, it is argued, be obtained by merely doubling the area of a single outlet, for the effective peripheral distance of the blades is limited to the space where the tangential action exists. A blade cannot discharge air back of it, nor beyond the point where it crosses the line



CHAMPION FAN, LONGITUDINAL SECTION.

of flow. The double discharge gives a large capacity for a given area of fan, or in other words, a smaller fan can be used to match a given outlet. As forcing fans (blowers) these give large volumes of air in proportion to size. There are manifest advantages in reducing the size of a fan. Exhausters are built on a similar principle.



THE SMITH DOUBLE DISCHARGE FAN.

The Davidson Fan.—This is an open disc-wheel fan of peculiar construction. The blades are shaped with the design of cutting through the air and forcing it off, instead of carrying it along with the wheel. The blades are not perpendicular to the axis of the shaft at the center, and have a feeding surface the whole length of the blade from the periphery to the center delivery. Each surface of the blades is both concave and convex. This fan gives pressure as well as volume, and though not specially made for mine work has been used in ventilating long railway tunnels, one 15 ft. fan moving 160,000 cubic feet of air per minute through a 3,800 ft. tunnel, and another 20 ft. diameter (said to be the largest disc-wheel fan ever made), moving 250,000 to 300,000 cubic feet per minute through a 4,900 ft. tunnel.

As to disc-wheel (propeller) fans in general, it may be said that there are situations in mining where they would be useful. For example, where electric plant is already installed for other purposes, such fans could be placed underground where most needed, and readily moved from place to place as required. Even small hand-power fans of this class would be available under certain conditions, especially in mines having no power plant. Or, placed horizontally over an air shaft not giving satisfactory ventilation by natural draft, disc-wheels driven by wire rope from the hoisting works, or by

DAVIDSON DISC-WHEEL FAN.

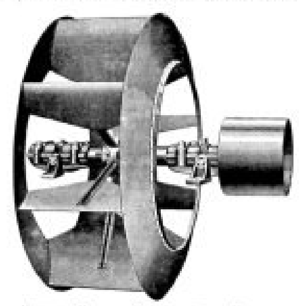
electric motor, would serve a useful purpose. It might also be possible to reduce the section of an air shaft (that is, a shaft intended solely for ventilation, and not as an air shaft, and for other purposes also), to the smallest dimensions that could be conveniently cut out, if a fan were added.

The Buffalo Fans.—As the Buffalo Forge Co. makes such a variety of fans, usually to order for special requirements, it is impossible to give a general description of the machines. For mine ventilation the specialties are exhausters of all sizes in wood or brick housings and and "volume blowers" (fans) with electric motor directly attached, made in many sizes.

POWER.

Almost all the makes of blowers and fans are built in a variety of ways as regards the application of power, and the user has a wide choice. It is of course cheaper to belt on to some other machinery, and if there are Cornish pumping engines it is pretty certain that they are constantly running. Artificial ventilation, if required at all, should be constant, not intermittent. Pumping engines and (usually) stamp mill engines run pretty steadily, but the hoisting plant may not. Hence, if there is urgent demand for machine ventilation, and that on a large scale, it is better to have the blowers or fans driven by their own engines or motors, and for this purpose the arrangement should be self-contained; that is, the engine should be on the same bed plate and the electric motor directly connected.

As to the kind of power best suited to driving high-speed fans or blowers, electricity is undoubtedly the best; and what is termed a "slow speed" motor is now available, which can be attached to the blower or fan



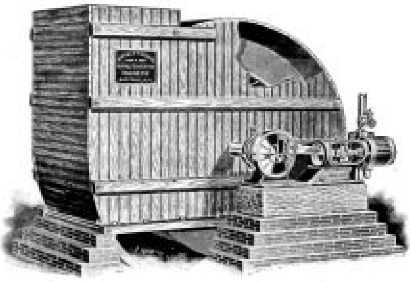
BUFFALO FAN FOR WOOD OR BRICK HOUSING.

shaft direct. But if electric power is not used at the mine otherwise, then special high speed engines, designed for the purpose, can be used.

There are many other forms of American made fans which might be used in ventilating mines.

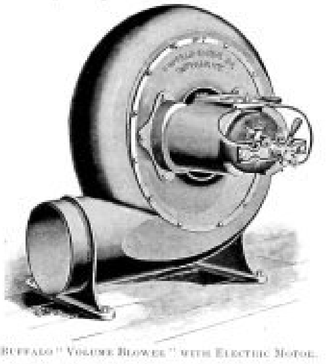
AIR PIPES FOR BLOWERS AND FANS.

Ventilating pipes should always be as tight as possible, and when air is used under strong pressure, as with blowers and high speed fans, the pipes should be per-



BUFFALO EXHAUST FAN IN WOOD HOUSING.

fectly air-tight. Small leakages are not allowable, for as much power is used upon every cubic foot of air lost as upon the same volume utilized. The higher the pressure, the greater the leakage through holes of the same area. Wrought iron pipes are commonly used, while steel is coming into use also. The best styles are the spiral riveted or the welded seamless, when the air is at considerable pressure. For low pressures a cheaper style will answer. To protect against rusting, in wet mines, the pipes may be either galvanized (and regalvanized after riveting) or coated with coal tar or asphalt applied at high temperature.



BUFFALO "VOLUME BLOWER" WITH ELECTRIC MOTOR.

FORCE AND EXHAUST SYSTEMS COMPARED.

In a colliery the essential thing is to draw off the gases escaping from the coal. Hence, if the gas emission comes mainly from one or a limited number of points it may be better to suck it out at once through exhaust pipes, rather than diffuse it through the mine.

This is in addition to the necessity of supplying fresh air to the men and animals (if any). But in metal mines the conditions are different. Elaborate systems of brattices, sollars, air doors, etc., are not often needed. All that is required is that all the workings through which men pass should be fairly ventilated, and that particular attention should be given to the actual working places, the most important being the upper parts of stopes and upraises, the headings of drifts and tunnels, and (when sinking) the bottoms of shafts and winzes. It would seem more logical to send the fresh air from the surface direct to the spots most needing it, this air driving out the foul air. As for the general ventilation of all the workings, taken as a whole, there is little to choose between the exhaust and plenum or force systems, and for the reason given the force system is usually preferred. Still the direction of natural draft, however slight it may be, must not be opposed, and the whole arrangement of the ventilating pipes made accordingly. In very deep and hot mines, if several levels are being worked simultaneously, special attention should be given to the lowest and hottest one.

It would be better that the hoisting shaft should be a down-cast and the air shaft an up-cast, if the mine is opened on this plan; yet this consideration is not so important as that the working faces be kept wholesome.

Most of the blowers and fans act equally well as forcers or exhausters, but some are made for one purpose only, and when a fan is ordered for suction it should be specified that an "exhaust" fan is required.

(To be Continued.)

An Automatic Mine Door.

No matter how good a ventilating plant is used at a mine, it is never positive in its results unless the doors in the air passages are either closed or open as the case may require. *Open* doors are seldom used, except at such points where it is desirable to temporarily cut off the air current from some section of the workings. *Closed* doors are necessary in every well ventilated mine, and the efficiency of the ventilation depends very largely on their being *kept closed* except when trips or workmen are passing through them. This necessity, has in the past required the employment of door boys, or trappers, whose duty is to see that the doors are kept closed as much as possible. Where no door boys are employed the rule is "leave every door you pass through just as you found it." This rule is frequently violated, and as a result trouble with the ventilation and sometimes serious accidents are the results.

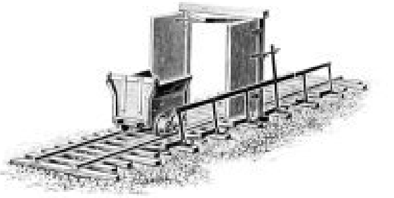
An automatic mine door that is positive in its action, simple in construction, and one that does away entirely with door boys, and the trouble of doors left open through neglect, is desirable at all mines. Such a door is illustrated herewith.

This door is manufactured by the Standard Mine Door Co. of Glouster, Ohio, and it is either put in on royalty or sold outright. Its construction is remarkably simple, and it works equally well on either straight or curved roads. It is very durable and if at any time repairs are needed, they can be made by the ordinary mine blacksmith. This feature is a valuable one, for if a mine owner purchases one of these doors he can have it repaired whenever necessary by his own blacksmith, and the one purchased will last during the life of the mine. The track bar is so arranged that the trip of cars will either open the door or stop before reaching it. It is impossible for a car to ride the track bar. The door can be adjusted to open slowly or fast, and to accommodate trips of any number of cars desired. The door and its operating mechanism are so arranged that there is no danger of coal falling off the car breaking any part.

What one door saves in trapper's wages will more than pay for it in the first year.

This door is not placed on the market as an untried appliance. There are a number of them in use giving excellent satisfaction. We have seen several letters from users of them, which heartily commend them.

Mr. D. S. Williams, superintendent of the Chicago and Central Ohio Coal Co., Jacksonville, Ohio, writes



THE STANDARD AUTOMATIC MINE DOOR.

under date of January 28, 1896, as follows: "The Standard Automatic Door, placed in our mine No. 4, is doing excellent work. It is a perfect success. We cheerfully recommend it to all coal companies as a good thing."

Mr. J. A. Hopkins, Supt. mine No. 10, of the Sunday Creek Coal Co., Derthick, Ohio, writes under date of Dec. 17, 1895, as follows: "The two Standard automatic trap doors, placed in this mine some time ago, are giving excellent satisfaction. While the place we are using them is a severe test, they are giving us better ventilation and saving money. No superintendent will make a mistake by having them put in."

Mr. Lewis Jones, Supt. of Phenix mine No. 2, of the Phenix Coal Co., Glouster, Ohio, writes under date of Dec. 17, 1895, as follows: "The two Standard automatic trap doors placed in mine No. 2, some time since have been given a very fair trial, and so far they have worked entirely satisfactory, performing all claims made for them."

"Jeffrey Labor Saving Appliances" is the suggestive title of a handsomely illustrated pamphlet recently issued by the Jeffrey M'f'g Co., of Columbus, Ohio. It illustrates and describes the various styles of Jeffrey handling and conveying machinery, and successful Jeffrey electric mining machinery.

THE COLLIERY ENGINEER

....AND.....

METAL MINER.

WITH WHICH IS COMBINED THE MINING HERALD.

Established 1881. Incorporated 1890.

PUBLISHED MONTHLY AT SCRANTON, PA.

Entered at the Post-Office at Scranton, Pa., as second-class matter.

THOS. J. FOSTER, RUFUS J. FOSTER, MINING ENGINEERS, } EDITORS.

THE COLLIERY ENGINEER COMPANY, PUBLISHERS.

DENVER OFFICE, 502 Boston Building.
PROF. ARTHUR LAKES, Assist. Editor in Charge.
POTTSVILLE, PA., OFFICE, 12, Morris Building.
BAIRD HALBERSTADT, E. M., Special Representative.

TERMS.

Subscription, (Postage in the U. S., Canada, or Mexico, prepaid.) **$2.00 a Year.**

To Foreign Countries in the Universal Postal Union, $2.50.

THE COLLIERY ENGINEER AND METAL MINER and HOME STUDY, $3.00 per year.

Remit by P. O. Order, Express Money Order, Bank Check or Draft or Registered Letter.

P. O. Orders.—You can buy a Money Order at your Post-Office payable at the Scranton Post-Office.

Express Money Orders can be obtained at any office of the American Express Company, the United States Express Company, and the Wells, Fargo & Co.'s Express Company.

Registered Letters.—If a Money Order Post-Office, or an Express Office is not within your reach, your Postmaster will register the letter you wish to send us on payment of eight cents.

We Cannot Be Responsible for money sent in letters in any other way than by one of the four ways mentioned above.

EXPIRATION OF SUBSCRIPTION.

The date after your name on the wrapper of THE COLLIERY ENGINEER AND METAL MINER shows to what time your subscription has been paid.

RENEWALS, ETC.

If you do not want THE COLLIERY ENGINEER AND METAL MINER continued for another year after your subscription has run out, notify us by postal card to discontinue it. The courts have decided that subscribers to newspapers who do not order their paper discontinued at the expiration of the time for which it has been paid, are held liable for the payment of their subscriptions up to the date when they order the paper discontinued.

NOTICE OF DISCONTINUANCE.

THE COLLIERY ENGINEER AND METAL MINER is sent to subscribers until an explicit order for its discontinuance is received by us, and all payment of arrearages is made, as required by law. *Papers returned are no notice of discontinuance, as we cannot tell where they are from.*

CHANGES OF ADDRESS.

A subscriber wishing to have his address changed should be careful to give his *former* as well as his present address; otherwise we cannot find his name on our mailing list.

All communications should be addressed,

CERTIFICATED MINE FOREMEN.

A RATIONAL law providing for the examination and certification of mine foremen, and for the appointment of mine inspectors by competitive examination, has been found advantageous in every coal mining state that has such a law.

There is no good reason for opposition to such a law on the part of either miners or mine owners. A mine foreman who is naturally of good executive ability, energetic and temperate in habits is not injured by the acquisition of technical knowledge. On the contrary, he is improved. He can, by thoroughly understanding the laws governing the flow of air through mines, distribute his available air current to better advantage, and can also frequently increase its efficiency. By a knowledge of the forces of nature and of the sciences connected with mining he can produce coal cheaper and can increase the safety of both the miners and the property entrusted to his care.

Certificates of competency for mine foremen do not mean fewer practical men, they mean practical men with broader views, men who are equipped not only with their own experience, but also with the experiences of others.

We do not claim that every man who secures a certificate of competency as a mine foreman will be a success. His certificate merely shows that he has the technical knowledge necessary to keep a mine safe and to get out coal in the best manner. Whether he has the executive ability to handle men must be determined by actual trial just as it must be with non-certificated men.

In fact, the case may be stated briefly as follows:—

Without certificates of competency neither mine owners nor miners can be sure that a foreman has either mining knowledge or executive ability, unless he has been a foreman for years.

With certificates of competency issued by a reliable board of examiners, the question of mining knowledge is settled, and it is safe to assume that men intelligent enough to prepare themselves for an examination, are more likely to know how to handle men than those who have not enough ambition to increase their knowledge on mining subjects.

As for the selection of mine inspectors by competitive examination, we will only give the following reasons for its superiority over other methods:—

First.—It insures the selection of a competent man.

Second.—It removes the office from partisan politics.

Third.—The man appointed on merit is under obligations to neither miners nor operators, and can therefore fulfill his duties in an impartial manner.

THE DETERMINATION OF THE COKING QUALITY OF A COAL.

AS is well known, the chemical analysis of a coal is no guide as to its coking quality, and the question as to whether a coal will produce good coke has only been satisfactorily proved in the past by actual trial. The chemical analysis, which gives the percentages of fixed carbon and volatile matters, will furnish an idea of the nature of the coke to be obtained, but it does not determine whether the coal will coke or not.

M. Louis Campredon, in a paper read before the Academy of Sciences in Paris, in December last, describes a method for obtaining the binding power of coal which he has used at the Vignac Works for three years with signal success. To show the lack of relation between the composition of the coal and its binding quality, Mr. Campredon furnished the following table of analyses:—

	Volatile matters, per ct.	Ashes, per ct.	Fixed carbon, per ct.	Binding power.
1. Through coal from Aberdare, Merthyr (South Wales)	10.90	6.20	82.90	0
2. Through coal from Newcastle	34.25	10.80	54.95	2
3. Through coal from Scotland	34.72	8.35	56.93	4
4. Small coking coal from Cardiff	19.80	7.70	72.50	6
5. Through coal from Lens (Pas de Calais)	27.20	8.70	64.10	15
5B. No. 5 oxidized by heating at 100° during one year	28.12	8.55	63.33	0
6. Small coking coal from Newcastle	27.83	8.75	63.42	14
7. Small coking coal from Newcastle	29.50	8.50	62.00	17
8. Pitch from Beckton (London)	44.82	0.60	54.58	20

As will be seen from the table, he has taken 20 as the binding power of pitch, and he makes that of a coal giving powdered coke 0. The most binding coal he had found, up to the date of the preparation of his paper, had a binding power of 17. M. Campredon's method is similar to that used in estimating the binding power of cement. The principle involved is the mixing of the coal with an inert substance, and the carbonization of the coal in a closed vessel. The amount of the inert substance the coke produced contains measures the binding power.

The method of operation as given by M. Campredon, is as follows:

Pulverize the coal so that it will pass through a sieve of 2,580 meshes per square inch. As an inert body take some siliceous sand, (sea, river, or quarry sand), of a fine and uniform grain, which will pass through a sieve of 645 meshes per square inch, but over a sieve of 2,580 meshes per square inch.

To a constant weight of powdered coal (one gramme, for instance) mix variable weights of sand, and heat the mixture to a red heat in small porcelain crucibles, so as to carbonize the coal. After cooling, either a powder without consistence or a more or less hard dross will be found. Then determine the maximum weight of sand the coal can agglomerate in forming a solid dross. Assuming the weight of the coal used as a unit, the binding power is given by the weight of the agglomerated sand.

A little coke indicates a small binding coal, and a swollen and bright, or a hard and compact coke shows a coal having the binding properties necessary for coke making.

UNDERGROUND TEMPERATURES.

THE question of the rate of increase in temperature from the surface of the earth downward has long been one on which prominent authorities differ, and no law on the increase of temperature expressed in arithmetical progression has ever been found applicable in a universal sense.

Among the scientists who have recently given this subject considerable thought is M. Joseph Libert, who records observations made at Produits colliery, Flenu, Belgium. These observations, owing to the depth of the shaft, have been carried to a depth of 3,772 feet. Taking 82 feet as the depth at which atmospheric variations of temperature cease to have any influence, it was calculated that the rate of increase of temperature given by the tests at Flenu was 1 degree Fahrenheit for 53.97 feet of vertical depth. This result agrees closely with that obtained some years ago by M. Cornet in the same district, his rate of increase being 1 degree Fahrenheit for 54 feet, only, however, for depths up to 1,679 feet.

Prof. Prestwich's mean, derived from English and Belgian mines, was 1 degree Fahrenheit for 49.5 feet. M. Libert, does not, however, think that the law of increase of temperature can be correctly expressed as arithmetical progression, but that the rate of increase is greater at greater depths. Taking the results obtained at Flenu with those obtained at the Grand-Buisson colliery in the same field, he concludes that the rate of increase down to depths of 2,263 feet is 1 degree Fahrenheit for 65 or 69 feet, while for depths from 2,263 feet down to 3,772 feet it is 1 degree Fahrenheit for 43 feet.

At a bore hole sunk by the Wheeling Development Co., at Wheeling, W. Va., which was 4,500′ deep and $4\frac{3}{4}$″ in diameter, and which was cased to the depth of 1,570′, the strata in nearly as normal condition as possible, and dipping only 50′ to the mile, the following results were shown:

The increase of temperature between points 1,350′ from the top and 2,236′ from the top, which is very nearly M. Libert's intermediate distance, was about 1° per 100′. From a point 2,236′ from the top to a point 3,730′ from the top the increase in temperature was about $1\frac{1}{10}$° per 100′. From a point 3,730′ from the top to the lowest point at which observations were taken, 4,462′, the increase was at the rate of $1\frac{11}{14}$° per 100′. In other words, from a point 1,350′ deep to a point 2,236′ deep the increase of temperature was about 1° for 100′; from a point 2,236′ to a point 3,730′ deep the increase was at the rate of 1° for each 77′ in depth, and from the point 3,730′ deep to the point 4,462′ deep the increase was at the rate of 1° for each 58′ in depth. The average increase in temperature from the point 1,350′ feet from the surface to the point 4,462′ from the surface was at the rate of about 1° for each 75′ in depth. The average rate of increase of temperature at the Sperenburg bore hole near Berlin, which is 4,170′ deep, was at the rate of 1° for each 60′ in depth. At the bore hole of Schladabach, near Leipsic, which is 5,740′ deep, it is at the rate of 1° for each 68′ in depth. A comparison of the results found at these different bore holes makes evident the fact that no positive rule for increase of temperature with depth can be adopted.

PROPOSED SCHOOL OF MINES AT BUTTE, MONTANA.

EFFORTS are being made to establish a school of mines at Butte, Montana, on the lines of the State School of Mines at Golden, Col. At the start it is proposed to erect a building large enough to accommodate one hundred students, so arranged as to permit of enlargement when needed. The proposed school building will be of stone and pressed brick, 100 ft. x 120 ft. in area, two stories and basement, and its estimated cost is $80,000. This building will contain the following compartments: A chemical laboratory, 34 ft. x 48 ft.; a chemical lecture room, 32 ft. x 32 ft.; a scale room, 16 ft. x 32 ft.; assay furnace, 16 ft. x 24 ft., to contain about twelve assay furnaces;

two laboratories, 24 ft. x 32 ft.; a professors office, 12 ft. x 16 ft.; a store room, 16 ft. x 48 ft.; a class room for geology and mineralogy, 32 ft. x 32 ft.; lecture room, 24 ft. x 32 ft.; a library, 24 ft. x 32 ft.; an office for the president, 16 ft. x 16 ft.; physical lecture room, 24 ft. x 32 ft.; metallurgy and mining room, 32 ft. by 32 ft.; two class rooms, (drawing), 32 ft. x 32 ft.; mathematics, room, 24 ft. x 32 ft.; also several reserve rooms.

Montana is one of the most important mining states in the Union, and the efforts of her enterprising citizens in the line of increasing the knowledge and skill of her mining population are most praiseworthy and deserving of encouragement. The better equipped a state's mining men are, the more valuable are her mineral possessions. If the Legislature liberally encourages this school, the state will reap profit from the investment. Intelligent mine officials, equipped with a first class mining education, invariably make the most of the mineral resources of any locality. The safer and more economically the great mineral wealth of Montana is developed the greater the wealth of the state. Therefore the investment in a first class school of mines will be a profitable one.

CARBON MONOXIDE AS AN ELEMENT IN DUST EXPLOSIONS.

THERE is some ground for a theory that a small percentage of carbon monoxide, (white damp), such as results from the discharge of a heavy shot of blasting powder, in the atmosphere of a dusty bituminous mine, will form an exceedingly explosive mixture. This theory has been advanced in Great Britain by Prof. Vivian B. Lewes. Prof. Lewes ignited a small weight of carbonite in a closed bomb, a part of the resulting gas (40% of which consisted of carbon monoxide) was mixed with air in a small gas receiver, and the gaseous mixture did not ignite on the application of a lighted match. A similar mixture was then formed, and coal dust being sprinkled into it, the whole was readily ignited by a lighted match. This experiment showed that the mere presence of a flame, without detonation and consequent compression, in such a mixture will produce an explosion.

Prof. Lewes states that experiments which he made early in 1895 showed clearly that carbon monoxide, when added even in small quantities to a dust laden atmosphere, caused it to become highly explosive. This fact seemed to him to be so important, in the view of the presence of this gas in the products of combustion of many explosives, that he thought it well to bring it to the attention of mine managers. Stress of other work prevented him from making further experiments to determine the exact quantity of carbon monoxide needed to make a dust laden atmosphere explosive. He, however, satisfied himself that the products of the combustion of many explosives used in mines produce exactly the same effect as pure carbon monoxide.

BRUTAL MURDER OF A PROMINENT MINE OFFICIAL.

MR. GRIFFITH G. ROBERTS, assistant superintendent of the Honeybrook division of the Lehigh & Wilkes-Barre Coal Co., with headquarters at Audenreid, Pa., was brutally murdered on the night of the 21st ult. Mr. Roberts was found that night between ten and eleven o'clock, alongside the Lehigh Valley tracks near the Lehigh Valley machine shops in Hazleton with his skull fractured. The engineer of a passenger train noticed Mr. Roberts alongside the track, stopped the train and he was taken to the Church street depot, Hazleton, for recognition. His features were so covered with blood that he was not identified by those present, and as there were still signs of life in his body he was immediately taken to the Miners' Hospital, where he lay in an unconscious state until he died early the next morning.

About twenty feet from where Mr. Roberts was found, a piece of gas-pipe about two feet long and two and one-half inches in diameter, with traces of blood and some human hair on it was found, and it is believed that the blow which killed Mr. Roberts was struck with this section of pipe. While it is certain that Mr. Roberts was murdered, the police and detectives are at a loss to assign a motive for the murder. The money in his pockets and his watch had not been taken, which proves conclusively that robbery was not the motive of the crime.

Mr. Roberts was one of the best known mine officials in Luzerne county, having moved to the Lehigh region some years ago from the Wyoming valley, where he also held an official position. Personally he was very popular, not only among the employes under him and with his official associates, but among people in general. He was a kindly, charitable man.

As a mine official he ranked among the most competent in the anthracite region and enjoyed the confidence of his superior officers to a remarkable degree. His death under any circumstances would have been a shock to hosts of friends throughout the region, and his brutal murder has intensified this greatly. Mr. Roberts was a comparatively young man, being but forty-four years of age, and is survived by a wife and two children.

Luzerne county is gaining an unenviable reputation for the number of brutal murders committed in that section of the country. There are fully a score of unconvicted murderers in the Luzerne county prison, and the fact that such is the case is a disgrace to the county and to the county officials. The immunity which murderers have enjoyed in that county during the past few years is, in a measure, responsible for the death of Mr. Roberts. It took over a score of executions in the Schuylkill region to effectually check the work of an organized band of assassins some years ago. The measures that were effective in breaking up a murderous organization in the Schuylkill region will be equally effective in checking murders in the Lehigh region.

BOOK REVIEW.

THE PRACTICE AND SCIENCE OF MINING ENGINEERING, by W. Fairley, Ph. D., F. G. S., Mining Engineer. Octavo; cloth; 366 pages. Published by James Fairley, Shafto House, Chester-Le-Street, England. This is Mr. Fairley's latest, and certainly one of his best books on mining. The plan of the treatise is such that the student is carried by an easy grade through the successive stages of the subject by a series of well arranged questions and answers. The text of the book is excellent, and the only adverse criticism we can make is that the numerous illustrations are too roughly made. They are clear enough and fully explain Mr. Fairley's ideas, but the mechanical work on them is of such a nature as to cheapen the appearance of the book and thus give the hasty examiner of it a wrong impression as to the sterling value of its contents. We regret that this is the case, and trust that in future editions Mr. Fairley will see that the illustrations are redrawn in better shape so that they will be in better harmony with the text.

PENNSYLVANIA GEOLOGICAL SURVEY, a summary description of the geology of Pennsylvania, Vol. 3, Parts I and II, and an index in separate volume. These publications complete the Second Geological Survey of Pennsylvania, as far as it could be completed, under the adverse circumstances imposed on it by a legislature that could not recognize the value of a full knowledge of the great mineral wealth of the state. Some day the majority of districts of the great State of Pennsylvania will realize the necessity of intelligent representatives at Harrisburg, and when that day arrives a *third* geological survey will be considered necessary, and its cost will be infinitely greater than a rational continuance of the last survey would have been.

A PRACTICAL HAND-BOOK ON THE CARE AND MANAGEMENT OF GAS ENGINES, by G. Lieckfeld, C. E., translated by G. Richmond, M. E., with instructions for running oil engines. 103 pages, cloth, $1.00. Published by Spon & Chamberlain, 12 Cortlandt St., New York. The adaptability of gas or oil engines for mining work, and their economy and success wherever used makes this little volume a very useful and important one for mine managers. It is one of the series of practical hand books issued by Messrs. Spon & Chamberlain. It is a very practical and useful publication.

THE OHIO MINING JOURNAL, official organ of the Ohio Institute of Mining Engineers, Nos. 22 and 23, embracing the proceedings of the winter meetings held at Columbus in January 1893, and 1894, and the excursion to Congo, Ohio, on January 19, 1894. Published by R. M. Haseltine, Secretary of the Institute. Both parts of this publication contain, besides official addresses and reports, papers on mining subjects by practical mining engineers and mine managers, and intelligent discussions of the subjects treated on by the members of the institute.

HANDBOOKS FOR MINING STUDENTS, PART III. Paper; 48 pages. Published by *The Science and Art of Mining*, Wigan, England. Price, sixpence, by mail seven pence. This Part III of the series of handbooks treats on ventilating methods and appliances, and the use of the anemometer, barometer, thermometer and water-gauge, by a series of 146 questions and answers. The author's work is well done and cannot fail to be a boon to mining students, and is worthy of the attention of all practical mining men.

PERSONALS.

Mr. James McLaughlin, recently with the Philadelphia Engineering Works, Ltd., has been elected secretary and treasurer of the Barr Pumping Engine Co. of Philadelphia. Mr. W. W. Lindsay is general manager of the latter company.

Mr. E. Webster, the well known expert in steam appliances, for many years with the Stillwell & Bierce and Smith & Vaile Co., has been appointed western representative of the well known Goubert Manufacturing Co. of New York, with office at No. 1403 Monadnock Block, Chicago, Ill. Mr. Webster will look after the western demand for the Stratton separators, feed water heaters, engine condensers and steam traps, manufactured by the Goubert Co.

LEGAL DECISIONS ON MINING QUESTIONS.

(Reported for THE COLLIERY ENGINEER AND METAL MINER.)

Correction of Certificates of Mining Claims.—Where an original certificate of location of a mining claim is subject to amendment, a certificate amendatory of it will relate back to the date of the original. But where the original is void, a subsequent certificate cannot, as an amendment of it, so relate back.

Moyle v. Bullene (Ct. App. Col.) 44 Pacific Reporter, 71.

Measure of Damages for Trespass on Coal Lands.—In an action for an intentional trespass to land, consisting of the mining of coal from same, the party suing may recover as damages, the highest value of the coal after severence until suit was brought, without any allowance for the cost of mining the coal.

Sunnyside Coal & Coke Co. v. Reitz (App. Ct., Ind) 43 N. E. Reporter, 47.

Negligence in Blasting.—Under the laws of Maine (and other states) it is the duty of persons engaged in blasting lime or other rocks, before each explosion, to give seasonable notice of same, for the protection of persons within the limits of danger. Failure to give such notice is in itself negligence, and renders the party liable for injuries resulting, whether caused by flying debris or the frightening of horses by the noise of the explosion.

Wadsworth v. Marshall (Sup. Jud. Ct., Me.) 33 Atlantic Reporter, 30.

Lien for Coal Furnished Manufacturing Company.—Under the law of North Carolina disabling corporations from conveying their property, by mortgage, freed from liability on a judgment obtained against such corporations "for labor performed, for material furnished, or wrongs committed by such corporations, their agents or employes," liens for coal furnished after making the mortgage are superior to it; the coal being used by such company to enable it to operate its plant.

Pocahontas Coal Co. v. Henderson Elec. Light and Power Co. (Supreme Court, N. C.) 24 S. E. Reporter, 22.

Mining Partnership in Montana.—To constitute a mining partnership under the provisions of the laws of Montana, two or more persons must not only own or acquire a mining claim for the purpose of working it, but must actually engage in working the same; and the fact that one part owner of the claim is charged by another with unlawfully extracting ore from a portion of a vein, the apex of which is alleged to be within the claim, does not create the relationship of mining partners between the parties.

Anaconda Copper Mining Co. v. Butte & B. Mining Co. (Supreme Ct., Montana) 43 Pacific Reporter, 924.

Knowledge of Danger by Employe.—A complaint alleging that an employe's injuries were caused by the negligence of a company in removing four consecutive bents, and the accumulated rocks and dirt on them from the interior of a tunnel, for the purpose of reconstructing such tunnel, and without making any inspection of the top of said tunnel and in ordering the employe—a youth of tender years, who had no experience and was not instructed in such work and its attendant dangers—to remove said bents and the rock and dirt from the place where they fell, which was so dark that he could not see the impending danger, and that while engaged in removing the debris from said tunnel, he was injured by a fall of rock from the top, does not show that the employe must have perceived the danger with reasonable exercise of his faculties.

L. N. A. & C. Ry. Co. v. Cornelius (App. Ct. Ind.) 43 N. E. Reporter, 31.

To Whom Royalties are Payable Under Gas Lease.—An owner in fee simple makes an oil and gas lease for a term of five years, and as much longer as the premises are operated for oil and gas, or the rent for failure to commence operating is paid, for, among other things, one-eighth part of the oil produced and saved, to be delivered in the pipe lines to the credit of the lessor. The lessor then sells and conveys one undivided moiety of the one-sixteenth part of all the oil produced and saved. Afterwards, but before any oil is bored for or produced, the lessor sells, conveys and grants the land in fee simple to his six children, to each one a part by metes and bounds, in consideration of natural love and affection, by deed of general warranty "except that the party of the second part takes the same subject to any lease for oil or gas made by the party of the first part or any sale of royalty for oil or gas made by him"; and by the same deed he retains full control of said land in all respects, and for all purposes during his life time. Soon afterward oil wells are bored, and oil produced, saved and put in the pipe lines in large quantities. The Supreme Court of Appeals of West Virginia held that, the one-eight royalty goes of right to the tenant for life (the lessor) and his grantees, during the continuance of his estate for life, and not to the owners of the fee expectant.

The tenant of an estate for life, unless restrained by covenant or agreement, has a right to the full enjoyment and use of the land and all its profits during his estate, including mines of oil or gas open when his life estate begins, or lawfully opened and worked during the continuance of such estates.

Koen v. Bartlett, 23 S. E. Reporter, 664.

LARGEST CIRCULATION.

In all America no other mining publication has credit for so large a circulation as is accorded to THE COLLIERY ENGINEER AND METAL MINER, published monthly at Scranton, Pa., and the publishers of the American Newspaper Directory will guarantee the accuracy of the circulation rating accorded to this paper by a reward of one hundred dollars payable to the first person who successfully assails it.—*Printers' Ink*, May 6, 1896.

Our mailing list is open for the inspection of any person desiring to assail the rating given this journal. What other mining publication will show how many subscribers it has, and how its clientage is distributed? This is a pointer for advertisers.

Correspondence

This department is intended for the use of those who wish to express their views, or ask, or answer, questions on any subject relating to mining. Correspondents need not hesitate to write for supposed want of ability. If the ideas are expressed, we will cheerfully make any correction in composition that may be required. Communications should not be too lengthy, and personal reflections should be carefully avoided.

All communications should be accompanied with the proper name and address of the writer—not necessarily for publication, but as a guarantee of good faith.

The Editor is not responsible for views expressed in this Department.

Correspondence should be in as simple language, and as free of technical terms and formula as possible, consistent with clear solution.

Questions on subjects not directly connected with mining will not be published.

An Algebraic Problem.

Editor Colliery Engineer and Metal Miner:

SIR:—Please publish the following in your next issue: A and B dig a ditch 100 feet long for $100. Each receives $50; but A receives 25 cents per foot more than B, how many feet does each dig. J. P. WOLFE,

May 11, 1896. Big Stone Gap, Va.

Machinery Catalogues.

Editor Colliery Engineer and Metal Miner:

SIR:—I wish to state that among the many valuable catalogues that I have received from progressive establishments that of the Lidgerwood Manufacturing Co., entitled "Contractors Methods," second edition, is one of the most interesting on conveying machinery. With their usual liberality the pamphlet is sent free on application to the company's offices in New York, Chicago, or Boston. Respectfully, E. W. BAILEY,

Rock, W. Va.

May 12th, 1896.

The Fifth Root.

Editor Colliery Engineer and Metal Miner:

SIR:—I hope Mr. Thomas Hannah will be interested to find that *any root* can be found *correctly* by the rules of Ajax.

To find the fifth roots of the examples he furnishes, proceed as follows: Raise each of the numbers to the sixth power with a false root, as in the case of 9, make the false root 2, and in the case of 21035.8, make the false root 8, then extract the sixth roots of the products. Next lower the numbers 9 and 21035.8 to the fourth powers by dividing with the false roots, when half the sum of the sixth and fourth roots will be the fifth root nearly correct, and to find the absolutely correct root, let him now take the approximate root found, and raise and lower with it as before when he will find that he can repeat the process until the fourth root will come out the same as the sixth root, and then he will know that the root is found absolutely correct.

Find the fifth root of 9.

$$\left(\sqrt[6]{9\times 2}+\sqrt[4]{\frac{9}{2}}\right)\div 2 = 1.50489.$$

Now, we know that this root will be too small, therefore we next take 1.55 as,

$$\left(\sqrt[6]{9\times 1.55}+\sqrt[4]{\frac{9}{1.55}}\right)\div 2 = 1.55192.$$

Again, $\left(\sqrt[6]{9\times 1.55192}+\sqrt[4]{\frac{9}{1.55192}}\right)\div 2 = 1.55184$ +, and the correct root is 1.55184 +.

Next let us find the fifth root of 21035.8, then,

$$\left(\sqrt[6]{21035.8\times 8}+\sqrt[4]{\frac{21035.8}{8}}\right)\div 2 = 7.27126.$$

We know this root will be rather too small, as 8 reduces the fourth root, more than it increases the sixth, therefore let us take 7.32 for the next trial; then

$$\left(\sqrt[6]{21035.8\times 7.32}+\sqrt[4]{\frac{21035.8}{7.32}}\right)\div 2 = 7.3212 +$$

therefore repeat again and find the correct answer, which is 7.3213.

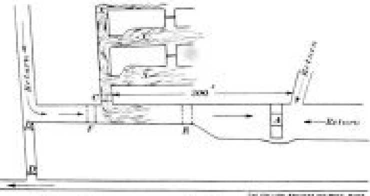
The correct roots can be found by shorter cuts, with the exercise of a little judgment, but the processes here carried out, are purposely made roundabout to afford explanation.

The fourth and sixth powers are employed because the root of one is found as the square root of the square root, and the other is found as the square root of the cube root. Yours etc., AJAX.

Fighting Gob Fires.

Editor Colliery Engineer and Metal Miner:

SIR:—In looking over the February, 1896, issue of THE COLLIERY ENGINEER AND METAL MINER, on page 163, Fig. 125, the writer of an article on "Gob Fires" says that the stopping *R* should be built first and the stopping *F* last. As this is the reverse of the practice I followed for two years in fighting gob fires, I respectfully disagree with the writer and desire to draw his attention to his error. There may be a mistake in the description of the sketch which may mislead others in such work and cause an explosion. He said that to remove large quantities of gas from a mine plenty of fresh air should be used. This is all right, but the reverse of this is just what he should have said in the case of an uncontrollable gob fire as shown on his sketch. It is evident that oxygen is the supporter of all combustion and the quicker it is shut off the sooner the fire will be extinguished, and the products of combustion will neutralize the fire-damp. One of the claims of Sir Humphrey Davy on his famous safety lamp was that the products of combustion neutralize the gases that enter the gauze of the lamp. The Mueseler lamp is constructed on the principle that only sufficient air is allowed to enter to support combustion and when the air is contaminated with an explosive mixture, the lamp will go out. These furnish good examples in this very case of stopping building. If the stopping *F* is constructed first, there will be no danger of an explosion as I have shown that the products of combustion generated from the fires will neutralize the fire-damp. To allow the volume of fresh air which enters the mine to flow into the heated space and there mix with the fire-damp while building the stopping *F* on the intake (which should be built first) there is great danger of an explosion. On the other hand, if the stopping *F* on the intake is built first the heated products of combustion from the fire will find their way leisurely to the upcast while the stopping *R* is being erected on the out-take end. There should be a pipe or valve on the stopping *R* to allow water gauge and thermometer readings to be taken so as to show the pressure and temperature.



A—Air Shaft. *X*—Gob Fire.
D—Door. *C*—Stopping Blown Out.

In continuation of this subject I submit a sketch of a gob fire which actually occurred in No. 5 shaft at Staunton, Ill., in 1889, and I refer the following question to some of your able readers: In this case there was a small percentage of gas in the return air. Which stopping should be built first, that marked *F* or that marked *R*, and how should the stopping *R* be built with the smoke and heated gases generated by the fire coming out in large volumes? The stopping *C* was blown out.

Trusting that some of your able readers will discuss this matter and bring out points which will effectually settle the controversy of which stopping should be built first, I remain Yours respectfully,

WM. M. MORRIS,

April 15, 1896. Pueblo, Colo.

The Natural Philosophy of a Ventilating Regulator.

Editor Colliery Engineer and Metal Miner:

SIR:—Thanks for copies of journal sent to me. In the March issue I see that you review my "Philosophy of a Ventilating Regulator" in a curious manner.

1st. You describe myself as "a young man of small experience." As a matter of fact, however, I have been a pitman for 31 years.

2nd. You are at "a loss to understand why Mr. Pamely should be singled out for attack," and you think that my ideas of respect for such writers "require a little regulating." Did it never occur to you that it was just my very profound respect for Mr. Pamely which led to my naming him? Errors by unknown writers may pass unnoticed, but their reproduction by eminent men like Mr. Pamely creates the very *raison d'etre* of works like my own.

3rd. You "remind" me that "in our issue of November last we gave on page 92 of the COLLIERY ENGINEER AND METAL MINER the correct expression for the velocities of air currents through regulators, and that is the month in which Mr. Halbaum printed the treatise under consideration."

I am not sure that I see the point of this "reminder." Do you wish to imply that mine is *not* a "correct expression?" If so, you must have read my pamphlet very carelessly, for although expressed in different letters, my formula is exactly the same as yours, and brings out the same results; the only difference arising from your taking vena contracta at .65, while I take the mean of .62 and .65. Hence our formulæ are practically the same.

If you don't impugn the accuracy of my formula—and you cannot do this unless you impugn your own—the object of your "reminder" can only be to suggest literary piracy on my part. If this is your object, the boot is entirely on the other leg. It is true that my work was printed in the same month as you gave your formula (which, after all, is really Murgue's) but it is not true that my work was then printed for the first time, for the pamphlet you reviewed was simply a reprint of articles that had previously (March-August 1895) run through the *Science and Art of Mining*. Hence your "reminder" only shows that you gave the "correct expression for the velocities of air currents through regulators" some months *after* I had published the same in another journal that circulates all over the world.

4th. Your next "reminder" is entirely beside the question. I was not discussing fans, but regulators. Hence it did not come within my province to controvert errors affecting the "velocities of currents entering fans." I was speaking of the fact that an extra resistance of one kind (as friction) in one split, might be compensated by an extra resistance of another kind (as velocity) in the other split. And I quoted Murgue's theory as an illustration of equivalent values of different resistances. And I did say, as you quote, that "to refuse to grant *its truth as an abstract statement* would be to call in question the whole theory of the conservation of energy." And you will, I think, admit that the truth of an abstract statement is one thing, while the truth of a sub-theory supposed to be based on that statement is quite another thing.

I think, sir, that you will see that the tone of your review was rather unfair, and I hope you will publish this letter as I have written it. If you have any rejoinder to make, I have no doubt you will be kind enough to send me a copy, as you have already sent me the other copies. I am, sir,

Yours faithfully,

H. W. HALBAUM,

116 Blenheim Street, Newcastle-on-Tyne, England.

April 25, 1896.

[In our review of Mr. Halbaum's book, we did not mean to imply literary piracy on his part, for we said then, as we repeat now, his work is a good one. What we principally criticized was his sharp criticism of Mr. Pamely's formula for regulator quantities, and we merely mentioned our own method of treating the subject (written before we saw Mr. Halbaum's formula) as a better way of treating the matter. That Mr. Halbaum is technically correct, and Mr. Pamely wrong on the subject of regulators, we frankly admit, but we must say that the latter's efforts to advance the science of coal mining are deserving of courteous treatment, for his excellent publication is unquestionably the most complete book on coal mining as yet published, notwithstanding that in its nearly 700 pages there is one incorrect formula. Mr. Halbaum deserves credit for correcting this error, but we must deprecate the caustic manner in which it is treated.—EDITOR.]

PRIZE CONTEST.

Prizes Given for the Best Answers to Questions Relating to Mining.

For the best answer to each of the following questions, the value of $1.00 in any of the books in our book catalogue, or six months' subscription to THE COLLIERY ENGINEER AND METAL MINER.

For the second best answer to each question, the value of 50 cents in any of the books in our book catalogue or three months subscription to THE COLLIERY ENGINEER AND METAL MINER.

Both prizes for answers to the same question will not be awarded to any one person.

Conditions.

First—Competitors must be subscribers to THE COLLIERY ENGINEER AND METAL MINER.

Second—The name and address in full of the contestant must be signed to each answer, and each answer must be on a separate paper.

Third—Answers must be written in ink on one side of the paper only.

Fourth—"Competition contest" must be written on the envelope in which the answers are sent to us.

Fifth—One person may compete in all the questions.

Sixth—Our decision as to the merits of the answers shall be final.

Seventh—Answers must be mailed us not later than one month after publication.

Eighth—The publication of the answers and names of persons to whom the prizes are awarded shall be considered sufficient notification. Successful competitors are requested to notify us as soon as possible as to what disposal they wish to make of their prizes.

Competition Questions for June.

QUES. 229. If we burn acetylene gas, from the liquid acetylene, in our new lamp, do you think it will be safe? Our object is to obtain a small white light of high potential without the use of a wick. Should your judgment be favorable, will you please say what advantages this light will give us in restricting the size of the lamp, and further, say if you think the burning of this gas will produce over much soot and choke the meshes of the gauze.

QUES. 230. What very decisive proof can you give us in support of the conclusion, that there were immense stretches of dry land on the globe during Cambrian and Silurian times?

QUES. 231. The number 390,000 is ½ times the eighth power of the length of one of the sides of a cage guide in inches, and if the guide is square, what is the measure of one of the sides, and what is the length of the guide in feet?

QUES. 232. How many units of heat should a pound of coal of the following composition develop: Carbon, 82 per cent.; volatile and combustible matter, 6 per cent.; oxygen, .6 per cent.; nitrogen, .8 per cent.; ash, 10.6 per cent.

QUES. 233. We are about to introduce an endless rope haulage at our mine for an output of 800 long tons per day, and we will require a main haulage for the total delivery at the shaft, and the length of this road will be 1,325 yards. The coals from three separate districts will feed on to the main haulage rope, with belts worked by sheaves in gear with the return sheave of the main haulage. Now if we call the districts *A*, *B*, and *C*; then from the terminus of the main haulage the lengths of the district roads are *A*, 412 yards; *B*, 804 yards; *C*, 601 yards; the delivery of coals from each district will be *A*, ¼; *B*, ⅓; and *C*, 5/12 of the total output, and what I wish to know is two things, and the first is this: If all the four bands of rope are run at the equal velocities of two miles an hour, how far apart will the cars be on each band of rope, supposing the load of a car to be one ton. The second thing I wish to know is, if I were to put a chalk mark on each of the four bands of rope on the junction sheaves, that is, where the four bands of rope come together, at 6 o'clock in the morning, when would the marks on the four bands come together again at the same place? and say what practical lesson you would learn from this experiment.

QUES. 234. During the working of regular stratified coal seams, sometimes a seam cuts out, or appears to be cut off by an upper stratum of rock that is not conformable to the seam. At other times the seam is cut out by a conglomerate-like deposit. Now, if you were a mine superintendent and either of these occurrences were met with in a mine under your charge how would you report the matter to the operators?

Answers to Questions Which Appeared in the April Issue and for Which Prizes Have Been Awarded.

QUES. 217.—During the course of some experiments we have been making with a Mueseler lamp, with the view of perfecting our new safety lamp, we have found that when we make the top diameter of the conical funnel five-sixteenths of an inch, the lamp flame dies out when the entering air contains about 7 per cent. of marsh gas, and when we make the top diameter of the funnel five-eights of an inch the lamp is not safe in an explosive mixture. We will therefore feel obliged if you will explain to us how it is that the lamp is safe with the small diameter and absolutely unsafe with the large one.

ANS.—The expansive force of the exploded gas in the lower chamber of the lamp is not strong enough to overcome the resistance of the conical chimney and force the flame through the small aperture at its top, but is sufficient, however, to develop an outward and upward pressure large enough to prevent the inflow of the outer air to the lamp flame, thus extinguishing the same by excluding the oxygen necessary to support it.

If we increase the diameter of the top aperture of the chimney from $\frac{5}{16}$ to $\frac{5}{8}$ of an inch, we not only increase the area of this aperture four times, but we also change the converging sides of the chimney to a more perpendicular position, thereby diminishing the resistance to the upward movement of the burning gas sufficiently to allow the flame to reach the upper part of the lamp and explode the gas contained there.

In this case the lamp flame will not be extinguished, because the unobstructed upward flow of the burning gas through the chimney will cause the gaseous mixture outside of the lamp to enter the lower chamber with an increased velocity; explosion will quickly follow explosion inside of the lamp and in a few moments it will become as dangerous as an open light.

JOHN VERNER, Lucas, Iowa.

Second Prize.—ROBT. REAY, Holsopple, Somerset Co., Pa.

QUES. 218.—We are ventilating a mine with a furnace, and the quantity of fresh air entering per minute is 100,000 cubic feet. The furnace consumes 1.5 long tons of coal per hour. The composition of the coal is 78 per cent. fixed carbon, 10 per cent. volatile hydro-carbons and 12 per cent. ash. The volatile hydro-carbons may be taken at the average composition of $C_2 H_4$. Now, we wish to know what will be the volume measure per minute of the air and gases ascending from the furnace in the upcast shaft, when the temperature of the descending air is 60° F., and that of the ascending air is 200° F.

ANS.—The 100,000 cu. ft. of air at 60° F. would become at 200° F., $100{,}000 \times \frac{459 + 200}{459 + 60} = 126{,}973.4$ cu. ft.

The furnace consuming 1.5 long tons per hour would consume per minute $\frac{1.5 \times 2{,}240}{60} = 56$ lbs. coal per minute, composed of:

Fixed carbon	$= C$	$56 \times 0.78 = 43.68$ lbs.
Volatile matter	$= C_2 H_4$	$56 \times 0.10 = 5.60$ "
Ash		$56 \times 0.12 = 6.72$ "
		56.00

In the 5.60 lbs. $C_2 H_4$ there are $5.60 \times \frac{4}{32 + 4} = 0.62216$ lbs. hydrogen and $5.60 - 0.62216 = 4.97784$ lbs. carbon. Hence, the total combustible is $43.68 + 4.97784 = 48.65784$ lbs. carbon, and 0.62216 lbs. hydrogen. The carbon will burn to carbonic acid $C O_2$, but in doing so will not add to the total amount of air and gas, as the $C O_2$ composed of one volume of C and two of O is only two volumes or the same as the contained O which is already summed above in the air. The H burning to water $H_2 O$ will form two volumes, but one volume of O is included above, so we add one-half the H to get the increment in volume. 1 cu. ft. H at 32° F. weighs 0.00558 lbs. and $\frac{0.62216}{2}$ lbs. would be 55.75 cu. ft. at 32° or $55.75 \times \frac{459 + 200}{459 + 32} = 74.8$ cu. ft. at 200° F. Hence, total amount of gas and air passing per minute out the furnace is $126{,}973.4 + 74.8 = 127{,}048.2$ cu. ft.

CHAS. E. BOWRON, Tracy City, Tenn.

Second Prize—DAVID P. BROWN, Dunbar, Fayette Co., Pa.

QUES. 219.—We have a seam of bituminous coal 4.5 feet thick; it is lying nearly level. The bottom rock is hard and strong, but we have a following of 4 feet of slate that we cannot keep up. The shafts when sunk will be 800 feet deep, and we will therefore be obliged to you if you will explain with a sketch how we should work this seam so as to obtain the highest possible percentage of large coal, and yet be able to keep the roads and rooms in safe condition without the loss of much timber.

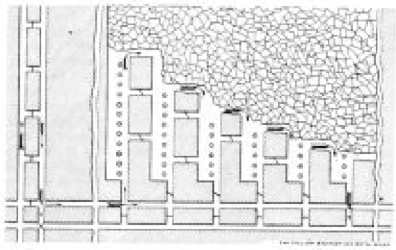
ANS.—Perhaps, generally speaking, a method of longwall would give the best answer to this question; but as there are many reasons why longwall would not be successful if applied to such a seam (under the conditions stated), we shall give the answer which we think will give the most satisfactory results in North America.

Further, the question refers to rooms, and as the term room is seldom used in connection with longwall working we presume longway is not the answer expected.

We take it that the "following" can be maintained in its position for a short distance and at least for two days, so that it can be removed from the roadway to the gob. The "following" from the roadway will fill the gob and support the part of the "following" in the gob. The gob being thus closely stowed will make a strong support to the superincumbent strata over the entire mine as the work progresses, even when the pillars are removed, and only the stumps (entry stumps) are in. Four feet of "following" will stow or nearly stow the waste behind, when the pillars are drawn, and as the pressure due to 800 feet will not compress the stowing to anything like its original compactness we will have only a small amount of subsidence and that so slowly that it will cause little inconvenience.

Now, that I have given a reason for the answer I will proceed with it:

In the sketch are shown gob entries in order that space may be furnished for the "following." It shows rooms with only one road so that the dirt may be stowed on one side and the road located so that it will be ready



to convey the coal from the pillars as it is drawn back, as well as forming a haulway for the coal from the advancing room. By this method, if the timber put in is a greater item of cost than that due to removal it can be readily removed. In the first place only side props (and perhaps a few cross bars) need be used. The props, used to keep up the "following" until the gob is stowed, can be removed as the room advances or the pillar retires and be used over and over again. The roadside props and any cross bars that have been used in the roadway, can be removed as the pillar coal is taken out.

The width of rooms has not been specified as that must depend upon the per cent. of increase of the "following" taken out of the roadway.

The writer has worked by this method a seam averaging about 3 feet with a "following" varying from 18 inches to 4 feet with good results, but owing to the lack of skilled labor and other causes, longwall was an utter failure.

W. D. L. HARDIE, Box 793, Birmingham, Ala.

Second Prize—JOHN FLETCHER, 428 Tonti St., La Salle, Ill.

QUES. 220.—We have a ventilating fan exhausting from our mine 150,000 cubic feet of air per minute with a water gauge of .8 inch, and we wish to set up another and larger fan to increase the ventilation to 250,000 cubic feet. We will, therefore, be obliged to you if you will furnish us with the following values for the new fan, so that we may secure the best results:

First—The diameter of the fan.
Second—The breadth or length cylinderwise.
Third—The number of revolutions.
Fourth—The radial length of the blades.
Fifth—The area of the orifice of entry.
Sixth—The area of the throat.
Seventh—The area of the orifice of discharge.
Eighth—The effective horse power of the fan, taking T instead of M for the pressure per square foot.

ANS. $150{,}000^2 : 250{,}000^2 :: .8 : 2.2$ inches W. G.

First—The diameter of the fan:

$$D = \sqrt{\frac{250{,}000}{200}} = 35.36 \text{ feet.}$$

Second—The breadth or length cylinderwise:

Taking the average velocity at 5 feet per second $\frac{250{,}000}{5 \times 60} = 833.3$ sq. ft. area. Then, $\frac{833.3}{3.1416 \times 35.36} =$ 7.5 feet wide.

Third—The number of revolutions:

$$R = \sqrt{\frac{8{,}000{,}000 \times \text{W. G. } 2.2}{6 \times 35.36^2}} = 50 \text{ revolutions per}$$

minute, nearly.

Fourth—The radial lengths of the blades:

RULE.—There should be 7 inches in the radial lengths of the blades for every pound per square foot in the mine resistance. Then, $\frac{2.2 \times 5.2 \times 7}{12} = 6.67$ feet, the length of blades.

Fifth—$\frac{250{,}000}{1{,}300} = 192.3$ sq. ft., area of orifice of entry.

Sixth—The throat of the fan is equal in area to the port of entry $\frac{250{,}000}{1{,}300} = 192.3$ feet.

Seventh—The area of the orifice of discharge:

$$A = \frac{250{,}000}{2{,}600} = 96.15 \text{ square feet.}$$

Eighth—The effective horse power of the fan:

$$H = \frac{250{,}000 \times 2.2 \times 5.2}{33{,}000} = 86.6 \text{ H. P.}$$

JOHN FLETCHER, 428 Tonti St., La Salle, Ill.

Second Prize—WM. DONALDSON, Kangley, Ill.

QUES. 221.—In looking over a topographical map and the text of the notes of the survey, I observed three hills, and their apices were lettered S, T and U. The apices of S and T were shown to lie in a line that was bearing North 63° East from S, and the apex of U was shown to bear South 27° East from that of T. The mean angle of elevation of the southwest slope of S, measured from the foot of the slope at A, was 32° 15′, and the mean angle of elevation measured at B at the foot of the slope at the southeast side of U was 19° 56′. The vertical heights of the hills were: S, 784 feet; T, 472 feet, and U, 320 feet. The angle of elevation of the apex of S, measured from the level of the apex of T, was 6° 25′, and the angle of depression of the apex of U, measured from the level of the apex of T, was 4° 43′. I will be pleased to receive from you a sketch with the necessary explanation, showing the process by which you have found the distance in a straight line from A, at the foot of the southwest slope of S, to B, at the foot of the southeast slope of U.

ANS.—Let H = horizontal distance, V = difference in elevation, and D = the angle of depression or elevation, between any two points.

$$\text{Then } H = \frac{V}{\tan D}$$

$$\text{Hence, } A \text{ to } S = \frac{784}{\tan 32° 15'} = 1242.57 \text{ ft.}$$

$$S \text{ to } T = \frac{784 - 472}{\tan 6° 25'} = 2774.26 \text{ ft.}$$

$$T \text{ to } U = \frac{472 - 320}{\tan 4° 43'} = 1842.25 \text{ ft.}$$

$$U \text{ to } B = \frac{472}{\tan 19° 56'} = 882.39 \text{ ft.}$$

The triangle $A\ T\ B$ is right-angled at T, hence,

$$A\ B = \sqrt{A\ T^2 + T\ B^2} =$$

$$\sqrt{(1242.57 + 2774.26)^2 + (1842.25 + 882.39)^2} = 4853.72 \text{ ft.}$$

HERBERT A. WILCOX, Aspen, Colo.

Second Prize—JOHN A. RAY, Westville, Picton Co., N. S.

QUES. 222.—In a mine shaft in course of being sunk an iron kettle full of water was hoisted from the bottom at a mean velocity of 6 feet per second. The kettle was cylindrical in shape and 3.5 feet in diameter and 3.5 feet deep, and by some unknown cause a round hole had been cut through the bottom, and it had a mean diameter of 3 inches. The result was that the kettle left the sump in the shaft bottom full of water and arrived at the top of the shaft empty, and by coincidence the discharge of water just ceased at the moment the kettle reached the surface. Now, I will be obliged if you will deduce for me, out of these facts, the depth to which the sinking has advanced.

[A great number of competitors attempted this question, and none of them have succeeded in obtaining the correct depth of the shaft. In the next trial please notice four things: First, take the vena contracta at .62; second, take $2\,g$ at 64.32; third, take the fall of the center of gravity or the mean pressure at 1.75 ft; fourth, many gave the depth as 880 ft. and as many more gave it at 548 ft., but it is neither, for the one is too much and the other too little.—ED.]

Anti-Rust.

Mr. B. E. V. Luty, editor of the *Tin and Terne* of Pittsburg, estimates the quantity of tin, iron and steel roofing used in the United States at 600,000,000 square feet per annum. Metallic material now enters into buildings of all kinds so largely, in place of the wood which was formerly used, that it is safe to say that one thousand million square feet of metal—tin, iron and steel—are used each year in the United States in structural work of all kinds.

In mining operations millions of square feet of metal are used in pipes, roofs, stacks, shafting, head-frames, breakers, tipples, mill structures and bridges, not to speak of the great amount of machinery used in the industry. All of this great quantity of metal is constantly menaced by its arch enemy, rust, and much of it is subject to corrosion from acidulated mine water, gases, etc.

It may be truly said that there is hardly a single owner of any amount of this metal that has not, at some time or other, been disappointed in the paint used for its protection, frequently finding it ineffective and utterly unreliable; and, without proper protection, the process of destruction, being constant, ceases only when nothing is left for the insidious and omnipresent destroyer to attack.

Recognizing the extent of the vast field before them, Messrs. Allen, Ackley & Co., of 413 Vine street, Cincinnati, Ohio, some years ago placed on the market an anti-rust paint made especially and particularly for the protection of metal from rust or corrosion. *This material is a paint for metal, and is not made for any other purpose.* Its use is extending rapidly, the demand coming from all parts of the continent. The manufacturers include in their large list of patrons many of the largest manufacturing plants in the world, and the United States government.

It is not surprising that such a material should meet with a quick demand when we consider the needs of the world. It fills a requirement long felt and supplies a remedy urgently needed. It is with pleasure we note that the manufacturers are meeting with marked success and even in the present greatly depressed condition of general trade they have found it necessary to quadruple the capacity of their works in order to keep step with the demands of their growing business.

In the use of this excellent material there is an application of the old and truthful proverb that "An ounce of prevention is worth a pound of cure." The idea of mine managers erecting buildings at an expense of hundreds, and sometimes thousands of dollars, and machinery, that more frequently runs into the thousands than into hundreds of dollars, and not protecting them by a reliable and cheap preventive of rust and corrosion is wrong, and results in constantly increasing repair bills, and finally, the destruction of the metal in a comparatively short time.

THE METAMORPHISM OF COAL.

HOW IT OCCURS AND WHAT CAUSES IT.

The Conversion of Bituminous Coal into Anthracite and Graphite, and the Conversion of Carbonaceous Matter into Diamond.

BY H. BOLTON, F. R. S. E.

(From Transactions of The Manchester Geological Society.)

The subject of the metamorphism of coal presented itself to me during the course of an examination of the anthracites of Castlecomer, County Kilkenny, Ireland, and in a paper communicated to this society last session,* I drew your attention to what I supposed to be a thin layer of graphite upon the bedding planes of the coal.

In following the matter up since, I have found that whilst the general question of coal metamorphism has not been dealt with, yet a large number of cases have been recorded in which coal has been changed in various ways by the action of heat and other agencies. Cases in which bituminous coals have been metamorphosed into anthracite are numerous, whilst, as we shall see later, metamorphism has proceeded to an even greater degree and graphite has been produced; furthermore, it is by no means unlikely that the diamond owes its origin to a metamorphism of carbonaceous matter by the heat of intruded igneous rocks. The general features presented by coals, and their arrangement in an ascending series from wood and peat to anthracite, are well known.

The various stages of the process may be said to be marked by an increase in density and coherence of the coal, and a loss of volatile hydrocarbons in the form of gaseous compounds and water.

The general composition of a coal seam in its various stages from wood or peat is very well indicated in a series of analyses published by Professor T. Thorpe.† From these analyses the following table has been constructed:

	Carbon.	Hydrogen.	Oxygen and Nitrogen.
1. Wood and Vegetable Humus	54.8	4.8	40.4
2. Peat (4 varieties)	60.8	5.9	33.35
3. Lignite (2 varieties)	67.45	5.55	27.0
4. Brown Coal (4 varieties)	72.9	5.4	21.7
5. Bituminous Coals (30 varieties)	83.37	5.48	11.4
6. Anthracite	95.23	2.58	2.3

To these we may add graphite with usually 99 per cent. of carbon; and the diamond, which is almost pure carbon.

The analyses show that the conversion of one coal into another higher in the series is marked by an increasing percentage of carbon and hydrogen, and a decreasing percentage of oxygen and nitrogen. In the case of anthracite the carbon percentage is very high, and that of the hydrogen, oxygen and nitrogen low.

The fact that bituminous coals can be converted into anthracite is known chiefly by reason of the phenomena presented in the South Wales coal field, where the seams are wholly bituminous in the easterly portion, but pass into semi-bituminous or steam coals as they reach the center of the area, and into pure anthracites further west. The change from one to another is so gradual that no sudden modification is seen. There is no evidence of the change having been brought about by intrusive igneous rocks, such as we shall see occur elsewhere.‡ It has been determined, however, that the change from bituminous to anthracite coal takes place along a definite plane, which dips to the south-south-east.

In Pembrokeshire, which contains only anthracite coal and forms the western boundary of the coal field, violent crumplings and rock folding have occurred, to which the formation of the anthracite may be in some measure due. In Ireland, the coal measures are capable of division into an anthracite series, which is developed in the southern fields of Limerick, Clare, Cork, Tipperary, Queens County, Kilkenny, and Carlow; and a bituminous series occupying the northern fields of Arigna, Tyrone, and Ballycastle.

The greatest deposits of anthracite in the world are found in the eastern Pennsylvania region of the United States, where they cover an area of close upon 16,000 square miles. This field presents phenomena very similar to those of South Wales. There is the same passage from bituminous coal in one end of the field to anthracite in the opposite extremity, and a gradual loss of hydrocarbon compounds is associated with the conversion into anthracite. There is also the same development of earth-folds in the areas containing anthracite as is presented in the Pembrokeshire area.

Whilst whole coal fields of vast extent have been converted into anthracite, there is not wanting direct evidence of various agencies by which this change has been brought about in small and comparatively unimportant areas. Boue, Delesse, and others drew attention many years ago to the occurrence of a bituminous coal at New Cumnock, Ayrshire, which had been partially changed into anthracite and graphite by the intrusion of a basalt.

Similarly, at the Rowley Hills, in the South Staffordshire coal field, the thick coal has been penetrated by intrusive rocks, such as basalt, resulting in considerable metamorphism of the coal along the lines of contact. Usually the coal has been converted into a black powdery mass of a dull color, very friable, and almost destitute of inflammability,§ but in other cases it has undoubtedly been converted into anthracite.

Professor J. J. Stevenson** has most excellently summarized the American evidence relating to the occurrence of anthracite, and has given cases where it has been formed by contact alteration with erupted rocks. He instances localities in New Mexico, Colorado, Virginia, and North Carolina, and also records other cases where, with precisely similar contact, no alteration into anthracite has followed.

Instances of the conversion of bituminous coal into anthracite by intruded igneous rocks have been recorded in New Zealand.

In the Donetz coal field of South Russia, between the rivers Krinka and Miuss, the coals are bituminous in the west and change into pure anthracite towards the east.*

In the intermediate districts, the coal is frequently in an intermediate condition between bituminous and anthracite, and no satisfactory term can be applied to it.

The close analogy between the features of this coal field and that of South Wales in this country was commented upon by Murchison, as was also the close coincidence between the line of anthracite coal and the crystalline axis of the Southern Steppes, a subterranean prolongation of which was supposed to have been the agent which converted the former bituminous coal into anthracite.

From the cases we have enumerated, it will be evident that the passage of bituminous coals into anthracite has been most clearly established and that this change has been brought about in a variety of ways, of which those by means of erupted rocks and the proximity of flexures and foldings are perhaps the most evident.

That graphite has been formed in some cases as a result of the same causes which induced the formation of anthracite, and either as a further stage of metamorphism of it, or along with it, is not commonly known, the metamorphism of coal rarely proceeding so far.

The occurrence of graphite with anthracite at New Cumnock, Ayrshire, was first described by Nicholt in 1844, and has often been mentioned by late observers. The mine is traditionally reported to have been in operation for nearly a hundred years, and was finally closed in 1848. I am indebted for a considerable amount of information relating to this mine to the kindness of Mr. John Smith,‡ of Monkredding, Ayrshire, a gentleman who has devoted considerable attention to the Ayrshire coal field. With great generosity, Mr. Smith has further sent me a valuable series of specimens which illustrate the special feature of the mine, and which he desires me to pass over to the Manchester Museum, Owens College, on the completion of this paper.

The conditions under which the coal occurs in the Craigman mine are so peculiar that I purpose dealing with them at some length in a later part of the paper.

A section at the entrance to the mine is as follows:

	Ft.	In.
Boulder clay	—	—
Sandstone, coarse-grained, hardened and shivery	4	0
Porcelainized shale, light colored	0	11
Hard shale, bluish colored	0	11
Porcelainized shale, bluish colored	3	1
Decomposing trap (basalt)	6	4
Solid trap (basalt), coarsely crystalline	5	0
Altered coal	6ft. to 8	0
Basalt?	—	—

Mr. Smith writes me that he has examined nearly every accessible part of the mine, and has come to the conclusion that the basalt penetrated the coal bed in such a manner as to break it up into detached patches, the smaller of which have been converted into graphite.

Nearly all the coal patches are much charred, and present a columnar structure, the columns lying in every possible direction, but more usually parallel to the basalt. When the coal approaches the basalt, it passes into a thin layer of massive graphite, which is closely applied to the latter.

These features are well demonstrated by the specimens which are now before you.

Much of the graphite presents a similar columnar structure to that of the coal, the columns however holding together much more firmly, those of the coal often falling away from each other when dug out.

In the paper by Professor Stevenson, which has just been read,§ you will have noticed that the conversion of coal into graphite is a familliar feature of certain mines in the United States, especially in New England, where the anthracite coal is stated to be largely graphitic, the coal at Mansfield being "like graphite or plumbago."

Mr. E. W. Parker, in his coal report for the year 1892** says: "In the New England basin the original coal beds have been metamorphosed into graphite and graphitic coal, which have special uses, although not classed by the trade as anthracite."

At Cranston, and also at Worcester, Mass., the coal is anthracitic and rich in graphite. From the latter locality, Professor Stevenson has kindly sent me a specimen which is so rich in graphite that one would be naturally inclined to doubt its origin from coal.

In a letter which accompanied the specimen he states "the piece of coal which I send you does not exhibit much completely changed carbon, and is less graphitic than some specimens which I have seen."

Graphite is also mentioned as occurring in the Laramie beds of New Mexico. In the latter case, the conversion into graphite has been brought about by an intrusion of basalt.

Graphite has also been found in association with coal beds of Upper Cretaceous age at Karsok, in Greenland, where the whole series of beds were found to rest upon gneiss, and to be in close association with basalt, which was ejected subsequently to the deposition of the Cretaceous deposits, and before the commencement of the Tertiary period.††

My colleague in the Manchester Museum, Mr. F. G. Pearcey, has kindly furnished me with the accompanying note extracted from the journal which he kept whilst attached to the "Challenger" expedition of 1872-6.

"At Port Darwin, in the Falkland Islands, some beds, locally known as coal beds, are found. They are beds of bituminous material, interbedded with clay slates, which form the most striking geological feature of the islands. The bituminous beds sometimes run out into a sort of culm, the transition of the latter into a typical graphite being also clearly marked."

Fragments of this graphite were often used by Mr. Pearcey on board ship for the purpose of marking boxes containing specimens prior to their being stored.

Whilst in the cases just enumerated the conversion of coal into graphite is undoubted, in the great majority of cases there is no evidence to show what was its original condition. It is, however, significant to note that whilst the purest forms of graphite are associated with igneous and more especially metamorphic rocks, and graphitoid anthracite with sedimentary rocks more usually of Carboniferous age, yet in the mica schists and clay slates of the Saxon Erzgebirge there is a graphite or "graphtoid" which still retains the property of combustion.*

In rocks of Pre-Cambrian age in Canada, Sir J. W. Dawson has found large quantities of graphite, in some of which he could distinguish traces of vegetable tissues.†

Pure graphite in its most familiar form has been obtained in the British Isles from Borrowdale in Cumberland, Beary in the Isle of Man, Grampound and Boscastle in Cornwall, and Killimuir in Scotland. Amongst other countries may be mentioned Ceylon, Canada, Bohemia, Algeria, Norway and Finland. It has been found in association with mica schist, gneiss, basalt, quartz and slates.

If we except the graphitoid of the Saxon Erzgebirge, graphite is destitute of volatile hydrocarbons, and consists of a slightly higher percentage of carbon than anthracite, together with a slight quantity of mineral ash such as silicate of alumina, sesquioxide of iron, and other compounds. In the development of graphite and anthracite from an originally bituminous coal—as in the case of the specimens before you from Worcester, Mass., U. S. A., and New Cumnock, Ayrshire, and in the occurrence of a combustible graphite in mich schist—we have, I think, conclusive evidence of the possibility of the origin of graphite from a vegetable source, the theory upheld by Dawson and others in respect to the graphite found in the Pre-Cambrian rocks of Canada.

The purest mineral in the carbonaceous series is the diamond, which consists of more than 99 per cent. of carbon. The diamond occurs in association with a variety of rocks, but in most cases these are of sedimentary origin, and show unmistakably that the diamonds which they contain have been derived from pre-existing rocks destroyed by denuding agencies.

In most cases, as at Bingera, in New South Wales, the matrix of the diamond is either a conglomerate or coarse sandstone; rocks whose nature is an evidence of their derivation from older rocks. In regard, however, to the diamond fields of South Africa, there is good reason to believe that the diamonds are still in the parent rock, and that they owe their origin to that agency which has operated in the origin of certain anthracites and graphites.

In the De Beers mine at Kimberly, which may be taken as typical of all, a volcanic "pipe," which forms the diamantiferous area, is surrounded by a series of deposits of a mixed character, in which carbonaceous shales of Triassic age predominate.

The deposits in descending order are as follows:

	Feet.
Surface soil	5
Basalt	51
Black carbonaceous shale	250
Melaphyre	400
Quartzite	400
Black carbonaceous shale	100

The material of the pipe has been described by Prof. Bonney‡ as a serpentinous breccia; by Mr. E. J. Dunn as a decomposed gabbro; and by Messrs. Hudleston, Rupert Jones, and Davies as a volcanic mud. The general feature of the diamantiferous areas, for there are four "pipes" already known, have been well described by a number of observers.§

Mr. Dunn showed that the material of the pipes, called "yellow ground" and "blue ground," whilst igneous in origin, yet contained large masses of the surrounding carbonaceous shales, often to such an extent as to constitute a breccia, whilst the beds in immediate contact with the "pipes" were abruptly bent upwards. All the included rocks showed traces of fusion, whilst in the outer portions of the pipes, where the blue ground is most heavily charged with carbonaceous shale, there is the richest yield of diamonds.

Professor Carvill Lewis has also drawn attention to the passage, at a depth of 600 feet, of the material of the volcanic pipes into two distinct types of rock. One only is diamantiferous, and is also crowded with fragments of carbonaceous shale, the non-diamantiferous type being free from inclusions, and is a typical volcanic rock.

The conclusions arrived at by Professor Carvill Lewis are stated as follows: "It seems evident that the diamond-bearing pipes are true volcanic rocks, composed of a very basic lava associated with a volcanic breccia and with tuff, and that the diamonds are secondary minerals produced by the action of this lava, with heat and pressure, on the carbonaceous shales, in contact with and enveloped by it."

Some support is lent to this theory by the researches of Professor Roscoe into the chemical composition of the "blue ground."** Noticing a peculiar smell somewhat

like that of camphor, Professor Roscoe digested a portion of the material with ether, from which he afterwards obtained a small quantity of a crystalline aromatic hydrocarbon which burnt very easily with a smoky flame.

Professor Lewis has added to the abstract of his paper, which appeared in the *Geological Magazine*, a note stating that a similar association of volcanic and carbonaceous rocks has been found at other places.

In New South Wales, the diamond grounds lie near the junction of serpentine or basalts with carbonaceous rocks. At the Bingera diamond field, for example, a boss of eruptive serpentine is almost surrounded by carboniferous rocks containing coal seams. In Western America, the diamantiferous grounds are in close proximity to an area where serpentine and carbonaceous rocks occur together.

The evidence is fairly conclusive that diamonds have been formed in the areas mentioned, as the result of metamorphic changes induced in carbonaceous matter by the action of heat derived from adjacent igneous rocks which have penetrated the beds. In other cases where diamonds have been found in coarse sandstone and gravel, we may infer that their source was some area similar to that of Kimberly which was subjected to denuding agencies, and more or less destroyed.

It is well within the bounds of probability that as alluvial gravels are worked out in the search for diamonds, future prospecting will lead up to the original diamantiferous areas where an association of carbonaceous and igneous rocks may be expected to occur; indeed, this is what happened in the case of Kimberly.

The causes which have operated in the conversion of bituminous coals into anthracite have attracted many workers, and various theories have been put forward.

Metamorphism of bituminous coals into anthracite by intrusion of igneous rock is generally admitted, although it sometimes happens that the coal is simply charred, or converted into a friable dull earthey mass, as in the Staffordshire coal field.

The influence of earth-folds, earth-heat, and deep-seated igneous rocks is not so widely accepted, although these agencies have each been selected by various workers as affording the best possible explanation of the conditions which obtain in various areas.

De la Beche in attempting to determine the formation of the anthracite of South Wales,* showed that the bituminous seams changed so gradually into anthracite that it was difficult to mark one off from the other. In this field the passage into anthracite is towards the west, the best and purest occurring in Pembrokeshire, where the rocks have been most disturbed and folded. A similar feature had been noticed in the anthracite fields of Pennsylvania, U. S. A., by Professor Rogers, who sought to explain the metamorphism by accounting for the dissipation of the original gaseous contents of the coal, as the result of superheated steam and heat developed by the folding which the rocks had undergone.

But De la Beche in this country and Professor Stevenson in America, have shown that this theory is not wholly satisfactory. The former pointed out* that certain of the bituminous coals of South Wales had been more disturbed than the anthracites; for example, the bituminous coals of Volseter, in the Mendip Hills, being far more contorted than the anthracites of Glamorganshire and Carmarthenshire.

The latter has shown† that Professor Rogers' conclusions are not wholly correct for the Pennsylvania field, and that as in South Wales, certain bituminous areas are more folded and contorted than others which contain pure anthracite. As a more workable theory and as agreeing more closely with the facts of the Pennsylvania coal field, Stevenson has sought to explain the formation of the Pennsylvanian anthracites by supposing that they represent the oldest portions of the coal field, or the marshlands which first commenced to grow out from the old shore line over the shallows, and that being the oldest, they have undergone a more complete chemical change and greater loss of volatile compounds than is the case with the younger deposits of coal further west, which still retain their bituminous character.

By this theory, as I understand it, the loss of hydrocarbon compounds must be taken as indicative of the relative ages of the coal bed.

This argument would prove very useful as an explanation of the origin of graphite deposits so common in the older rocks, but I have not been able to find it capable of application outside the Pennsylvanian area. It does not seem satisfactory in such a coal as that of South Wales, where in a single seam there is a gradual passage from a bituminous coal to a perfect anthracite, unless indeed it can be proved that the most westerly portion of the seam was formed at an earlier period than the easterly. Though we cannot apply Prof. Stevenson's hypothesis outside the Pennsylvanian area, it is almost certain that the progress of chemical change in the course of ages, to which he draws attention, must always be reckoned an important factor in the ultimate passage of coal to a high state of carbon purity.

Dr. D. D. Owen‡ explained the formation of the undisturbed anthracite fields of Arkansas by supposing the existence of deep-seated igneous rocks giving off heated gases, which in their passage upward through the coal carried away the volatile hydrocarbons. A similar conclusion was also arrived at by Professor Hull for the Irish anthracites, and by Sir R. J. Murchison for the anthracites of the Donetz coal field in Southern Russia.

Prof. Lesley,§ taking up the question in its physical aspect, put forward the suggestion that the action of earth heat, due to the loading of the coal measures by overlying deposits, might have been adequate to drive off the gaseous constituents of the coal.

Where it can be shown that the loading to which the Coal Measures have been subjected can only be reckoned by thousands of feet, this supposition may be correct, but the difficulty often is in proving this overlying thickness of deposits. That a comparatively low heat, if long continued, is sufficient to convert a bituminous coal into anthracite has been proved experimentally. De la Beche mentions a case* in which bituminous coal was converted into anthracite by a very gradual application of heat. Dr. Lyon Playfair,† who afterwarde examined the specimens so produced, speaks of them as much like native anthracite. In damped down furnaces anthracite and coke may be produced, the former owing its origin to a lower heat than the latter.

*Memoirs Geol. Survey, Vol. I., p. 217.

‡Owen, "First Report of a Geological Reconnaissance of the Northern Counties of Arkansas," 1858.

§Lesley, "Second Geol. Survey of Penn., Second Report of Progress in the Laboratory" 1879.

In reviewing these various theories and seeking to apply them it becomes very evident that whilst any of them may be sufficient to explain the conditions of a particular case or area, none of them are held to satisfy all requirements.

In all cases anthracite is formed by the elimination of volatile hydrocarbons from the original bituminous coal, and since it has been demonstrated that a temperature lower than that required to coke the coal will, if long continued, be sufficient to effect the change, we may assume that where it can be proved that heat has been developed, whatever may have been the cause, it, and it alone, will accomplish the change. Cases, however, must have occurred where, by the formation of earth folds, intrusive dykes, and similar agents, considerable heat has been developed, only to be rapidly dissipated by the conductivity of the surrounding rocks, or by finding some avenue of escape, or even by acting more easily upon associated strata. An instance of the latter occurs at Craigman, New Cumnock, Ayrshire, where the clay shales which overlay the coal have undergone much more alteration than the coal itself, and partake very largely of the character of jasper.

Where a dyke-like mass has been suddenly injected into a coal bed, as in the South Staffordshire coal field, the great and sudden accession of heat has converted the adjacent layer of coal into a friable carbonized mass somewhat in the nature of a lampblack. The layer thus formed would act as a protecting layer to the rest of the coal by reason of its low conductivity, and little or no anthracite would be produced.

The conversion of bituminous coal into anthracite is, I believe, chiefly accomplished by heat, and as heat is developed in all manner of ways in the earth's crust, it is but natural that various heat-producing agents have been advocated from time to time as the sources of all anthracite formation. No statement has been put forward hitherto, so far as I am aware, of the stages of metamorphism of coal into graphite; but that graphite has been formed artificially in many ways, and in various manufactures and metallurgical operations, as a direct product of coal when subjected to great heat, is well known.

In the retorts of gas furnaces large quantities of graphite are deposited on the inner sides of the retorts from the gases driven off from the coal, and by the kindness of C. Nickson, Esq., I am able to lay before you several specimens of graphite formed in the retorts of the Manchester Gas Works. Graphite is not unfrequently formed in blast furnaces, where, under varying degrees of heat, coal has been seen to pass through the stages of burnt coal, anthracite, charred coal and coke, into graphite. This fact is of considerable importance as furnishing a clue to the metamorphism of coal into graphite in the earth's crust, and is probably paralleled by the series of changes induced in coal in the Ayrshire coal field.

Mr. Smith, of Monkredding, writes me that his observations of the Ayrshire coal field show that the changes which coal undergoes as it nears a trap dyke or an intrusive mass is as follows:

1. Charred coal (generally columnar, but sometimes massive, and often reduced to a black powder).
2. Anthracite (not inflammable, with a glittering surface).
3. Burnt coal (slightly inflammable).
4. Free coal (inflammable).

The coal near the intrusive masses in the South Staffordshire coal field appears to have passed through a similar series of changes, but has stopped short at the charred or coke condition. Some specimens of coal only a few inches in diameter obtained from this coal field seem to consist of a confused mixture of anthracite and compact charred coal.

The specimen of "graphitoid anthracite" from Worcester, Mass., U. S. A., kindly sent me by Professor Stevenson, of New York University, is very largely graphitic, so much so that it is difficult to say what was the stage immediately antecedent to the graphite. A portion of the specimen shows a few dull compact fragments which seem included in the general graphitic mass, and which bear a general likeness to the charred coal of South Staffordshire. From one specimen we cannot postulate that the same changes from anthracite to charred coal and then to graphite occur in the Worcester area of Massachusetts as at Craigman mine, but an inference that such is the case can at least be held.

The present condition of the beds in the case of the Craigman mine, Ayrshire, point to two intrusions of igneous material. By the first, the shale which lay upon the coal was lifted up and porcelainized, the coal being probably charred to some degree. The second intrusion took place along a plane dividing the coal and the basal portion of the first intrusive mass, which is now much decomposed. The overlying shales having been already porcelainized served to retard the loss of heat, the coal thus becoming subjected to a higher temperature than in the first case and for a much longer period, with an ultimate conversion into graphite. This theory is held by Mr. Smith, of Monkredding, and agrees so well with the facts that I see no reason why it should not be the correct one. The changes induced in the coal are exactly analogous to what is seen in blast furnaces, and can be demonstrated experimentally.

*Mem. Geol. Survey, Vol. I., p. 252.

† Lyon Playfair, "On the Gases Evolved During the Formation of Coal," Mem. Geol. Survey, Vol. I., p. 477.

For the artificial conversion of coal into anthracite we have already cited Sir H. de la Beche and Sir Lyon Playfair; for its further conversion into coke by the application of heat I may instance the effects of combustion in coke ovens and gas furnaces; and for the still further change of coke directly into graphite I would draw your attention to certain striking experiments of Henri Moissan, which are described in detail in the *Comptes Rendus*.*

Moissan found that a small crucible of very pure coke fitted with a lid of the same material was entirely converted into graphite by heating for *ten minutes* in the electric arc. That no fusion took place was proved by the lid of the crucible (which was also converted into graphite) being perfectly free in its place.

Further experiments with charcoal of sugar showed that the mass was entirely converted into graphite, whilst still retaining its form, and showed no traces of fusion even when examined with the microscope.

But even without these experiments there is clear evidence that when rocks containing carbonaceous matter as a constituent are subjected to heat metamorphism, the carbon is converted into graphite in the metamorphosed rock.

Rosenbusch, Brogger, Rudeman, and Sauer agreed in regarding the graphitic particles in the rocks of contact areas as having an original carbonaceous origin.

This fact has been proved by Messrs. Beche and Luzi,† who have most recently studied the question.

They state that the Upper Silurian clay slate and Kiesels Schiefer of Pirna and Kreischa are rich in particles of carbon, and that these rocks are converted into chiastolite slate rich in graphite and into graphitic quartzite, in the contact zone of the Dohna granitite and of the Weesensteiner hornblende-granitite.

Examples of chiastolite slate and of graphitic quartzite were taken by these authors and carefully examined, petrologically and chemically, and also compared with the unaltered Upper Silurian slates and Kiesel Schiefer, from which they had been undoubtedly derived. It was shown that the quartz of the clay slates and Kiesel Schiefer had been entirely recrystallized when the rocks passed into chiastolite slates and quartzite, with an increase in the size of the crystals. This recrystallization took place after, or at least contemporaneous with, the conversion into graphite of the particles of carbon.

The carbon particles in the unaltered slate are so excessively minute that they can scarcely be measured, and are usually under .001 m. m. in diameter; but in the metamorphosed rock they are represented by graphite particles which vary in size between .003 and .01 m. m., and rise as high as .02 m. m.

Not only do large crystalline aggregates of graphite occur in the chiastolite slate and graphitic quartzite, but isolated crystals having a well defined hexagonal outline.

Messrs. Beche and Luzi seem to have clearly demonstrated by both petrological and chemical means what had previously been asserted by Rosenbusch and others, and as a result of their work it may be taken for granted that when a sedimentary rock containing carbon is metamorphosed, the carbon is converted into graphite.

A consideration of the foregoing facts shows that, whether by artificial means or by natural means, the conversion of bituminous coal into graphite is by well defined stages, by an anthracitic condition being first reached, which gives place to coke, and that in turn to graphite.

Certain researches of Moissan, to which we have not alluded, but which are dealt with in his paper, seem to show that when carbon is vaporized and afterwards condensed, graphite always results,, and it may be that in some of the oldest known rocks volatilization of the carbonaceous matter has first taken place, and afterwards condensation in veins and pockets as graphite.‡

The few known cases in which eruptive rocks have penetrated carbonaceous shales have not yet yielded any clue as to the mode of origin of the diamond, and we may safely assert that no theory at present propounded for coal metamorphism throws any light upon it.

Moissan is of opinion that in the case of carbon subjected to high pressure and heat, increased density ensues, and the diamond results, and claims to have formed diamonds under these conditions. He says: "In my ingots of iron refrigerated in lead I have produced small diamonds presenting an appearance of an elongated drop, as it is sometimes met with in nature. We know that there are found at the Cape and in Brazil diamonds possessing no trace of apparent crystallization, and have rounded forms like those which a liquid might assume if kept in the midst of a pasty mass. Carbon under pressure might, therefore, take a liquid state, and solidify like water, presenting either a confused mass of crystals or taking a rounded and amorphous figure."

The association of carbonaceous shales and a diamantiferous area at Kimberly are, however, so remarkable that all who have worked upon the subject have expressed a belief that in some way the formation of diamonds has been due to the action of erupted material upon carbonaceous matter.

*Henri Moisson, "The Evaporation of Carbon," *Chemical News*, December 21st, 1894, Vol. LXX., and *Comptes Rendus*, Vol. CXIX., p. 776.

†R. Beche and W. Luzi, "Ueber die Bildung von Graphit bei der Contact Metamorphose," Neues Jahrbuch fur Mineralogie, Geologie, und Paleontologie; Jahrgang, 1894, p. 28.

‡Prof. Heddle, of St. Andrew's University, informs me that during the course of his studies of the graphite in Scottish rocks he has never seen a case where a true anthracite was converted into graphite and that more usually the latter arises from heat acting upon bituminous shales than upon coal.

The Goyne Pump Works, of Ashland, Pa., has recently completed, for the Delaware and Hudson Canal Company, for one of that company's collieries at Plymouth, a duplex compound condensing pump. Its high pressure cylinders have a diameter of 28″ while the low pressure cylinders are 42″. The plungers are 13″x36″. The Goynes have also recently shipped to the Penn Manor Shaft Co., at Manor Station, Pa., one of their Standard (24″x10″x36″) mine pumps.

ELECTRICAL MINING MACHINERY.

Description of the Electrical Machinery at the Scott Haven Mines, and Its Success.

Written for THE COLLIERY ENGINEER AND METAL MINER.

One of the most interesting electrically operated coal properties in America is that of the Youghiogheny River Coal Co. at Scott Haven, Pa. The mines of this company in which the different machines driven by electrical power are installed are scattered over a considerable extent of territory and lay on both sides of the Youghiogheny river.

The power house is located on the east side of the river contiguous to the line of the Baltimore & Ohio R. R. It was formerly a bonded warehouse and contains not only the machinery, but also the stores and offices.

The boiler plant consists of three $60'' \times 18'$ tubular boilers, each containing fifty-eight 4'' tubes. Each boiler is coaled through a chute, is independent and has its own stack. They were built by the Union Iron Works of Erie, Pa. Water for these boilers is pumped by a Downie deep well pump from a well 130' deep and such water as is not immediately used is stored in tanks.

The engine room is 74' long and 54' wide and is separated by a brick wall from the power house. The engine plant consists of three automatic engines each $15'' \times 16''$ cylinders with 72'' fly wheels running at 240 revolutions per minute. Each engine is belted to a four pole, 650 revolution 100 K. W. General Electric Co. generator wound for 500 volts and over-compounded for 10% loss in the line. The engines and dynamos are erected on brick foundations. The current from the generators is carried under the floor to the switch-board over heavily insulated cables laid on porcelain insulators.

The switch-board is of the skeleton type divided into two parts; one for the generators and one for the feeders, on a plan similar to that used in the ordinary electric railway stations. The generator board carries three automatic circuit breakers, three circular Weston ammeters, three main double pole double throw switches and three field rheostats. The volt meter is carried on a bracket on the side. The arrangement of the switchboard is such that the plant may be run under the most economical conditions and every precaution is taken against stoppage in its operation. Two sets of circuits are run, one of which is grounded for haulage work and the other, metallic, for the fans, coal cutters, etc. Any machine may be run on either the metallic or grounded circuit and any two or three may be run in multiple on either circuit. The feeder switch-board carries an automatic circuit breaker for each of the haulage circuits and a double pole switch for each pump circuit, fan circuit and the coal cutter circuit; and a double pole switch for throwing the metallic and grounded bars into multiple. Lightning arresters protecting the generators are placed behind the switch-board.

From the power house the circuits for No. 1 mine are run on poles to the mine mouth. This mine is about 900' from the power house and the circuit is used to drive fans, pumps, locomotives and coal cutters. The fan is a Capell exhaust fan 8' in diameter and 3½' wide with single inlet. It is driven by a belted 25-horse-power multipolar, moderate speed motor running at 650 revolutions per minute. The distance from the generator station to this fan is such that the loss of current is so unimportant that the mine management has not taken it into account in their tests, the results of which, given us by Mr. W. S. Gresley, superintendent, were as follows:

Revolutions of fan	268 per minute
Cubic feet of air produced	85,000 per minute
Water gauge	1.1 inches
Horse power in the air	14.7
Horse power in motor	17.25
Percentage of useful effect of fan on motor	85.2 per cent.

There is another Capell fan in use in this mine which, at the time the tests were made, was run by a temporary steam engine at 100 revolutions per minute. The fan is 12½' in diameter and 5' wide, single inlet. The volume of air produced was 80,000 cubic feet per minute; the water gauge was not taken. The maximum duty of this fan is 150,000 cu. ft. of air per minute at 7'' water gauge. With the new 50 horse-power motor which the General Electric Co. attached to this fan its output is on the basis of 190,000 cu. ft. of air per minute at 1'' water gauge, but with 50 horse power in the motor the water gauge will be much higher and the volume lower as the air road from the fan to the first split is so small that water gauge will be produced at the expense of volume of air.

All the coal cutting in this mine is done by five Jeffrey chain coal cutters. The mine is also provided with a Knowles triplex pump 6½'' x 8'' driven by a 7½ horse-power multipolar motor. The pump, motor and rheostat are mounted on an iron truck so as to be run over the track from place to place in the mine.

An electric locomotive is in operation in this mine with a length of haul a little over 1½ miles. The grades vary from 1% against loads to 0.25% in their favor. The track is laid with 30 pound rails and has a gauge of 43½''. The trolley wire is hung in the regulation mining style. The pump and haulage circuits are all grounded for the return.

The fact that the various mines are separated from each other by the river introduces a novel feature into the installation and illustrates the flexibility of electric power transmission. For each of the other mines in the Youghiogheny company's system current is carried under the Youghiogheny river by heavily insulated cables to a small cable house forming the center of distribution for the lines running to the mines on the west side of the river.

In No. 4 and the Southwest mines electricity is applied to pumping purposes only. The pumps are triplex pumps similar to those in No. 1 mine, and are driven by two multipolar slow speed motors of 10 horse-power and 7½ horse-power, respectively. These pumps are about 8,000 feet away from the power house.

In the Pacific mine the haulage is effected by a locomotive having a draw-bar pull of 2,500 pounds, with a length of haul of about 5,000' underground and 800' on the surface. This mine also contains a pump similar in size to that in No. 1 mine which is driven by a 7½ horse-power motor located about 16,000' from the power house. A 30 horse-power motor for driving a Capell fan is erected about 1,000' feet beyond the pump. This fan is a good sample of a small ventilating installation under conditions which with other methods would be both difficult and costly, and is of an efficiency (in transmission, certainly) not hitherto attained. The fan is 8' in diameter and 3½' wide, with a single inlet, and in other respects is the same as the fan first described. The power is carried across the Youghiogheny river into No. 1 mine through a labyrinth of active and old workings to the foot of a shaft 120' deep, thence up the shaft to the surface, where the fan and motor are erected. The first hour this plant started it ventilated the mine, the fan giving 61,800 cubic feet of air per minute on an output of 13 horse-power by the motor. In the forceful language of the mine foreman in reporting the start to Mr. Gresley, "She went off slick as grease."

Subsequent tests show the fan to give 65,000 to 70,000 cu. ft. of air per minute at 1.5'' water gauge (for 65,000 cu. ft.), the quantity varying with the opening and closing of doors and other conditions in the two mines. The results of the test in detail are as follows:

Speed of fan	200 revolutions per min.
Volume of air per minute	65,000 cu. ft.
Water gauge	1.5''
Horse-power in the air	15.4
Horse-power at motor	20.1
Horse-power at generator	22.1
Percentage of useful effect of fan as compared with motor	76.5 per cent.
Percentage of useful effect of fan as compared with generator	69.73 per cent.

From the above statement it will be seen that the current loss for 3½ miles, the distance the fan is away from the power house, is only 6.77%. In this connection it will be interesting to compare a German installation of the Capell fan with this Scott Haven plant. The Bonifacius plant, Kray, Westphalia, was erected about three years ago and a test was made by eminent mining engineers of which the following were the results. The fan was 10' in diameter and 4½' wide.

Speed of fan	190 revolutions per min.
Volume of air produced per minute	89,000 cu. ft.
Water gauge	2.4''
Percentage of useful effect of fan as compared with engine indication	60 per cent.

The engine used in this case was of superior finish and high speed, but the difference between the indicated and brake horse-power is not stated.

In the new steel tipple at No. 1 mine a 7½ horse-power motor drives a revolving screen and runs an emery wheel for sharpening bits for the coal cutters, etc. The installation of electricity in this mine has proved of more than considerable benefit from every point of view. A fair idea may be obtained of the economical value of electric haulage from the statement that the two locomotives have displaced eighteen mules and their drivers and the four pumps, which take only a small share of the attention of three separate men, are doing the work formerly performed by ten men, four mules, two steam boilers and two steam pumps, and they are doing it more efficiently.

The entire electrical apparatus used in the power house and in the mine, with the exception of the coal cutters, is of the General Electric Company's manufacture. Within the past three years this company has perhaps done more to develop electrical apparatus for use in mining work than any other electric company. It has over 50 of its mining locomotives in use at different mines in the country, as well as pumps, hoists, ventilators, coal cutters, drills, etc., and all are working satisfactorily and economically.

The Capell fans were put up under the supervision of Mr. Wm. Clifford, Mining Engineer, Pittsburg, Pa., who is Dr. Capell's representative in this country.

STEAM SPECIALTIES

At the National Electrical Exposition, New York City.

In arranging the great exhibition of electrical machinery and appliances, The National Electrical Exposition Co., of New York, decided that such an exposition would not be complete without a steam boiler plant supplied with first-class appliances so as to show a strictly modern plant.

The arrangement for supplying the boilers with fuel was constructed by the C. W. Hunt Co. The coal after being dumped at some distance from the boilers in the rear is taken by the C. W. Hunt coal conveyor and carried along the side and a little past the front of the boilers where it is lifted to a point near the ceiling of the boiler house from whence it is delivered through tubes to the hoppers of the stokers; from that point it is fed uniformly down inclined grates, burning on its way, and reaching the foot of the grates as ash. The Hunt conveyor next takes the ashes and carries them back to the dumping place somewhere in the rear of the boiler, dumping them there automatically.

The boiler feed water is supplied by a boiler feed pump constructed by Henry R. Worthington and is electrically driven. The pump is of the "steeple pattern" and combined with its motor presents a novel and elegant appearance.

The pressure carried by the boilers is 125 pounds. This pressure is carried along the main steam pipe to a point just beyond the first engine; there it is reduced by a Foster reducing valve manufactured by the Foster Engineering Co. of Newark, N. J., to 90 pounds, from which point it is carried to all the other engines on exhibition. The Foster Engineering Co. also exhibits a new automatic safety stop valve to be placed in the main steam pipe near the boiler. This valve will instantly and automatically close in case of a rupture in the steam pipe or the breaking of any of its fittings. By this means the steam in the boiler will instantly be stopped from rushing into the pipes and all such fatalities as have recently occurred due to ruptured steam pipes will be avoided. Another valuable feature used in connection with this automatic stop valve is found in a pipe leading from it, containing a quick closing lever gate valve. When this is opened quickly the main valve closes instantly, and thus the whole steam supply can be cut off from the main steam pipe at an instant's notice.

The visitor cannot fail to be struck with the beautiful finish of the water tube boilers. The fine, smooth, black finish contrasts strikingly with the nickel work and is produced by the use of Dixon's graphite boiler front paint, made by the Joseph Dixon Crucible Co., of Jersey City, N. J., whose exhibit is in the neighborhood of the boilers.

Among the engines used at this exposition is one of the well-known Weston engines which compares splendidly with any competitor exhibited.

The exhaust from all of the engines is passed through a Goubert feed water heater and then sent through spiral riveted exhaust pipes placed outside the building to a point above the roof. All the feed water used will pass through this heater, thus supplying the boilers with a bountiful supply of water heated to nearly 212 degrees.

The entire plant is so simple and safe in operation that a woman has been put in charge of it to show conclusively that if the steam user will adopt the modern type of appliances and equip his plant in an up to date manner throughout its operation becomes so simple that a woman can operate it as well as the most expert and strong fireman.

SUPERIOR GRAPHITE PAINT.

We have received from the Detroit Graphite Manufacturing Co., of Detroit, Mich., a piece of a boiler stack which had been in use for three years after being painted with *one coat* of superior graphite paint. The piece of iron, after this severe service looks as if it had been but recently painted. A piece of a 3½ inch boiler tube which had also been used three years after being painted with one coat of superior graphite paint looks as perfect as if it had been cut off of a new tube. The paint on this piece of tube is still bright and fresh.

A piece of canvass painted on both sides with the same paint accompanied the piece of stack and piece of tubing. The canvass is similar to old sail, or brattice cloth. The paint makes the canvass perfectly water proof and protects it from the action of mine water which soon renders ordinary brattice cloth rotten. This paint has been proven a wonderful protector of iron exposed to the action of acidulated waters and gases. As an example of the resistance of this paint to the action of acids and alkalis, the makers inform us that they have subjected it to the follow tests:

Pieces of iron painted with superior graphite paint, which are now being tested, have been dipped in muriatic, sulphuric and oxalic acids and then allowed to dry with the acid on the them for 19 days, at present writing, without showing a particle of damage to the paint. The longest time which other paints withstood these conditions without injury was 24 hours, when they were entirely destroced. Superior graphite paint has also been immersed in ammonia and sal soda for 19 days, in coal oil for several weeks, and in strong brine for six years without showing injury. They have also submitted pieces of iron painted with superior graphite paint to 24-hour tests in boiling alcohol, boiling beer, boiling brine and boiling sugar and water without the paint showing any injury. Red lead paint subjected to boiling alcohol stood 15 minutes; to boiling beer, 30 minutes; to boiling brine, 25 minutes; to boiling sugar and water, 15 minutes. Superior graphite paint has also stood in cold soft soap 24 hours without damage, while other paints stood for one hour only. These are extremely hard conditions, and, except possibly some of the simpler ones, it is seldom that a paint is ever subjected to them.

A paint which will stand such tests is of value to every mine manager, and we advise all such to give it a trial. Full particulars as to prices, etc., will be cheerfully furnished on application to the Detroit Graphite Manufacturing Co., Detroit, Mich.

Improved Car Door Fastener.

The Watt Mining Car Wheel Co., of Barnesville, Ohio, has recently had patented a door fastening for mine cars which possesses such merits as to make it exceedingly popular. It is simple in construction, quick in operation, and easily applied either to a new car or an old car having a door swung from the top. It will not easily get out of repair, as it is so constructed that it allows the door to swing freely, and there is no danger of it striking either the sides or the bottom of the car.

An illustration of this improvement is shown in the advertisement of the Watt Mining Car Wheel Co. on another page.

The Watt Co. is on the lookout at all times for any practical and useful improvement in the construction of mine cars. They are the exclusive manufacturers of the "Watt Self-Oiling Mine Car Wheel," and as they make a specialty of building mine cars for any gauge and of any capacity, they are prepared to do satisfactory work and get it out on reasonable terms and at short notice.

Bellis Mine Collars.

Mr. W. L. Bellis, sole manufacturer of the Bellis Mine Collar, so well known to many mine managers throughout the country as an excellent preventive of sore shoulders on mine mules, has just issued a convenient little catalogue of his collars and general harness.

The Bellis collar has made an enviable record in mines in all parts of the continent. They not only prevent sore shoulders but cure them as well. These collars are now regularly used by fully forty of the largest coal mining concerns in America, and have been thus introduced in several hundred of the most important mines.

CLASSIFICATION OF BITUMINOUS COALS.

What Constitutes Good Steam, Gas, Smithing and Coking Coals.

Written for THE COLLIERY ENGINEER AND METAL MINER by Baird Halberstadt, Min. Engr., Pottsville, Pa.

The question is often asked by young mining engineers and others interested: "In what particulars do soft coals differ chemically and physically, so that a coal which is excellent for a specific purpose will fail to give satisfactory results, should it be put to other uses." For example, why is it that the Clearfield or Pocahontas coals are superior to either the Connellsville or Westmoreland coals for steam generation, while the former for coke and the latter for gas manufacture are superior to either the Clearfield or Pocahontas coals?

Deservedly or undeservedly, the coals of certain regions have established for themselves high reputations, and have for a long period continued, notwithstanding the liveliest competition, to maintain them.

No region can long continue to monopolize a special trade unless its coals possess in a greater degree than do others, the essential characteristics required when put to special uses. So firmly indeed have some regions established reputations for their coals for certain uses, and so high do they stand in "Trade" circles that they have been accepted as standards, and as coals from newly opened fields approach or recede from, in chemical composition, these standards, their values are determined, *i. e.*, so far as the "Trade" is concerned. For instance, when a new coking coal field is developed, almost the first question asked is, how does the coal compare with Connellsville? Again, when new coals are placed on the market, for which are claimed especial value for use in generating steam, buyers will ask, how does this coal compare with Clearfield and Pocahontas coal?

In view of this, for it is beyond question that these regions have so firmly intrenched themselves that they seemingly cannot be dislodged, we must, for the present, at least, and until a better plan be evolved, acquiesce in this judgment. Assuming this to be correct, the question arises, why are they better? and through the possession of what peculiar characteristic or characteristics, are these coals made more valuable for specific purposes, than others?

In this paper will be considered coals for steam generation, the manufacture of gas, smithing purposes and the manufacture of coke. For each of these purposes, certain coals have achieved enviable reputations and continue to maintain them. They are as follows:

For steam purposes—Clearfield and Pocahontas.

For the manufacture of illuminating gas—Westmoreland and Youghiogheny.

For smithing purposes—Broad Top and Bradford Tioga.

For the manufacture of coke—Connellsville.

At the very outset, the requirements of each subject must be considered—and these it will be noticed differ widely.

What then are the requirements to be considered and what essentials must be possessed by a coal to make it more valuable for generating steam than others?

One of the best answers, if not the best, to this question, was given by the late Prof. Henry Darwin Rodgers, state geologist, in Vol. II, page 998 *et seq.*, "Geology of Pennsylvania." From it have been compiled the following:—

First—It should possess a high, absolute evaporative power.

Second—It should at the same time, as far as compatible with the foregoing property, kindle readily and burn with great celerity, generating a large body of steam in a short time.

Third—It should be readily managed and steady in combustion, and to this end its ashes or earthy matter should tend as little as possible to choke the draft of the grate by fusing, even at an extreme heat, into an adhesive clinker.

Fourth—The fuel should be free from any excess of incombustible matter, as this, all other things being the same, will materially impair its efficiency, and its ashes should produce but little clinker.

Fifth—It should be exempt from any considerable amount of sulphur, for this tends to corrode the flues and is otherwise detrimental.

Sixth—Volatile matters should not exist in any greater amount than will suffice to give great rapidity of combustion to the fuel. Any larger proportion is at the expense of its heating power.

Seventh—For certain uses it is important that a coal should unite with a high evaporative power such a degree of density and structure as will enable it to contain a relatively large amount of carbon in a given space. This compatibility of being economically stowed or packed away is a point of daily increasing consideration.

Eighth—It is likewise desirable that a coal should possess sufficient tenacity in the lump to bear the abrasion incident to its transportation without serious reduction to fine coal.

A study of the chemical analyses of standard steam coals seems to indicate that the best results have been obtained from coals wherein the percentages ranged as follows:—

	Per cent.
Fixed carbon	67 to 74
Volatile matter	17 to 22
Sulphur	0.5 to 0.9
Ash	5.0 to 8.0

CLEARFIELD COAL.

The following analyses of Clearfield, Cumberland and Pocahontas coals, all considered *standard*, made by Mr. Andrew S. McCreath, which is sufficient guarantee of their entire reliability, may be taken as typical:—

No. 1 sample taken from thirteen cars at Greenwich, Philadelphia.

No. 2 sample taken from five cars at Canton, Baltimore.

No. 3 sample taken from seven cars at Canton, Baltimore.

	(1)	(2)	(3)	Ave. (1, 2 and 3)
Water	1.528	1.166	1.654	1.180
Volatile matter	22.122	22.299	22.081	22.167⅓
Fixed carbon	70.051	67.558	70.199	69.270
Sulphur	.652	1.422	.726	.933⅓
Ash	5.825	7.555	5.900	6.443⅓
	100.000	100.000	100.000	100.000

CUMBERLAND COAL.

No. 1. Sample taken from coal supplied to the Shenandoah Valley Railroad company.

No. 2. Sample taken from six cars at Greenwich, Philadelphia.

	(1)	(2)	Ave. (1 and 2.)
Water	.912	.971	.968
Volatile matter	18.105	19.776	19.120½
Fixed carbon	73.154	72.263	72.707½
Sulphur	.806	.769	.787½
Ash	6.695	6.129	6.107½
	100.000	100.000	100.000

FLAT TOP (POCOHONTAS) COAL.

The average of 10 analyses of this coal is as follows:

Water	0.694
Volatile Matter	18.832
Fixed Carbon	74.066
Sulphur	.761
Ash	5.647
	100.000

The average of 8 analyses of coal taken from the No. 3 (Pocohontas) bed shows:

Water	0.628
Volatile Matter	18.750
Fixed Carbon	73.406
Sulphur	.792
Ash	6.388
	100.000

In writing upon this subject Mr. McCreath says: "While the analysis of a coal affords a fair opportunity of judging of its character as a steam coal, yet there are so many points connected with its physical structure and coking qualities which an analysis cannot show, that a practical testing under boilers is of the highest importance."

The requisites of a good coal for the manufacture of illuminating gas are:

1. That the percentage of volatile hydro-carbons should be at least 33 per cent. Above this amount, quality, rather than quantity, should be sought for; *i. e.*, richness in illuminating properties.

2. That the percentage of sulphur should be low, say from 0.5 to 0.8 per cent.

3. A low percentage of ash, say from 3 to 6 per cent.

4. That it should yield upon distillation from 75 to 85 candle feet per pound.

5. That it should leave, after the extraction of the volatile matter, a firm, bright, merchantable coke.

6. That it should be strong enough to bear transportation well, for long distances, without serious waste by reduction to fine coal.

In his brochure on the gas coals of the United States, read before the convention of the American Gas Light Association, in Savannah, Mr. H. C. Adams, of Philadelphia, says:

"The essentials of a good gas coal are a low percentage of ash, say five per cent., and of sulphur, say one-half of one per cent., a generous share, say thirty-seven to forty per cent. of volatile matter, charged with rich illuminating hydro-carbons. And it should yield under present retort practice, eighty-five (85) candle feet to the pound carbonized. It should be sufficiently dense to bear transportation well so that when carried long distances, it may not arrive at its destination largely reduced to slack or fine coal of the consistency of sand. And it should possess coking qualities that will bring from the retorts, after carbonization, about sixty per cent. of clean, strong, bright coke.

The following table showing the analyses of some of the principal gas coals will prove interesting and valuable for reference:

ANALYSES OF PENNSYLVANIA GAS COALS.

No.	Water.	Volatile Matter.	Fixed Carbon.	Sulphur.	Ash.
1	1.427	37.521	54.921	.713	5.418
2	1.310	37.100	55.004	.656	5.950
3	1.560	39.185	54.372	.643	4.260
4	1.780	35.360	59.290	.680	2.890
5	1.280	38.105	54.383	.792	5.440
6	1.490	37.153	58.193	.678	2.566
7	1.020	33.205	63.314	.861	3.280
8	1.070	35.515	56.458	2.257	4.700
9	1.540	37.805	56.762	1.101	2.990
10	1.570	38.275	54.720	1.325	4.090
11	1.350	39.645	48.592	1.228	9.265
12	1.120	34.500	59.050	1.550	4.000
13	1.400	32.400	63.011	.639	2.450
14	1.600	30.700	63.791	.639	3.270
15	1.490	29.220	65.022	.608	3.670
16	1.430	31.940	62.100	.532	3.900
17	1.415	32.435	61.930	.975	3.215

Nos. 1, 2 and 3 are of coals mined by the Westmoreland Coal company; Nos. 4, 5 and 6 are of coals mined by the Penn Gas Coal company; No. 7 is of coal mined by the Greensburg Coal company; No. 8 is of coal mined by Saltsburg Coal company; Nos. 9, 10, 11 and 12, coals from Jefferson county; Nos. 13, 14, 15, 16 and 17, coals from Reynoldsville region.

The requirements of a good coal for smithing purposes are that:

1. It should possess a high heating power.

2. It should be free from sulphur, or, if any, a very small percentage.

3. It should possess sufficient coking qualities to form an arch, or vault, on the forge.

4. The percentage of ash should be small.

The first requirement means a high percentage of fixed carbon.

A high percentage of sulphur is not only ruinous to the iron, but prevents good welding. The percentage of sulphur should never exceed 1 per cent. Coal containing but one-half of 1 per cent. would be better.

The advantages afforded by the third requirement are many, among them may be mentioned:

1. Its economic importance in saving a large amount of fuel, the interior of the pile only being in a state of combustion.

2. By concentrating the heat upon the iron to be wrought; the arch over the base of the fire is practically an oven, and in consequence there is but a slight loss of heat. It also affords protection to the smith.

3. The coke forming the arch, when broken down, makes a superior fuel for fine welding.

The following table exhibits analyses of standard Pennsylvania smithing coals:

No.	Water.	Volatile Matter.	Fixed Carbon.	Sulphur.	Ash.
1	.715	22.250	70.518	1.459	5.058
2	.615	17.935	76.503	.602	4.345
3	.800	18.535	77.112	.573	2.920
4	.730	17.910	75.239	.656	5.665
5	1.465	19.741	68.974	.686	9.134

Nos. 1, 2 and 3 are of Cambria county coals.

No. 4 is of coal from the Broad Top region.

No. 5 is the average of eight analyses of Blossburg coal.

Upon the subject of coking coal much has been written, but the question as to why some coals coke and others do not has not yet been satisfactorily answered. Neither has the question as to the percentage of volatile matter necessary to complete the coking, without the expenditure of any of the fixed carbon, been definitely settled. Twenty years ago John Fulton, then, as now, the best authority upon the subject in America, said (Report *L*, Appendix *A*, Geological Survey of Pennsylvania): "It is evident that the calorific power of coke is derived from its carbon, and hence the purest coke will produce the greatest heat. This requirement of pure dry coke is more evident when it is considered that all foreign matter and moisture not only do not contribute heat, but require the expenditure of it in disposing of the extraneous matter in slag and vaporizing the moisture. It is manifest that the character of the coke is determined *by the quality of the coal used*, and the latter should receive very careful examination before expending largely in plant for coking. The first requirement in the production of good coke is a pure bituminous coal—coal having small quantities of ash, sulphur and phosphorus.

"The second requirement is that it contains a sufficient proportion of volatile or gaseous matter to supply the necessary heat in coking without the expenditure of carbon.

"And, thirdly, that the coal produces a coke of sufficient tenacity to sustain, without crumbling, the burden and blast of the furnace, and to inherit *an open cellular structure, to facilitate its impregnation and solution by the carbonic acid gas in the furnace.*"

He further states that "ordinary analyses fail to indicate the essential qualities of a good coking coal. They are highly useful, however, in exhibiting the carbon, ash and sulphur, thus clearly indicating the strength and purity of the coal. The only sure method in the determination of the adaptability of coal for coking, is to have a quantity of it made into coke, and a study of its physical and chemical properties carefully made."

As has been said before, the coal mined from the Pittsburg bed in the Connellsville basin of Pennsylvania is considered the *standard* coking coal of America, and as a coal nears or recedes from it in chemical analysis or physical test, its value is determined. This concession may be said to be general, but there are not wanting those who assert that Pocahontas (Flat Top) coke is equally as good, if it be properly made. For comparison, analyses of typical specimens of each coal are given:

	Connellsville.	Pocahontas.
Water	1.260	.694
Volatile Matter	30.107	18.832
Fixed Carbon	59.616	74.066
Sulphur	.784	.761
Ash	8.233	5.647
	100.000	100.000

Upon examination it will be found that the percentage of fixed carbon is greater by 14.450 per cent., in the Pocahontas coal. It also has less sulphur and ash than Connellsville. These are all in its favor. In the matter of volatile hydrocarbons, however, it is deficient, Connellsville possessing over 11 per cent. more of this highly important constituent. Experiments have demonstrated that the loss of carbon in coking amounts, in the Pocahontas coal to 20 per cent., while in the Connellsville coal it is but 8 per cent. under like conditions. Pocahontas coal, as shown by chemical analysis, approaches the coals of the Allegheny mountain district of Pennsylvania rather than the Connellsville. From the foregoing it may be said that the volatile matter should be between 18 and 32 per cent. and that the composition of this has much to do with the character of the coke.

A difference of 14 per cent. of volatile matter in two coals is a wide one, yet here we find good cokes being made from each.

The percentage of sulphur should not exceed 8-10 of 1 per cent., while the percentage of ash should not exceed 9 per cent., the lower the better in both cases.

The question of cellular structure of the coke is of great importance and should receive the most careful consideration, not only as to number of cells, but also as to the strength of the material forming the walls thereof. For reference the following table is appended: charge and in the proportion of ore to coke, without giving away.

This improvement in the physical quality of the coke is accompanied by a further improvement in its chemical

Table Showing the Physical and Chemical Properties of Standard Connellsville Coke.

LOCALITY.	Grammes in One Cubic Inch.		Pounds in One Cubic Foot.		Percentage.		Compressive Strength per cu. in. (½ Ultimate Strength).	Height of Furnace Charge Supported Without Crushing.	Order in Cellular Space.	Hardness.	Specific Gravity.	CHEMICAL ANALYSIS.

COKE OVEN CONSTRUCTION.

Its Effect on Coke, With Special Reference to Semet-Solvay Ovens.

By R. M. Atwater. Read Before the Society of Engineers of Western Pennsylvania.

Prof. J. P. Leslie describes the well known Pittsburg vein of coal as follows:

"The Pittsburg region is an outspread of the Pittsburg coal-bed, 50 miles long by 50 miles wide, within the limits of the state of Pennsylvania. An average of eight feet in thickness for the whole region looks like a fair one. This gives 8,000,000 tons per square mile, and there are 2,500 square miles. Allowing 50 per cent. of the area to be interval, and 50 per cent. for pillars and bad mining, we may set down this coal, available for market in the future, at 5,000,000,000 tons.

On this basis, 2% of the Pittsburg coal is contained in the Connellsville vein, counting it all as standard, and not over 1% of the high grade standard coking coal; yet this 1% of Pittsburg coal yields 75% of all the coke made in Pennsylvania, over 8,000,000 tons in 1895.

The object of my paper is to offer methods of coking the Pittsburg coal, which will enlarge the boundaries of the standard coking coal to all of the Pittsburg coal fields that bear coal of standard chemical composition. The available coal left in the Connellsville field is estimated to produce 70,000,000 tons of coke, which, at the 1895 rate, will last 10 to 12 years. It is, therefore, only a question of a few years when other coals must be used, especially if the consumption of coke increases as it should increase, and the United States produce coke for the whole western hemisphere. There is, therefore, in the broad view of the question, no controversy between the Connellsville beehive oven and the retort oven. The existing ovens will have completed their useful life before the adjacent coal is exhausted. So, without sacrifice, they will disappear, and the new construction will take the form of the retort oven. It is this gradual and economical merging of the old method into the new which I desire to present and advocate.

The beehive oven makes no provision for the physical improvement of the coke. It is a broad, shallow basin, in which the coking follows out its own natural course. So far as the quality of the coke depends upon the oven, it is as primitive and unimproved a construction as when it was first devised. Consequently, the beehive oven is a happy-go-lucky oven, and in the lottery of its application the prize fell to the narrow and limited Connellsville valley, or, more strictly, to the middle of this valley, for both the north and south end are not of equal quality with the so-called "standard coke."

In this fortuitous application of the beehive oven, great regions of coal of equal chemical purity with Connellsville have lain dormant, or even sold at lower prices, because they did not make hard coke. If this one lacking quality of structural strength can be added to the coke, it will bring areas of coal land 10 times as large as the Connellsville field up to the Connellsville grade for coke. This will add 25% to the value of such fields.

BEEHIVE AND RETORT OVENS COMPARED.

In the beehive oven a shallow basin 12 ft. in diameter is filled with coal to the depth of 24 inches. As it gradually fuses into coke, the mass swells to a height of about 30 inches, it, on quenching, it falls back to the original bulk, it makes a hard coke. If it does not, it makes a soft coke. This is the apparent difference between the Connellsville coke and the coke from the Pittsburg vein.

Comparing this operation in the retort oven, which is a narrow chamber about 18 inches wide and six feet high, when the coking coal swells it cannot expand. It is compressed laterally between the narrow oven walls, and vertically by the overlying weight of over five feet of coal. The result is that the coke which is soft when coked in beehive ovens is hard when coked in retort ovens.

Further, the hydro-carbon gases, escaping through the mass of the coke in the beehive oven, form vertical passages or cells, and make their way in channels like the cells in a cornstalk, or other endogenous plant. These correspond to the cells of the coke structure. As they are parallel to the lines of pressure of the overlying coal, they have free course, and assume their full size. On the other hand, in the retort oven, the volatile gases pass off first horizontally from the sides of the oven, and uniting in the central part of the mass, pass up to the outlet of the oven through a middle line of cleavage. The whole weight of the overlying mass of coal presses upon these passages vertically, and so compresses the cells, and adds to the density of the coke. The result is, therefore, clearly evident that the retort oven adds density and structural strength to the coke. It will, therefore, carry a heavier burden in the furnace, both in actual height of composition. The three characteristic impurities of coke are sulphur, phosphorus and excess of ash over that required for structural strength. In the beehive oven, not only is all the surplus volatile wasted, but there is a greater or less destruction of the fixed carbon. This varies with good or poor operation of the ovens from 5% to 40%. This loss is inevitable with an internally fired oven.

On the other hand, in the retort oven, there is an actual gain in the amount of coke produced over the theoretical yield of the coal in the fixed carbon and ash. This gain is caused by breaking up the hydro-carbon gases and the deposit of graphitic carbon on the surface of the coke. This gain amounts to from 5% to 15% over the ordinary practice of beehive ovens.

In proportion as the product of coke from the retort oven exceeds the product from the beehive oven, the amounts of sulphur, phosphorus and ash in the retort coke will be decreased, since these impurities start from the coal, and remain to a large extent in the coke.

We may, therefore, sum up the effect of the coke oven construction on the resulting coke as follows. The yield of coke will be increased by the greater rapidity of coking, which never exceeds 24 hours, and may often require only 16 hours, and also by turning part of the volatile into coke. Second, the quality of the coke is improved chemically, by reducing the impurities, and physically by increasing the structural strength of the coke.

Considering the Fourth Pool coals as tributary to the Pittsburg and Valley region; the coals of the Upper Monongahela and West Virginia as tributary to the blast furnaces in the Ohio Valley; the Western Maryland coals as tributary to the Eastern Pennsylvania and Maryland furnaces; and the Pocahontas coals as tributary to the Virginia and Western furnaces—the results are of fundamental importance. The improvement in the quality of the coke produced should raise the value of the coke by at least 25%, and the increase in the product of coke, which may be fairly stated from present common practice as 20% is equivalent to a profit of 20% over that obtained by present methods. For every five tons of coke produced by present practice, one additional ton will be produced by means of the retort oven, and this extra ton, requiring no extra mining or manipulation up to the time of shipping, is all profit.

Still, it must not be forgotten that no oven will make good coke out of poor coal. The fountain cannot rise higher than its source. I have no doubt that the retort oven will produce coke better than Connellsville from coals that are better than Connellsville, if such can be found. The test of 1,500 tons of Semet-Solvay coke from Connellsville coal at the Buffalo furnace demonstrated conclusively that a coke, which did not represent the best practice of the retort oven, was equal in the blast furnace, both in calorific power, in burden-bearing, and in the quality and amount of the iron produced, to the best, selected 72-hour coke that the Connellsville region was able to offer. This is the verdict of the able and impartial umpire, Mr. John Fulton, in his report to the Johnson Co., in whose interest he conducted the test. When the retort oven shall have been developed to its full possibilities on Pittsburg coals, as the beehive oven has been, a new standard coke will be the result, and the beehive may not be in it.

THE SEMET-SOLVAY RETORT OVEN.

Among the various retort ovens that are offered to American engineers and operators, the classification may be broadly made between the recuperative, horizontal flue ovens and the regenerative ovens with vertical flues.

A metallurgical engineer, considering *de novo* the operation of coking coal, would certainly not consider the heat of the regenerative furnace as requisite for the low temperature of the coke oven, which rarely exceeds 1,500° C. or 2,800 F. The addition of the regenerative furnace was an afterthought to overcome the loss of heat in penetrating the thick flue walls of firebrick. Its inventor has himself already abandoned it, and now recommends recuperation with horizontal flues. Setting aside its expensive initial cost, its liability to serious injury from careless operation, and its expensive repair charges incurred, it is from a simple engineering standpoint, a needlessly complicated construction. It seeks to accomplish by a high temperature, applied through a very limited area, that which the recuperative furnace accomplishes by a uniform and more moderate temperature through a space ten times as great. The vertical flues of the regenerative construction must do their work in a single ascent and descent through the space of six feet, representing the height of the oven, a total of 12 feet working distance. In the recuperative construction, with horizontal flues, the burning gases traverse three horizontal flues along the side of the oven, each 30 feet long, and return under the sole of the oven, making a total of 120 feet through which the heat of distillation is applied to the mass of the coking coal. The initial heat in these horizontal flues is not as intense as in the regenerative vertical flues, but as they do their work through a thin tile of only 2½ in. section, while the vertical flues are 4½ in. thick, it is easy to see that the temperature produced in the interior of the oven is much easier obtained by the recuperative construction. The solid masonry construction between and above the Semet-Solvay ovens is itself a recuperator, in addition to the heating of the incoming currents of air adjacent to the chimney flues of the Semet-Solvay oven. Together, they form a natural recuperation, of equal effectiveness with the checker work of regenerative furnaces.

It is well known that the Siemens regenerator does not produce a uniform temperature, and that this temperature varies in proportion to the periods of the reversal of the currents. For high temperatures these reversals are frequently made at fifteen minute intervals, thus overcoming as far as possible the up-and-down result to the temperature of the working furnace. When these periods are extended, as in the regenerative coke oven practice, to two hours, it is evident that at the times just preceding and just following the reversals, the resulting temperature in the oven must be subject to large variations. On the other hand, the heat conducted to the oven through the horizontal flues by the continuous method is uniform for every section of the furnace. Moreover, this uniform temperature is under very complete control, since by the admission of proper proportions of gas and air to any one of the three flues, the resulting temperature of each individual flue is under control. Any chemist will understand that the heat of fusion and distillation is most effectually applied at the lower part of the retort, and this effect is produced, as seen in the temperatures on the diagram, in the flues of the Semet-Solvay oven.

On the other hand it is equally evident that where burning gases rise through vertical flues, and are then diverted by baffling plates, the temperature is greatest at the baffling point, and it therefore necessarily follows that in the regenerative coke ovens the highest temperature is produced at the top of the flues, the reverse of the proper application of the heat to the purpose required. When through carelessness or wilfulness, the periods of reversal become extended, as every Siemen's furnace man knows from his own experience they occasionally are, the result is a melting of these baffling plates, and enormous injury to the construction. This is the fatal record of more than one retort oven construction. It is such considerations as these that prompted the remark of Mr. Darby, of the Brymbo Steel Works, Wales, that if it is possible to avoid the regenerative construction in coke ovens, enormous trouble and expense will be avoided.

Mr. Fulton states as his conclusion about the comparative working of different retort ovens, that the Semet-Solvay oven is 30% quicker in operation than any of its competitors. As evidence of this we may point to the 2,000 tons of Connellsville coal for the Buffalo test, coked in 20 hours; to 100 tons of Pocahontas coal, coked in 16 to 18 hour; to 100 tons of Fourth Pool coal, in a recent experiment coked in 20 to 22 hours. From these results we can confidently assert that the Semet-Solvay oven will produce 2,000 tons of coke from Pocahontas coal in one year, or 1,600 tons of Connellsville or Fourth Pool coke. No oven in Europe or America has reported results within 30% of this record.

This rapid operation of the Semet-Solvay oven affects both the original and the operating cost. It will require twice as many ovens making 36 or 48 hour coke as Semet-Solvay ovens making 18 to 24 hour coke. The operating expenses in the Semet-Solvay ovens will also be greatly reduced. These are vital elements in American constructions. The Connellsville coal from the Valley mine sent to Europe in 1893 required 38 hours for coking in the regenerative oven with vertical flues. The coal from the same mine at Syracuse required only 20 hours.

When the direct object of the retort oven is for the production of fuel gas as well as coke, this rapid operation becomes of greatly increased importance. The distillation of the volatile is not even through periods of the time of exposure in the oven, but proceeds with great rapidity during the first half of the time, and very slowly towards the close of the coking operation. It is, therefore, possible, by shortening the coking period, to coke two charges in 24 hours, and produce nearly double the amount of gas and coke, which, for many purposes, will command as high a price as blast furnace coke. In the Semet-Solvay oven, this operation is practicable without any change in construction, but by a simple difference in operation.

In conclusion, we may consider it as fairly demonstrable that, whether for coke or gas, the Semet-Solvay oven is constructed upon correct principles; that it is, both in construction and operation, more economical and rapid than any of its competitors, and that it is available as a working device to the coal miners and blast furnace operators of the Pittsburg and Ohio fields as a profitable investment.

Mechanical Rubber Goods and Hose.

It is reported that the New Jersey Car Spring and Rubber Co., of Jersey City, N. J., and the Eureka Fire Hose Co. of New York, two of the largest and oldest manufacturers of hose in the country, and whose business relations have for the past twenty years been very close, recently completed arrangements whereby the two companies will be still closer connected in the manufacture of fire, mill and other kinds of hose.

All the brands of both concerns will hereafter be made and sold by each company. The line will be a most complete and extensive one, embracing as it does hose for every purpose, each brand of acknowledged superiority in its class. This arrangement, we take it, will not alone prove desirable for the New Jersey Car Spring and Rubber Co. and the Eureka Fire Hose Co., but will be a great convenience to the patrons of both concerns.

EASY LESSONS ON MINING.

This Department contains articles to assist ambitious Miners to educate themselves, and obtain Certificates of Competency as Mine Foremen, or to become Mine Superintendents.

The articles are written to be understood by the unlearned and the learned alike. Plain language is used, no obscure terms are employed, and each subject treated, is made as clear and easy to understand as possible.

Further: The Questions asked at the different Examinations for Mine Foremen and Mine Inspectors, are printed and answered.

☞ The Series of Articles "Geology of Coal," "Chemistry of Mining," "Mining Methods" and "Mining Machinery" was commenced in the issue of March, 1894. Back numbers can be obtained at twenty-five cents per single copy, $1.00 for six copies, and $2.00 for twelve copies.

MINING MACHINERY.

The Knock in Pump Valves—The Halt of the Cornish Engine—The Double Beat Valve—The Cornish Valve—The Piston Balance Valve—Recapitulation of Facts.

117. **The Knock in Pump Valves.**—To secure more than the average efficiency in the working of mine pumps, valves of the best construction and mode of action must be used, and as this is so, pump valves have been made the subject for study in this lesson.

To make the investigation progressive, however, we will begin with the primitive example, and this is illustrated by Fig. 151. The word valve means a folding door, and the valves of a pump are said to be self acting, because at the moment of opening or closing, the pressures at opposite sides of the door are different, as for example, when the valve lifts, the pressure under it is greater than the pressure above it; and at the moment of closing, if the piston of the pump is stationary, then the valve falls by its own weight, or on the other hand, if the engine begins its reverse stroke before the delivery valve has had time to fall, then the velocity of fall is accelerated with a weight on it equal to that of the delivery head, and it is in the latter case that the heavy strain on the delivery valve, called knock occurs.

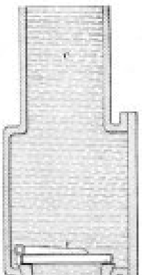

Fig. 151.

There are still some rod pumps and Cornish engines at work in mine drainage, and on that account, and also to explain the knock, we introduce this valve for our first consideration.

With the rod pumps and the old Cornish engine there was no real knock, because the engine halted for three or four seconds at both ends of the stroke. At the top of the stroke, the halt allowed time for the suction valve to fall, and at the bottom of the stroke, the halt allowed time for the delivery valve to fall, so that in this case the only knock that could occur, was due to *only a portion* of the weight of the valve, because the valve was moving in water. The comparatively light construction of the valve seat was such that it could not withstand a knock of relatively small amount and this fact can be at once realized by reference to the figure, where the delivery valve is seen at *V*, and *C* is the vertical column of water resting on it. We see then, that this valve could only be employed in cases where a halt was made at each end of the stroke, and therefore, in pumps worked by a rotary engine that does not make the required halt, if some provision is not made to avert the knock, it is sure to occur, and its severity is proportionate to the piston speed of the pump and to the height of the delivery column; for at the moment of suction, a slight fall of the water column resting on the valve occurs, and should the pump be running at a relatively high speed, and the height of the delivery column be considerable, it does not require much mechanical intuition on the part of the student to discover that ordinary fall valves, like that in the figure, or butterfly valves, that is, those with two doors opening in opposite sides of a middle hinge set over the waterway, or common button valves, that is, round valves working on a guide spindle, will fall onto their seats with such destructive force that they soon become inoperative.

118. **The Halt of the Cornish Engine.** The object, then, of the halt at the ends of the strokes of a Cornish pumping engine is to prevent the knock of the valves, and we can therefore see that for the continuous action of a rotary pumping engine some provision must be made to prevent the occurrence of an excess of pressure on the upper sides of the valves, and we may be sure that like all other modes of action in mechanics the prevention of the knock has been accomplished by various devices in the construction of the valves. There are so many different makes of this class of valves in use that we can only treat with profit on the three fundamental ones that embody the principles of construction and modes of action of all the others.

119. **The Double Beat Valve.** Fig. 152 is an illustration of a double beat valve, sometimes called an equilibrium valve. The valve in the figure is not, however, a true equilibrium valve, because the top valve *V* is larger in diameter than the bottom valve *v*, but it belongs to that class of valves. The difference between *V* and *v* is much greater in the figure than in a real case, but in the diagram the exaggeration is necessary to give clearness to the principle involved. To understand the "equilibrium," or "double beat" valve in the figure, let it be granted that the area of the under side of the top valve *V* is equal to the area of the top side of the bottom valve *v*, and that these two valves fit close on their seats. Now, under the conditions granted, the ingoing water *I* will exert the same pressure under the top valve *V* as it exerts on the bottom valve *v*; consequently, we have here an upward force exactly equal to a downward one, and the result is the double valve will not rise until the upward force is made to exceed the downward one by an amount equal to the weight of the valve. It so happens, however, that the valves never fit their seats with such perfect accuracy as to make the bottom side of the top valve exactly balance the top side of the bottom valve, and therefore the excess of lifting force is easily provided for in the case of water valves.

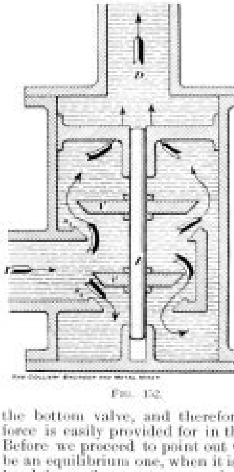

Fig. 152.

Before we proceed to point out where this valve fails to be an equilibrium one, when it is set under a great water head, let us first try to comprehend its principles of construction. By the figure, we can see that one chamber is set within another, and that the inner chamber *I* only communicates with the outer one by the valve ports s_1 and s_2, and therefore, when the valves *V* and *v* are down on their seats, the communication between the inner and outer valve chambers is entirely cut off. In the figure, the valves are up off their seats, and it will be further seen that both valves are fast to one spindle, and therefore they both rise and fall together. The course of the entering water *I* is indicated by the arrows as passing up through the top valve port and down through the bottom valve port into the outer chamber, from which the flow from both valve ports passes into the delivery pipe at *D*. This valve has done good work as a steam valve, and in that case its movements were controlled by the engineer or the cams of the engine, and it can, indeed, be used as a perfect equilibrium valve at the moment of the lift, but at the moment of the fall it is entirely out of balance, as the result of having two seats, and it is therefore subject to a serious amount of knocking force. Let us suppose it is used as a delivery valve; then at the moment the plunger takes the suck a depression occurs at *I*, and then the weight of the column *D* gives a greater downward force on the top than on the bottom valve, because their top areas are unequal, and as this inequality cannot be taken off, the equilibrium valve cannot be taken as a shockless valve for a pump. We next have to consider the claims of the Cornish double beat valve as an equilibrium valve for pumps, and this is illustrated by Fig. 153.

120. **The Cornish Valve.** This valve is the same in principle as the double beat valve we have been noticing, but it is different in construction, and it is to explain this divergence that we introduce it. The valve consists of a case, *C C*, that may be likened to a pot inverted with a hole in the top end; the edges of this hole are the counter seat of the top valve, and rest on the mitre seat of the valve that is fast, and therefore, does not move on the supporting spindle, *S*. The wide end of the case, or pot, has its edge mitred, and therefore the top seat of the valve is shown as s_1 s_1 and the bottom seat at s_2 s_2. This case valve then, is a truly double beat one, and the case is at once the two valves, and the analogue of the inner chamber of the equilibrium valve with a double seat. For steam it is an equilibrium at the moment of opening, but for water it has the same defect as the former one, namely, a heavy knock at the moment of closing. Many modifications of these valves have been tried for pumps, but none of them have given the required result, namely, a valve that is nearly in equilibrium at closing. The valves in common use have a small lift and the knock is prevented by a counteracting spring that can have its cushioning power increased or diminished at the will of the engineer in charge, but the defect in this case arises more from mistaken management, than from any fault in the mode of action.

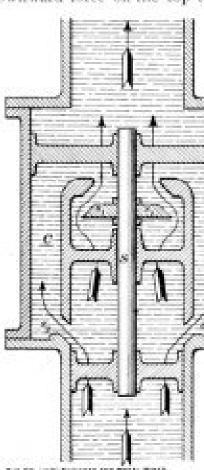

Fig. 153.

121. **The Piston Balance Valve.**—Fig. 154 is a true equilibrium valve, and can be made to balance both at opening and closing as it has only one valve seat and therefore the knock can be reduced to a minimum without the use of a percussion prevention spring. The construction and mode of action is as follows: The valve *V*, is fastened to the same spindle as a piston *P*, and the area of the piston is made sufficiently less than the area of the underside of the valve to provide for lifting pressure. In the figure the seat of the valve is mitred, but in practice the mitre does not answer for a valve of this kind, for a *narrow* flat seat renders it possible to reduce the difference of the areas of the piston and the under side of the valve to a minimum and thereby prevent the possibility of knock. The mode of the balance in this case is very interesting, and it will now be explained. *C* is the delivery column and its weight presses the under side of the piston *c* and the upper side of the valve *d*; *D* is situated between the suction valve and the delivery valve *V*; the equilibrium pipe *E* connects the water space above the piston at *b* with the water space between the suction and delivery valves at *a*. During the suction stroke the pressure under the valve at *a* and above the piston at *b* is considerably less than the pressure of the atmosphere, and the result is the pressure under the piston and above the valve is at that time equal to that due to the head of the delivery column, but the pressure on the valve being a little greater than that under the piston, the valve falls at this period gently into its seat. During the forcing stroke the pressures above the piston, and beneath it, and above the valve, and beneath it, are all equal, and therefore the valve opens gently. The secret, then, of this valve's action is this, the pressure per square inch of the water above the piston, and beneath the valve, are always *equal*, and the pressure per square inch of the water beneath the piston, and above the valve, are always equal, and the result is this valve is always balanced in opening off and closing on one seat. The guide for the valve and piston spindle is left out, to prevent the obscurity it would introduce into the diagram. Such then is a summary of the devices that have been tried and practiced to prevent the knock of pump valves.

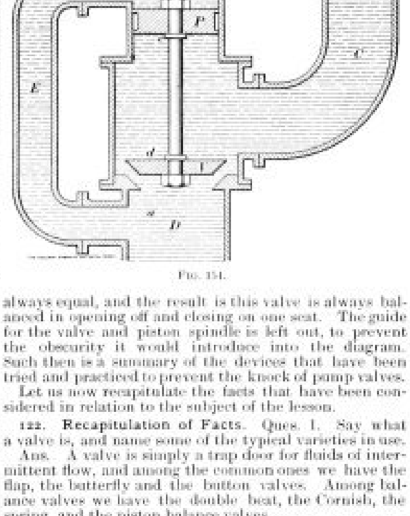

Fig. 154.

Let us now recapitulate the facts that have been considered in relation to the subject of the lesson.

122. **Recapitulation of Facts.** Ques. 1. Say what a valve is, and name some of the typical varieties in use.

Ans. A valve is simply a trap door for fluids of intermittent flow, and among the common ones we have the flap, the butterfly and the button valves. Among balance valves we have the double beat, the Cornish, the spring, and the piston balance valves.

Ques. 2. How was the knock on the valves of the rod pumps, worked by Cornish pumping engines, prevented?

Ans. The pump piston was made to halt at each end of its stroke, to allow time for the valves to fall with their own weight, and the duration of the halt was controlled by the cataract, which is a small cylinder and piston that fills with air like a bellows during the upstroke, and the period of discharge is regulated with an adjustable valve.

Ques. 3. How does it occur that the latest makes of pumps for mine drainage, do not contain the flap, or butterfly valves of the Cornish pumps?

Ans. The latest makes of pumps are continuous in their action, and therefore, the valves are closed before they have time to fall in water, and the result is, a slight fall of the column occurs at the period when the valve closes and this produces a severe blow, called "the knock," and therefore the old class of valves are unfit for this hard usage.

Ques. 4. How does it happen that the equilibrium, or double beat valve, does not prevent the knock when used as a pump valve?

Ans. The equilibrium or double beat valve is only a balance at the moment of opening, but on closing it is so much out of balance that it is subject to a severe knock and this is the result of two valves falling on *two seats.*

Ques. 5. In what respects are the equilibrium and Cornish double beat valve alike?

Ans. The Cornish valve is in all respects a double valve, and consequently has two seats, that make the difference of the areas so great that, on closing, a severe knock is produced.

Ques. 6. What is the special advantage of the piston balance for a valve that has to support a high head of discharge?

Ans. The special advantage of the piston balance is, the valve only falls on one seat, and therefore by making the valve seat narrow and flat, the valve falls with very little knock.

Ques. 7. How does the piston balance the valve?

Ans. The pressure of the delivery column under the piston and above the valve is equal, and by the connection made with the equilibrium pipe the pressure between the suction and delivery valves is always the same as that above the piston and under the valve, and as the valve and piston areas are nearly equal, the piston balances the pressures on and under the valve.

CHEMISTRY OF MINING.

Facts Relating to Safety Lamps—The Glass Shell for a Light—The Claims of a Small Flame—The Diffusion of the Lights of Lamps—The Heating of Lamp Glasses Should be Prevented—General Recapitulation.

105. **Facts Relating to Safety Lamps.**—As this lesson will conclude the series on "lamp glasses," we are anxious to eliminate from our decision all errors of misconception; but even after we have done our best, let it be remembered that there is no finality in investigations of this kind, and therefore, we only claim to have initiated an inquiry that will, we hope, bear good fruit in the construction of lamps that will give a better light than those in general use.

The summation of the facts will proceed in such a way as will best support the conclusion we have arrived

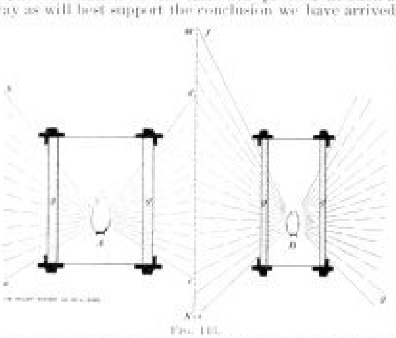

Fig. 143.

at, namely, that a good small light in a glass cylinder of relatively small radius, will give a better light, and secure a safer lamp, than a large dull light within a glass shell of relatively large radius.

106. **The Glass Shell for a Light.**—The importance of a glass shell to incase a light, is not a question for the miner only, but one that affects all classes alike, for with the exception of the candle, all artificial lights are set within the screen of a glass shell. And why? Simply to reduce the painful dazzle or glare of the light near the eye, for the flame consists of a stream of white-hot gases convolving in little cyclones, and as the rays from the light are constantly having their diverging courses deflected, the result is, the dancing rays fatigue the eye and weary the mind. The dazzle is the same in character as the twinkling of the stars; and the chief cause of injury to the eye in looking at the sun arises from the same cause intensified, for the heat rays of the sun cause convolving movements in the air while passing through it. Who can recount the patents that have been secured for the protection of glass shades for gas lights? and yet we have not seen one yet that is satis-

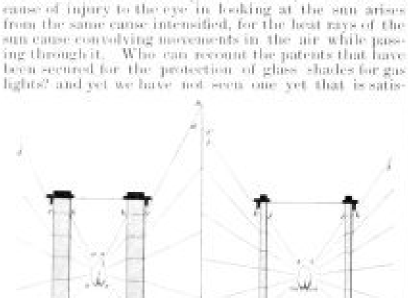

Fig. 144.

factory in use, for all of them waste 60 or more per cent. of the light, and yet people are willing to suffer the loss of light so that they may be spared the pain produced by the dazzle of a naked flame.

107. **The Claims of a Small Flame.**—A small flame does not always mean a low intensity of the light, for in the case of a safety lamp the illuminating power of the light ought rather to be increased than reduced, but if we can get a better light with a small flame of high intensity, than with a large flame of low intensity, then the small flame is the best. Again, if a better and safer lamp can be made for a small flame, than a large one, by all means find how to make the small flame give sufficient light. Perhaps the following furnishes a decisive claim for the small flame; the volume of the light diffused is greater from a glass cylinder of small diameter, than from one of large diameter, as demonstrated by Fig. 143, where the volume of the diffused

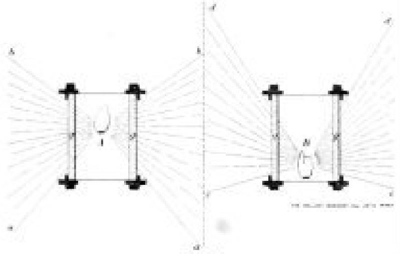

Fig. 145.

light from the narrow glass *B*, has a depth equal to *f c*, and that from the wide glass *A*, has a depth equal to *d c*. It has already been shown that the lighting of the floor and the roof as well as the sides, is an important requirement for the miner's safety, and that to obtain this by the refraction of the light from a thick glass is a mistake, as it seriously hinders the passage of the light, and even a cursory glance at Fig. 144, suggests this fact, but a thick glass does more than that, it increases the size of the lamp frame without furnishing any compensating advantage.

108. **The Diffusion of the Lights of Lamps.** We see, then, that the question before us is not only one of diffusion, but also of economy; and, therefore, diffusion as good as that shown by the depth of the bundle of rays at *A B* should be obtained with a glass whose inside diameter is no less than that of the figure, yet much thinner in the shell. With a flame proportionately reduced, however, a glass still smaller in diameter could be used, and then the depth, or volume of the light would be increased, or the vertical range of diffusion would be increased. It may occur to the reader that the reduction of the light will be attended with some difficulty, but this will form the subject of inquiry in the succeeding lessons.

The length of the glass for a safety lamp is a matter of first importance, because however small we may make the diameter, unless the length is proportionately increased, no advantage can occur, for if we inspect that portion of Fig. 143 marked *B*, we can see that any reduction in the length would reduce the vertical ranges of diffusion, and this being so, it is clear that a proportion of the length to the diameter should be fixed on, and and here we may say that the length of a lamp glass should never be less than twice the diameter, but as we propose that the flame shall be small, and yet give a light of high intensity, and, further, as we will ultimately propose that the length of the gauze cylinder should be shortened, we may say that the best length of the glass shell, to secure good diffusion and an ample motive column for the ingress of air, should be 2½ times the diameter.

109. **The Heating of Lamp Glasses Should be Prevented.** The heating of the glass ought not to occur for three reasons. The first is, a hot glass is very liable to be cracked in the event of a drop of water falling on it from the roof; the second is, hot glass

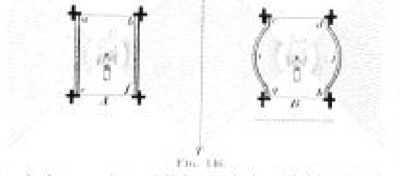

Fig. 146.

is a bad transmitter of light; and the third is, glass is a bad conductor of heat. The three properties of glass just noticed appear at first sight to favor the conclusion that a large glass could be kept cooler than a small one, but in the event of the air entering the lamp being an explosive mixture, then the sheet of flame within the glass would raise its temperature to the point of danger, and thus jeopardize the security that the lamp should provide. When gas and air are burning within a lamp the combustion of the oil at the wick is retarded, or, in other words, the normal flame is reduced, but still it continues to burn for a period that is more or less prolonged, according to the conditions that prevail, but if the entering air is dangerously charged with gas, and the lamp is a good one, the flame at the wick ultimately expires, but the period of the duration of the wick flame is longer in a lamp of large than in one of small capacity, and therefore the lamp with a glass of small diameter is again the best.

Now, the conclusion of the whole matter is this: A lamp glass ought not to be more than 1.75 inches in inside diameter, and our ideal ought to be 1.5 inches, then with a length of 2.5 times the diameter, the length of the glass should not be less than 3.75 inches.

Next let us recount the facts of the investigation by a series of questions and answers.

110. **General Recapitulation.**—Ques. 1. At what height should a flame be set on the wick within the glass of a safety lamp?

Ans. The center of the flame should occur at an elevation of one-third the height of the uncovered portion of the glass cylinder, for otherwise the light would be unevenly distributed on the roof and floor, as illustrated by Fig. 145, where at *A* the light is set too high and at *B* it is set too low.

Ques. 2. What advantages can be secured with a lamp glass of small diameter?

Ans. When the length of a lamp glass is the same for one with a small, as for one with a large diameter, then the one with a small diameter has the greatest range of vertical diffusion, and therefore provides greater safety for the miner.

Ques. 3. What are the advantages and disadvantages of a thick glass shell for a safety lamp?

Ans. There is only one advantage that can be claimed for a thick glass, and that arises from refraction, for this secures a greater range of vertical diffusion. The disadvantages are: First, loss of light by interference; second, a thick glass requires a wider frame; and third, the danger the glass is liable to of cracking in an explosive mixture.

Ques. 4. When the diameters of the ends of a spherical, or bulging glass, are the same as those of a cylindrical one, does the former give any greater range of vertical diffusion than the cylinder?

Ans. By Fig. 146 it is seen that the spherical glass does not increase the vertical range of diffusion, for the

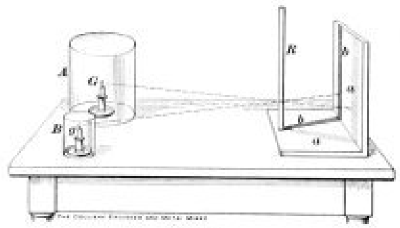

Fig. 147.

range of the cylinder *A* is equal to that of the bulging glass *B*.

Ques. 5. Does the surface area and thickness of a glass shell over a light affect the illuminating power?

Ans. We have already seen that a thick glass offers a greater resistance to the passage of light than a thin one, and, therefore, if we take the thickness in two cases to be equal, as in Fig. 147, the glass with the smallest surface area intercepts the least light, for as the resistances vary directly as the areas of the intercepting mediums, when the thicknesses are equal, then the shell *A* inter-

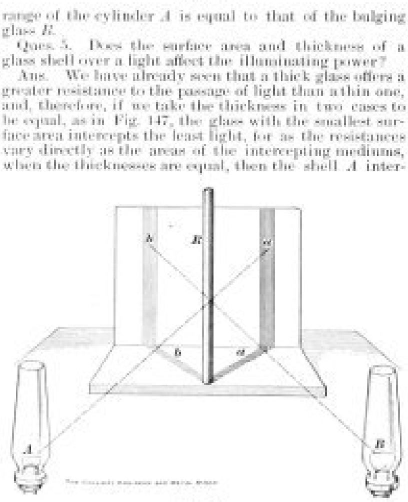

Fig. 148.

cepts more light than the shell *B*, in the proportions of their diameters. Again, it is further shown by the figure, that a strong light makes a deep shadow, while a feeble light makes a faint one.

Ques. 6. Why is a large flame objectionable in a safety lamp?

Ans. When the flame is proportionately large, the glass becomes overheated, and then offers a greater resistance to the passage of light, as in the case of the two kerosene lamps in Fig. 148. For after the large flame in *B* has increased the temperature of the glass chimney, the intensity of the light transmitted is

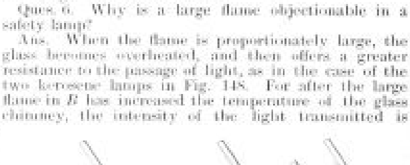

Fig. 149.

reduced, and then the smaller light seen in *A* is found to give the best light as shown by the photometer.

Ques. 7. What is the relationship of the length of the flame of a lamp to the radius of the glass cylinder?

Ans. This relationship is clearly shown by Fig. 149; for if the radius of the glass cylinder does not exceed the length of the flame, then the glass will be blackened and broken in the event of the lamp falling on its side.

Ques. 8. What should be the maximum diameter and the minimum length of the glass in a safety lamp?

Ans. The maximum diameter of the glass cylinder in a safety lamp should not exceed 1.75 inches, and the minimum length should not be less than 2.5 times the length of the diameter.

(To be continued.)

GEOLOGY OF COAL.

The Great Land Masses—The Areas of Land and Water Never Vary—The Axes of the Rock Waves. The Effects of Erosion—Hot Water Discharges. Recapitulation of Facts.

63. **The Great Land Masses.**—We cannot look at a map of the world through geological spectacles without observing that the present continents appear to be only the remains of a once greater land mass, that has been so much eroded that the present ones are only the fragments of the greater whole that once covered large portions of the present sites of the Atlantic, Pacific and Indian oceans.

It is not, however, likely that the area of the dry land surface of the globe was ever greater than it is now, for if we try to believe otherwise we find that to do so we must accept certain conclusions that cannot be sustained by evidence; as for example we would have to believe that the dry land was situated at greater elevations above the sea floor than now, for the volume of water on the earth would not be less, and if it was confined within more restricted lateral limits, the seas would have to be much deeper to contain it.

64. **The Areas of Land and Water Never Vary.**—After looking at the facts just related, we might say again, the contour or outlines of the present land masses is such that we cannot but conclude, notwithstanding the difficulty of the requisite elevation of the land or the increased depth of the sea, that somehow or other the continents belong to a former great whole; for if we associate Greenland with North America, it does seem to be a piece that has been just cracked off, and therefore if we join this piece to North America, Europe, Asia and Africa appear to be a large mass broken off from Greenland and the continents of North and South America, and that the present site of the Atlantic ocean lies in the great fissure.

Looking at the map again we can see traces of the outlines that have not been worn away by the great erosion that has taken place between Greenland and Europe, and some of them are Iceland with many other smaller islands, and some greater ones, as the British Isles.

The contour of the western coast of Norway fits that of the eastern coast of Greenland: The southern shores of the Gulf of Guinea fit the northern shores of the South American continent, and the promontory of the Sahara and the Soudan of Africa fit into the continental recess at the mouth of the Gulf of Mexico. That these contour lines are not the result of an accidental coincidence, but of the operation of laws that produced the rupture, cannot be doubted, for the lines of the former bond are still to be found in the North Atlantic, where between the Bay of Biscay on the European side, and Newfoundland on the North American side, we find unbroken lines of small islands and shallow waters, and dangerous rocks scarcely covered with water. Off the promontory of the Soudan in Africa, we have the Cape Verde Islands on precisely the same latitudes as that vast group of islands in the great recess on the eastern side of the two great continents of North and South America; that is, that vast group of islands near the entrance to the Gulf of Mexico, of which St. Domingo and Cuba are the largest. Now by placing these facts in order, no doubt whatever can exist of the former continuity of the continents of North and South America, the large land mass of Greenland, and the continents of Europe, Asia and Africa.

Coming to the western side of the continents of North and South America, we find the nose of Prince of Wales Cape at the extreme western limit of Alaska, nearly touching the extreme eastern limit of Asia at East Cape in Russia, and still more remarkable is an immense curved line of islands, reaching from the Alaska Peninsula in North America, to the Peninsula of Kamchatka in Russia in Asia. Perhaps the most singular bond has yet to be noticed, and it is this: From Japan on the north to New Zealand on the south side of the equator, an immense belt of *thousands* of islands extends from the eastern sides of Asia and Australia nearly to the western sides of the continents of North and South America, and if a general contour line is made to enclose this vast group of islands and join them to Asia and Australia, then we discover that all the great land masses have at some period in the past been parts of a great land whole that has been divided by some agencies we are now seeking to discover.

We have, however, established a conclusion that cannot be undone, and that is that the volume of water on the earth could not be confined within narrower limits than the present ones, and if this is so, we ask what mean these lines that indicate the former bonds of the land masses, for if we unite the continents by land that displaces the Atlantic, Pacific and Indian oceans, where would the waters of these seas that are the chief reservoirs of the whole earth find a lodgment? To this enquiry no reply can be given, unless we discover that erosion is not the only cause of the peculiar contours of the land masses.

65. **The Axes of the Rock Waves.**—To find the cause of the bond lines, let us look at the map again and observe that the general direction of the axes of the mountain systems of the land masses is north and south, and from this cause the great capes are all pointing southward. The general direction of the axes of the great mountain systems indicates that great rock waves are moving round the globe either from east to west or from west to east, and their advance is slow and majestic, but sure. The cause of these great waves is a common one, and is, no doubt, the result of the cooling and shrinking of the earth, for this shrinkage would cause an acceleration of the earth's rotation, or the higher linear velocity of a wide zone in the earth's shell will tend to give this mass a greater angular velocity than that of the interior kernel, with the result that this belt will buckle and advance eastward, making the direction of the motion of the rock waves from west to east.

The rock matter composing the dry land will then simply have a vertical motion, instead of one of translation, and, therefore, between the crests and the troughs of the rock waves the bond lines will occur just as we find them, and the contours of the continents will therefore arise chiefly from the parallelism of the axes of adjacent rock waves. That this conclusion is correct, is capable of proof, because the giant march of these waves is proven by the work they have done in building up the stratified rocks, for in no other way could these rocks ever have existed. The conditions required for the formation of stratified rocks are: First, elevated land, subject to erosion from various agencies, a condition supplied by the crests of the rock waves. Second, depressions in which the sediment of erosion can collect and be arranged by lamination, as in the troughs of the rock waves. We now see that the very existence of the stratified rocks is due to the constant march of the rock waves, by which the floor of the sea has been repeatedly upraised and depressed; and a further consideration of the subject still more establishes the conclusion, for if we examine a section of coal measure strata, we find that every stratum in the series tells the story of its own special submergence, and the coal seams the series enclose are the indices of the periods of emergence, or the times between which the intervening strata were deposited.

66. **The Effects of Erosion.** The stratified rocks, then, are the result of a a dual cause that may be studied under the heads of erosion and crust motion. The crust

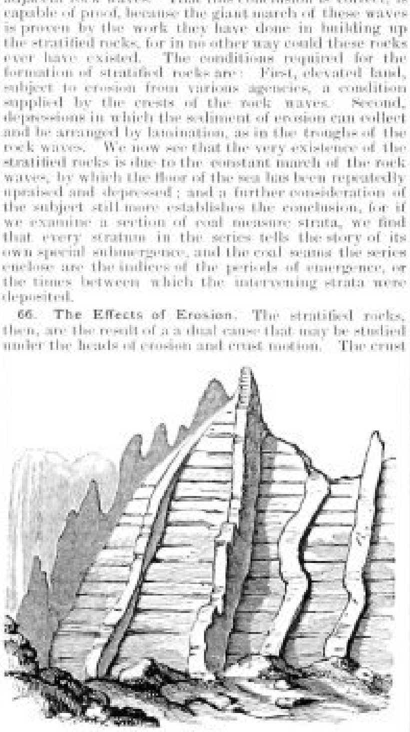

Fig. 100

motion we have just considered, and now, therefore, let us briefly notice some of the effects of erosion. Fig. 100 interests us as a very sharply defined example of the effects of erosion. Here the scoria of a volcanic mountain has been cracked, and then had the fissures filled with molten lava, and after the lapse of long ages the scoria has been eroded, and the contents of the lava dykes that have not been disintegrated by the agencies of waste are made to stand out in bold relief like the plates or walls of solid trap shown in the figure. These protruding dykes, then, manifest in a very marked manner the general fact that everywhere confronts us in geological investigations, and it is this: The different classes of rocks are differently affected by the forces of erosion,

Fig. 101.

and, therefore, by a still greater generalization, we see that all the various coast lines of the great land masses are rugged and indented in the proportion of their power to resist the agencies of waste.

67. **Hot Water Discharges.**—In coal mining we deal with the consideration of rocks that are organically derived, for such are the coal seams, but in metal mining we have to deal with rocks that are chemically derived, as the minerals and ores in the lodes, and to emphasize the cause of the deposition of many of the metallic ores, namely their solubility in hot water, we introduce Fig. 101. Now, the presence of quartz indicates a deposition from *very* hot water, and so much is this the case that when the solvent fluid begins to cool the dissolved silica at once begins to crystalize out in a gelatinous condition, and on further cooling it solidifies, and this is exemplified in the rough cone-like mass of silica that surrounds the mouth of the "Giant Geyser" before us. Let us in conclusion say to our readers, if you wish to master the principles of geology, or that branch of science that treats on the characteristics of the rocks in the earth's crust, do not be content with the deductions that are circumscribed by local considerations, but search for the laws of operation that comprehend the whole of the facts.

68. **The Recapitulation of Facts.**—QUES. 1. What thought strikes you on looking at a map of the world?

ANS. The thought that strikes me is that the land masses of the continents are but fragments of a once greater mass that included them, and covered the present sites of the Atlantic, Pacific and Indian oceans.

QUES. 2. Has the proportionate area of the dry land ever been greater than now?

ANS. The proportionate area of the dry land has never been greater than now, and on the other hand, the proportionate area covered by water has never been less than now, for if the land area was increased, and the water area reduced, the elevation of the increased area of dry land would have to be very much increased to make a proportionate depression for a depth of the sea, far exceeding what could take place without the water pouring into the heated kernel of the earth.

QUES. 3. What is the direction of the axes of the great rock waves?

ANS. Looking at the map of the world we see that the axes of the *great* mountain systems, and the land masses, are all nearly north and south, and therefore the axes of the rock waves are the same.

QUES. 4. What is the probable cause of the north and south direction of the axes of the rock waves?

ANS. The probable cause of the north and south direction of the axes of the rock waves is the shrinking of the earth, and the consequent shortening of its diameter, by which a portion of its linear velocity is converted into angular, and thus the shell of the earth between the latitudes 70° north and 70° south is subject to a relative advancing strain that produces the rock waves. The advance of a rock wave then causes the sea floor to be upraised on one of its sides and depressed on the other, and the cause of the direction of the axes of these waves is to be found in the fact, that the axes of all waves make a right angle with the direction of the force that produces them.

QUES. 5.—What two modes of action have produced the stratified rocks?

ANS.—The two modes of geological action that have produced the stratified rocks are first, erosion, resulting from the action of the agencies of disintegration; and, second, the rock wave action by which the sea floor is alternately raised and depressed.

QUES. 6.—In what way has hot water been an active agent in the deposition of metallic ores?

ANS.—Many compounds of the metals are soluble in hot water, and only partially so in cold water, and, therefore, where the compounds of the metals that are soluble were present in the rocks that were traversed by hot water, these metallic compounds were dissolved out and deposited by crystallization in veins or adjacent fissures.

MINING METHODS.

Dust Raised by the Wind—How the Clouds are Suspended—The Classification of Mine Dust. Recapitulation of Facts.

Erratum. In the recapitulation of our last lesson, page 236, question 6, an error occurs in the index of the root taken, and, therefore, the correct answer should be as follows:

ANS.—Yes, there is such a relationship when the cubes or spheres are of the same material, and that is, the limiting velocities are directly as the *sixth* roots of the weights or contents. For example, the limiting velocity of a cubic inch of coal is 75.24 feet per second, and in this case take a little cube of coal to have a content equal to the $\frac{1}{181,423,106,666}$ of a cubic inch; then the limiting velocity will be $\sqrt[6]{\frac{1}{181,423,106,666}} \times 75.24 = 1$; that is, the limiting velocity of this particle of dust is 1 foot per second.

100. **Dust Raised by the Wind.** Even the dust raised from the roads by the wind becomes a subject of engrossing interest when the laws that control its suspension are understood, and perhaps in the case of the miner this is especially so, for the only difference between the dust lifted by the wind from the roads and that lifted by the air currents of the mine is that of their specific gravities; and this being so, the dust lifted by the wind receives in this lesson first attention. Fig. 138 is an illustration of a dust cloud, and let us first notice that the velocity of the wind near the ground is lower than at higher elevations, and this is the result of the resistance due to the roughness of the ground, or the inequalities of its surface; hence, at *c* the velocity is proportionate to the length of the shortest arrow, and at *b* and *a* the velocity is shown to increase in the proportion of the lengths of the longer arrows. On closely watching a dust cloud, the highest stratum, as that above the line *D*, is seen to consist of the finest *visible* particles,

and that portion of the cloud above C is seen to consist of larger ones, and looking lower at the convolving dust and above the levels B and A, the particles appear much larger than those above, and if we watch the surface swept by the breeze, we will find that pieces of paper, sticks and straws are swept along as with a brush, but never rising to a high elevation unless the speed of the wind is at a dangerous velocity, and then portions of the roofs of houses and other erections may be carried off.

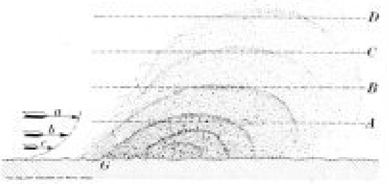

FIG. 138.

The dust cloud in the figure is shaded to sharply define the elevations of about six grades of dust, but the particles are so various in size that they could not be classified by a scale of millions. Again, it would appear as if all the fine particles were above the line D, but that is not correct, because before they reached the higher elevation they rose from a lower one. There are, however, particles under D that cannot rise above it, and there are other particles that cannot rise above C or B or A. The cause of the limited elevations that characterize the particles of different sizes is found in the varying velocity of the wind, for it does not move with a constant and uniform velocity, but blows in gusts, and therefore the grosser particles are lifted by the highest velocity of the gust, and never reach a high elevation before they begin to fall, while the small particles, with a relatively large surface area of suspension, move upward and onward to greater elevations.

101. How the Clouds are Suspended.—The clouds consist of little water spheres that are so small that if a rain drop was set beside them, it would look like a relatively large ball, and yet the particles of water dust that make the different clouds are of different sizes, and as we may expect, the smallest particles are found in the clouds that float the highest; for example, the cirrus or white feathery clouds that soar above the flight of the eagle, are composed of smaller particles than those that go to make the cumulus or mountain clouds that float at a medium elevation. The cumulus clouds are often taken as the precursor of rain, but the nimbus is the true rain cloud, and it is either produced by the opposition of winds that cross each other's path, and in doing so make the particles of the cumulus clouds collide with each other and coalesce as rain drops, or the cumulus clouds strike the sides of mountains, when the particles coalesce and form nimbus clouds. We see then that all kinds of dust consist of small particles of matter whose surfaces of suspension are so relatively large that they are easily lifted by the air. Fig. 139

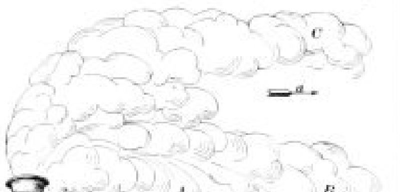

FIG. 139.

fully sustains the conclusions arrived at in relation to dust particles, for here we have illustrated the behavior of the particles in a cloud of water dust, that has been produced by the condensation of steam. The water dust in steam must consist of particles of *very* different sizes, because the water of condensation in the cylinders will be ejected as spray, the condensation of the steam as it passes through the valves and steam ways will generate particles of many sizes, and further, the varying velocities of the steam when exhausting, will affect the sizes of the particles produced. Now, as the result of the exhausted particles being so different in size, when the steam is blown out of the funnel of a steam engine, such as a locomotive, the cloud is seen to bifurcate, and trifurcate, just as the illustration indicates; for the heavy particles form a bottom prong, as at A, while the intermediate ones form the middle prong B, and the lightest particles form the top prong, as at C. We see then that the different sizes of the particles become associated as cloud tails, as at A, B and C. A cloud of smoke from a chimney where bituminous coal is burnt, furnishes the same phenomena, and to look at such a cloud when you know the facts, makes them not soon forgotten.

102. The Classification of Mine Dust. Fig. 140 brings us to the practical application of our subject, and we need not now waste time by doing more than explain the diagram, and then proceed to show the value of the facts here set before us. The little circles containing the arrows, are graphic illustrations of the velocities in different air passages in a mine, as for example, the velocity v, in the top drift, is only able to suspend *very* fine dust, while along the floor of this passage a larger gauge of dust is seen to be deposited, and this dust is easily lifted, because the current is just a little too slow to suspend it, and therefore, the movements of the feet of men and horses, and the shake produced by trains of cars, cause it to rise in clouds; the floor dust in this case is marked d_2.

The current in the middle drift holds in suspension d_1 and d_2, and the dust for which this current is a little too slow is d_3, and this lies on the floor, and in the current velocity that prevails it is easily lifted by the tread of men and horses and the running of the cars.

The current in the bottom passage holds in suspension dusts d_3, d_2 and d_1 and as this current is just a little too slow to suspend d_4, it lies on the floor, and it too is easily raised by the tread of men and the movements of the cars, and so we see that each class of dust is raised by a particular velocity of the air current.

The object of these lessons on coal dust is of a threefold character. First, to discover what *dust* is; second, to determine the nature of the conditions under which it becomes suspendable in air; and third, to find a method of classification by which different sizes of dust particles can be associated with air currents moving at different velocities. The first two points have been determined, and the third one now only requires for its complete development a finishing touch, and after the conclusion of much labor and thought we recommend the following mode of classification, for it is at once simple and correct: We now know that the sizes of the largest particles in suspension in a current are the limit-

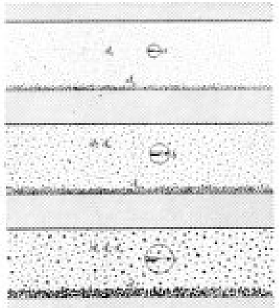

FIG. 140.

ing ones for that velocity, and on the basis of this fact we now propose to establish a classification by the velocity of the current in feet per second in which different sized dusts are suspended, as $10v$, $11v$, $12v$, for dusts carried in suspension at velocities of 10, 11, 12, etc., feet per second. Dust has been classed as flocculent dust from colliery A, or B, or C; but the dust from colliery A might, in a test, be more explosive than that from colliery B; but had the dust from colliery B been dropped at as low a velocity as that from colliery A, then the dust from colliery B might have been more explosive than that from colliery A. It is clear then, that all dust should be classed by its velocity of suspension, or otherwise any tests made with it will give varying results, according to the velocities from which it has been dropped. Again let us notice that the $12v$ contains all the grades that preceded it as, $1v + 2v + 3v +$ etc., + etc. Or to put the matter clearly $12v$ must be considered an addition to all the grades of dust below it. Now we have a guide by which we can direct our judgment to right conclusions.

103. The Deposition of Coal Dust.—Fig. 141 still further develops the idea of a correct classification. A current passes along the drift E with a velocity of $12v$ or 12 feet per second, and suppose it holds in suspension d_1, d_2, d_3, or by the present classification $3v + 6v + 12v$. Now let the current split into two airways whose sections are equal to that of E, and it is clear that if the velocity in each of the splits is

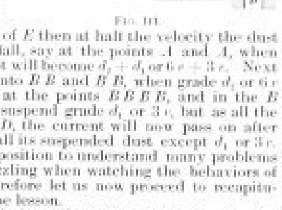

FIG. 141.

taken as half that of E then at half the velocity the dust of $12v$ grade will fall, say at the points A and A, when the suspended dust will become $d_2 + d_1$ or $6v + 3v$. Next let A and A split into B B and B B, when grade d_2 or $6v$ will deposit, say at the points B B B B, and in the B splits the air will suspend grade d_1 or $3v$, but as all the splits reunite on D, the current will now pass on after having dropped all its suspended dust except d_1 or $3v$. We are now in a position to understand many problems that would be puzzling when watching the behaviors of coal dust, and therefore let us now proceed to recapitulate the facts of the lesson.

104. Recapitulation of Facts.—Ques. 1. Is the velocity of a wind blowing along a road as high near the ground as above it?

Ans. The wind on striking the uneven surface of the ground is reflected and deflected, and therefore a stratum of the current near the ground has a lower velocity than at a higher elevation.

Ques. 2. In looking at the dust as it rises above the ground, what do you observe?

Ans. I observe that the cloud is more dense at the bottom and charged with large particles that do not rise more than two or three feet and then drop or are swept along at a low level.

Ques. 3. What do you observe at the top of the dust cloud?

Ans. I observe that the particles are very minute and moving in advance of those near the ground where the velocity is lower.

Ques. 4. In what respect is the mixture of sizes of particles different at different elevations?

Ans. At low elevations large and small particles are mixed, whereas at higher elevations only particles of a small grade are seen.

Ques. 5. How is the water dust of the clouds suspended?

Ans. The particles of water dust in the clouds are supported by their relatively large surface areas of suspension and are subject to the operations of the same laws as all other dust particles.

Ques. 6. Of what are you reminded when you look at the cirrus, the cumulus and the nimbus clouds?

Ans. I am reminded of the fact that as the cirrus clouds are suspended in an atmosphere of about half the density of the air resting on the earth, the particles of water dust that compose these clouds are like the very fine particles of coal dust suspended in nearly still air, and that the particles of a cumulus cloud are like particles of coal dust that can only be suspended by swift air currents, and that the particles in a rain cloud are unsuspendable in the reduced velocity of the wind, like the heavy coal dust that only rises with the shake of a passing train of mine cars.

Ques. 7. Is there any law associated with the peculiar appearances of the convolving clouds of steam escaping from the exhaust pipe of a steam engine?

Ans. Yes, there is a law relating to the stratification of the water dust of the condensed steam, and it is this, the larger particles arrange themselves like a tail projecting from the bottom of the cloud, and thus the cloud is sometimes bifurcated and and at other times trifurcated, according to the prevalence of the grades of the particles.

Ques. 8. How may different grades of dust be classified?

Ans. Different grades of dust may be classified according to the velocities by which they are suspended, as $1v$, $2v$, $3v$, etc.

Ques. 9. What is the object of these lessons on coal dust?

Ans. The object of these lessons on coal dust is to explain three of the characteristics of coal dust, and the first shows what coal dust is, the second shows how the particles of dust are suspended in air, and the third shows how particles of different sizes are suspended by different velocities of the air currents.

Ques. 9. How should samples of coal dust be obtained to test their explosive character?

Ans. Samples of coal dust from different mines should be collected on the floors of airways where the ventilating currents are moving with the same velocities.

(*To be Continued.*)

Mining in the Caucasus.

The immense supplies of foreign capital which have of late years been made available in Southern Russia, have also brought into prominence the mineral possibilities of the Caucasus, which were hitherto generally overlooked. Several new ventures are at present in more or less advanced stages of installation, and more are under contemplation. One syndicate is going in for quicksilver mining, and at its instance the various deposits are being examined and reported upon by an expert. The Crown works at Tachatoch will again be put in operation, and mining researches are to be instituted in various quarters. Touching upon the question of the desirability of an increase in the duty on zinc and lead ore, owners of Caucasian mines urge that they have never applied for this, and that they do not require it. The ore deposits are so easily accessible that no such protection is needed; what they require is an improvement in, and an extension of, the means of transport, which are almost everywhere inadequate, and in many parts almost *nil*. This cannot be done by private initiative, and it is expected that the government will ere long move in the matter. There are several striking examples of excellent ore deposits remaining literally unbroken for want of means of transport. At the Deyechra mountain, for instance, there are vast deposits of zinc and lead ore right on the surface which cannot be utilized, although the distance from the Black Sea (the Gudaupy port) is only 22 miles, but in order to get to the coast, a mountain ridge of 8,000 ft. in height has to be passed. What is required is a tunnel two miles in length, but, so far, no money has been forthcoming for this purpose. Similar instances might be mentioned where the absence of railroads or other means of communication almost completely stops the development of mining in various parts of the Caucasus.

A New Scoop Bucket.

Spencer Miller, engineer of the Lidgerwood Mfg. Co., New York City, has recently had a patent granted him for a novel form of scoop bucket, which has been thoroughly tested and has proved entirely satisfactory in loam and sand. It is employed on a cableway. The bucket is lowered to the toe of the sandbank and the carriage is run ahead so that the draw of the hoist rope is approximately parallel with the slope of the bank and the bucket is drawn up, thereby filling it. If the material be soft, the bucket will fill without guidance, but in harder material the bucket has to be guided by a man following it. The bucket is then conveyed back to the place of dumping and by virtue of lowering the bucket it is overturned and the load spilled. Mr. Miller has also had another patent granted him for a novel form of aerial dumping device.

Coal Washing Machinery.

Mr. Walter M. Stein, of Stein & Boericke, Ltd., 325 Walnut St., Philadelphia, informs us that his firm has recently closed contracts for a very complete coal washery of 300 tons capacity for the Jamison Coal Co. of Greensburg, Pa., and for remodeling a 300 ton lignite briquette plant for the Texas Briquette and Coal Company of San Antonio, Texas.

MISCELLANEOUS.

BENARES THE ANCIENT.

Five and twenty centuries ago, when Rome was not yet on the records of the world, and when Athens was in its infant splendor, Benares, on the noble Ganges, exerted a mighty power and her fame was established among men. Here the great Buddha proclaimed his doctrines first, sending forth missionaries from this center to Ceylon, China, Japan, Burmah, and Thibet, bringing in time nearly half the race of man under the influence of his teachings. But centuries afterward, during a powerful religious and political upheaval, Buddhism succumbed to Brahmanism, leaving behind only the ruins of its tones and temples. And to-day, what Mecca is to the Mohammedan, Jerusalem to the Christian, Benares is to the Hindoo.

The city is located along the crest of a hill, over 100 feet above the sacred Ganges. For three miles on the sloping west bank, palaces, temples and mosques, surmounted by domes, pinnacles, and minarets, rear their irregular tops. Giant flights of stone stairs, interrupted by wide platforms, on which are built shrines of every description, reach to the water, and on the edges of the bank are bathing ghats, which are crowded with pilgrims from every part of India, and from other countries, in every stage of dress and undress, whose supreme desire is to plunge into these holy waters before death overtakes them. These pilgrims are not all from the lower or middle classes, but include every rank of Indian society, from the elaborately dressed rajahs, followed by long retinues of attendants, to the unsightly looking ashes-covered fakir and the miserable deformed beggar, and from the little boys and girls to the aged grandfathers, lifted by bearers to the stream, all bent upon dipping in the mother Ganges for the remission of their sins.

Many of the women and girls carry wreaths of white and yellow flowers into the river, and as they most devoutly turn their faces toward the rising sun and inaudibly whisper their prayers, the garlands are broken into pieces and scattered upon the river. Hundreds of these devotees are seen with brass jars and other vessels, in which they carry away to their distant homes some of the holy water, and employes of the temples from central and southern India are there with their leather water bags, which are to be filled and borne on the backs of pedestrians for scores and scores of miles to their houses of worship.

Along the river bank there are not less than fifty of these ghats, which have for their background magnificent flights of steps leading up to imposing castles and palaces, great white mosques and soaring minarets. The Panchganga ghat, where five rivers are supposed to meet underground, leads to the noble mosque which the iconoclast, Aurangzeb, built on the site of the noted Krishna temple, which he destroyed.

This is the finest mosque in Benares, the foundations of which rise from the bed of the river in huge stone breastworks, which support the four walls and domes of the mosque, and springing lightly in the air are two graceful minarets, lifting the whole structure 300 feet above the swarm of bathers at the water's edge. In sailing up the river you pass the ghat where Vishnu dug his famous well, where Brahma made his celebrated sacrifice of ten horses, the Golden Temple, and many other spots that have made the city known the world over.

In the midst of these places of worship is located the Burning Ghat, where bodies are brought from all over India to be bathed in the Ganges, and then cremated on its banks. Smoke from four pyres was seen as we approached the ghat, and several corpses, wrapped in white cloth and lashed between two stout sticks, were being washed in the sacred stream, while the relatives of the dead were preparing the wood near by for the cremation. Bedecked with flowers, and sometimes wearing jewelry, the bodies are lain between layers of wood, the ashes are cast into the water, and we saw a number of men at work, who make a regular business of searching the shore and filtering the water through baskets in search of jewels or money that perchance might have dropped from the dead.

One of the most curious places visited was the Durga, or Monkey Temple. Durga is thought to delight in all kinds of bloodshed and destruction, and while we watched the worshippers, a man approached the blood-bedabbled altar in front of the shrine and, having placed a number of coins in the hands of the officiating priest, was given the privilege of having a little kid that he held under his arm beheaded, and after the sharp blade had descended he made an offering of the head and carried the body away to his home.

In the yards and trees about the temple are hosts of monkeys, who spring into your pathway, peer around the walls, snatch at your clothes, and make the most comical grimaces at you on the least provocation; but it is a crime to molest them, for they are gods and goddesses, held in the highest veneration. I could hardly suppress an irreligious laugh as I watched one of these goddesses, holding a baby god under her left arm, while she held a nut in her right hand, on which she was nibbling in the most human fashion, and during the whole performance she was making the most unholy faces at me because of my inferiority.

What the monkey is to Vishnu the cow and bull are to Siva. To slaughter these animals is a horrible crime, and in every part of India can be found temples dedicated to their honor, where they are kept with the greatest care.

One of the curiosities of humanity is the "holy man of Benares." His long continued acts of penance have worn his body to skin and bones. He is thought by many to be above all passion and sin; he declines to receive anything from visitors, and his bright eyes, sweet expression, and soft voice seem to indicate that he possesses a serenity in life that is enjoyed by few. His name is written Matparamahausaparinrajakacharyaswamibhaskaranandasaraswati!

To those who enjoy examining curios and artistic manufactures, the bazars of Benares will prove to be especially attractive. The city is famous for its beautifully engraved brasswork; and trays, water vessels, bowls, lotus dishes, candlesticks, lamps, fancy boxes, bells, spoons, and scores of other utensils, engraved most exquisitely, can be purchased for remarkably cheap prices. Rich brocades wrought with figures of animals in gold and variegated colors, the oldest survival of ancient loomwork extant and the finest of its kind in the world, are found in the tiny shops in the bazars; and this beautiful work is done by experts who receive about three or four dollars a week. When a piece is finished it is "worth its weight in gold," but the poor fellow whose genius created the masterpiece lives and dies in poverty, while some merchant in Europe or America gets the "weight in gold."—*Baltimore Sun.*

MAKING FOR THE HYDRANT.

To the bystander who sees a fire engine come dashing up to a hydrant it might easily seem, from his confident manner of approach, as though the driver had known from the start just what hydrant he was to take and had been all the time making for that particular one. As a matter of fact, the driver starts out of the engine house without knowing what hydrant he is to take, and he may not know until he is within a few seconds' drive of it. Still there is never a moment's uncertainty about the engine's movements, and it never slows down; it goes straight for the hydrant without the slightest delay. In answering ten calls from the same station, an engine may take as many different hydrants; but it goes to the right hydrant every time, and the manner of determining what hydrant it shall take is extremely simple.

Every engine hooks up at every alarm. On first alarms it goes out only to fires within its own district. When an alarm is sounded the horses rush to the engine, a catch or two is snapped, and the team stands hooked up ready to start; it is all the work of a very few seconds. But the harness is still held by the hanger from which it is suspended, not to be let go unless the call is one which the engine answers. The driver is up. With the last stroke, if it calls this engine, the captain says "go." Just a slight twitch of the reins frees the harness from the hanger, and it drops into place on the horses' backs. If it is in winter, the door is thrown open; if in summer, the chain is dropped, and away goes the engine, with the horses on the gallop, in the direction of the station whence the alarm has come, but without anybody knowing what hydrant it is to take.

The only man besides the driver who rides on the engine is the captain of the company or the officer in charge; he rides standing on the rear of the engine. All the rest of the company ride on the tender. Two blocks away from the signal box the captain jumps to the ground and runs ahead of the engine to locate the fire. He may find it before he comes to the box, or it may be beyond it. The location of the fire may be revealed by flames or smoke, or, perhaps, by the presence of people standing in front of the building in which the fire is, or by persons in the building itself. It may be that there are no such indications; that there are no visible indications whatever. But almost invariably the policeman or whoever gave the alarm remains standing by the box until the first engine comes up. He knows just where the fire is, and from him, in case he has not discovered it himself, the captain learns its location in an exceedingly brief space of time.

It may be around the corner. A wave of the captain's hand, as he starts on again, is enough for the driver, who has all the time kept coming. Then is the time when the bystanders in the side street might easily imagine that the driver had known from the start just what hydrant he was to take; for he sees the engine come tearing around the corner, the driver calculating the turn with the greatest nicety and straightening up and coming down the street booming, making for that hydrant as though he had never dreamed of taking any other.

The simple fact is that, the fire having been located, he is taking the hydrant nearest to it; it is always sought to take the hydrant nearest the fire. He comes up with a rush, firemen yank off a suction pipe and connect the engine with the hydrant, and the engine is ready for business. The captain is in the building. He sees at a glance whether water is needed; if it is, he orders a line of hose stretched and then begins the work of putting out the fire.—*N. Y. Sun.*

REPTILES OF THE DESERT.

From the standpoint of a zoologist there is probably no class of animals so characteristic of the desert as the reptiles. True, there are numbers of birds and mammals found all over the arid wastes of sand, but these either migrate or spend most of their time underground, as is the case with most of the smaller mammals. The birds choose the sheltered canyons, where, perhaps, a few drops of water will ooze out from between the rocks, or even venture out into the great sun-baked plains, seeking the shelter of the bushes and stunted trees which here and there manage to eke out an existence. The smaller mammals are almost all nocturnal in their habits and only venture out after nightfall when the earth begins to cool a little, and, with the exception of, perhaps, a few coyotes or the little desert fox, one may travel for hundreds of miles through the deserts without seeing a single animal except the reptiles and insects. The burning sands and the copper skies seem to have no terrors for them. At nearly every step one seems to awaken a fresh lizard from his rest under a bush or beside a stone, and away he goes, scurrying along over the sand, perhaps his long tail dragging in the sand, but more frequently elevated high in the air. In fact, this uplifted tail often looks like a little gray twig moving rapidly along the ground, but always retaining its upright position. And these lizards can run, too. In a twinkling they are gone, and then it is only the practised eye that can see them, for when they lie at rest their dull gray color makes it almost impossible to see them.

But these are not all; often from the side of the road, disturbed by the passing traveler, a horned rattlesnake or sidewinder will move sluggishly away, but ever keeping up an incessant rattle. Again, big sluggish lizards are found, nearly always a dull gray above, but beneath or around the head iridescent in the most gorgeous colors. And, too, the big tiger rattler of the desert canyons, though a trifle more sluggish than the sidewinder, seems ever ready to call attention to his bright colors by sounding the terrible rattle which strikes fear to the heart of any animal, no matter how large or how small. The tiger rattler is found in the desert regions of America, and is comparatively rare, being found only in the canyons of the barren ranges which traverse the desert in all directions. Though very dangerous, and sometimes growing to four feet in length, it cannot compare in viciousness with the little sidewinder or horned rattlesnake. The sidewinder prefers the open desert in which to live, and may often be found lying quietly beside some desert bush, waiting for its prey. It gets the name sidewinder from the fact that, in moving along the ground, instead of pursuing a straight course, it has besides the forward movement a sidewise, crab-like motion. It is much less sluggish than the other rattlers, perhaps on account of its small size size, as it seldom exceeds a foot and a half in length. It is lighter colored than the other rattlers, and directly over the eyes are protuberances, which give it the name horned rattler. It seems to be the most dreaded of all snakes by the desert traveler, probably on account of its being so hard to see owing to its small size and quick movements. In fact, it is about the only reptile which the desert prospector really dreads.

One of the most plentiful of the lizards which live on the desert is the blue-spotted lizard. It is about eight inches long and of a light ashen color on the back, but down each side runs a row of black spots, extending out on the tail. It receives its name from the two sulphur-blue patches, one on each side of the abdomen, and the little blue spot on the chin. One variety is blue nearly all over, giving out beautiful iridescent metallic colors. Probably the most characteristic of the lizards of the lower desert regions of California is the long-tailed or gridiron-tailed lizard. This species is found nearly everywhere in the lower parts of the desert and never fails to attract the attention of the traveller by its exceedingly rapid movements and its very strange habit of carrying its tail curved up over its back. In fact, the tail is the largest part of the animal, being longer than the head and body together. The movements of this little gray lizard are so quick as to make it hard for the eye to follow, and when it shoots off along the sand, with its tail high in the air, it looks almost as if a stick, standing on end, were scurrying away.

There is, living in the mountainous parts of the Mojave desert, a very strange lizard, which often reaches a length of over a foot, and which is nearly as wide as one's hand and of a uniform dark slate color, or even black, while the tail is spotted with white, and often nearly uniformly white. At a distance this species looks like a Gila monster, and many people, unacquainted with the latter, have supposed them to be the same, and I think it is due to this mistake that many people believe the Gila monster an inhabitant of California.

There is a very pretty and withal a very strange lizard found in several localities in the Mojave desert, which has been named by scientists "dipsosaurus dorsalis," on account of its near resemblance to the ancient saurians, which inhabited the earth many hundreds of years ago. Until the last few years it was not known that this strange lizard lived further north than Lower California, but recent explorations have proved that it inhabits the desert region as far north as the Panamint Mountains, in Inyo county. It has a thick, finely scaled neck and heavy legs, which support a rather clumsy body, and a long, tapering tail. The body is beautifully mottled, while the entire length of the tail is covered with transverse bars. The under surface of the body is whitish, while blotches and lines of red on the shoulders and sides, with the white spots on the sides, make it a very pretty lizard. The tail is longer than the head and body together, the total length over all measuring nearly fifteen inches in an adult male.

There are at least three species of horned toads living in California, one on each side of the Sierra, but the one that is found on the west and which is so well known to every boy in California, has been found so near the eastern borders of the Sierra foothills as to be almost included as one of the reptiles inhabiting the desert. The third species never gets into the Sierra. In general appearance the desert species is very similar to the one found in the inland valleys, but is of a lighter color, and the arrangement of the scales is somewhat different. The color may vary, however, from a dull white to a vivid brick red.—*From the San Francisco Chronicle.*

A WORD WITH THE DOCTOR.

The moisture of the eye is a genuine solvent. Many persons have gone to bed troubled with a foreign substance in the eye, and have waked up in the morning to find it gone. In many cases of this kind the foreign matter has been dissolved by the moisture of the eye.

⁂

All decay of the teeth begins from without.

Consequently, if the teeth's surfaces be kept scrupulously clean they cannot decay.

When ought cleaning begin?

As soon as there are teeth.

Let the child early acquire the habit of using a small toothbrush dipped into chalk flavored with some aromatic drug and let it understand that the places most needing the brush are those between the teeth.

This is the place where decay almost invariably appears.

Mucous secretions and secretions of food are always found between the teeth after a meal. They may be removed with a toothpick.

⁂

It is almost an art to use a toothpick. One must beware of injuring the fleshy parts and leaving splinters, which in some cases may cause the loss of a tooth. Metal toothpicks should be altogether avoided. Those of dull and hard wood are best.

⁂

There is no better aid to digestion, in certain cases, than the cooked apple. It is a recognition of this truth—though doubtless the recognition came before the truth was fully appreciated—which assigns apple sauce as an accompaniment of roast pork, goose, and other rich meats, which are apt to make trouble with the digestive powers. The derangements arising from eating too freely of meats, of almost any kind, are corrected by the use of an apple regimen, the fruit being used either cooked or raw. Paradoxical as it may sound, the free use of fruit acids, of which the apple is the very best repository, tends to decrease that very common disorder, acidity of the stomach, the chemical action of the related elements changing the acids into alkaline carbonates, which tend to neutralize any acid condition of the system.

⁂

Soap used on the hair is apt to make it brittle. If any is to be used, tar soap is the best, and after using, rinse the hair in several waters in which a little powdered borax has been dissolved.

⁂

Sometimes adults, but more frequently infants, are troubled by hiccough to a distressing degree. Take a teaspoonful of granulated sugar, and moisten with cider vinegar, and, for an infant, give small portions at a time, and the trouble will very soon disappear.

⁂

There is but one way of getting rid of blackheads, and that is by forcing them out of the clogged pore. But in pressing them out before the skin is properly softened and prepared for their ejection the patient ruptures the delicate tissue, causing either an ugly little scar or, more likely, an enlargement of the opening, which immediately fills up again, each time increasing in size and more malignant in appearance. Blackheads may not only be removed without leaving any scar, but once rid of, the patient need never again be troubled with them if he will carefully follow directions. For two or three weeks, until the skin is thoroughly softened, apply a cream or ointment at night after scrubbing the face with soap and water. Be sure to rinse the soap well out of the face. Dry thoroughly before applying the cream or ointment. Where the blackheads appear in the back and also between the breasts, the same treatment is required. Friction, combined with an emollient, is death to blackheads.

⁂

Perspiration of the feet sometimes amounts to almost a disease; and, when this is so, they should be bathed, night and morning, in soda and water, or water with the addition of one of the many disinfectants, and afterwards powdered with equal parts of powdered alum, tannin and boracic acid. The stockings should also be changed daily.—*From The American.*

THE MESQUITE TREE.

It is a common saying in the arid regions of the southwest that the natives climb for water and dig for wood. This being interpreted means that the water for drinking purposes is kept in an earthen jar, or olla, upon the top of the house, where, by means of the more rapid evaporation, caused by this direct exposure to the sun's rays, the contents of the jar are kept continually cool. And the digging for wood is explained by the fact that the only timber through much of that region is the mesquite, a low-growing shrub rather than tree, the roots of which are very hard and make an excellent fuel. For a whole winter I have been warmed by them, broken into little pieces, for they are too brittle to chop, and have found that they give out an amount of heat that is in undue proportion to their bulk.

The mesquite groves are a striking feature of the wide, level expanses of these regions. From a distance they look like peach orchards, only their vast extent precludes the idea that they are such. As timber a man accustomed to living among real forests would hardly give them a thought, but they are very much better than no timber at all. When in New Mexico recently I found that the tree had another use besides that of supplying fuel. It produces a bean which is an important article of food among the Indians, and in times of scarcity with the Mexicans as well. The bean is produced in pods which are seven to nine inches long, and of a buff color. They begin to ripen in midsummer, and as they have the quality of preventing thirst as well as of satisfying hunger, they are often of the greatest value to travelers through the desert country. The Indians, who know their value, do not hesitate to go a long distance away from water if they can be assured of a supply of mesquite beans along their route.

When used for food the beans are prepared in various ways. When fresh and newly ripe they are put into a mortar of stone or wood, and bruised, then emptied into an earthen dish, mixed with water and allowed to stand for a few hours. The result is a kind of cold porridge or mush, which has a very agreeable blending of sweetness and acidity, and upon which many of the people would willingly exist the year through. As the fruit or bean pods ripen they are gathered for winter use, thoroughly dried and stored in cylindrical-shaped baskets, made of twigs, and covered with grass or earth to keep the rain out. In this way they may be preserved for a long time. When needed for food the pods are reduced to a fine powder, by means of a mortar, and this flour cooked as fancy may dictate. The flour thus prepared is also often kept for a long time, sometimes in its pulverized state, and again by being mixed with a little water, and then pressed into large cakes of several pounds weight, which are dried in the sun and put away until needed. Among certain of the less civilized of the southern tribes of Indians, such as the Cucupahs, who live along the Colorado river in Lower California, the mesquite beans form an important part of the winter food supply. The only labor needed to secure them being that of gathering the crop, they appeal especially to these indolent people, who are constitutionally opposed to the labor of cultivating a crop. The mesquite has also other uses besides those of supplying fuel and food, as Indian women make rope and twine of the bark and weave it into baskets.

Horses and cattle feed upon the beans, which are very nutritious, and often find sustenance, and, indeed, the very means of keeping alive in them, when grasses of all kinds are burned up by the drought.—*New York Independent.*

NATURE'S PLAN OF DISTRIBUTING PLANTS WITHOUT THE AID OF MAN.

The terrible eruption of Krakatoa, in the Sunda Strait, in 1883, furnished the opportunity for illustrating the ease with which nature can replant with vegetable life a district that has become completely desolated. The volcanic eruption was one of the most destructive recorded in history, the loss of human life being estimated to exceed 100,000. Of the thirty-five volcanoes on and near the Island of Java, twenty-six were in violent eruption at the same time. The center of disturbance was the island volcano of Krakatoa, which emitted molten lava and burning ashes in such abundance that everything living, whether animal or vegetable, on the island was destroyed, and an observer from a ship which approached close to the land declared that the whole island was red hot. Four years from the date of the eruption the island was visited by an eminent naturalist, who found that the ashes and lava had cooled to such an extent as to permit the beginnings of vegetable life, and on making a closer examination he discovered that during the brief space of four years nature had stocked the island with 246 different kinds of plants.

There are many seeds which seem, by their formation, to be specially designed for transmission through the air, and of these several are quite as good illustrations as the thistle. The seed of the common dandelion, a plant to be seen on every common, has wings which will carry it away on the slightest breath of air. The wings are very slight filaments, radiating backward from the seed, so that, when the latter finally lodges, it falls tip first, in the most favorable position for taking root. Country children in the United States often find amusement in blowing the seeds from the stalk and watching to see how far they will go before falling to the ground, but whenever there is even a moderate breeze the experiment is uniformly a failure, as the fleecy seeds fly out of sight and are gone in an instant, and the next season a dandelion springs up in somebody's lawn, where the plant was never seen before. The common tumble weed is another example of the winged seed. The plant grows in a woolly bunch, which, when dried, is easily separated from the stalk, and a light breeze sets the ball rolling over the ground, to scatter its seed wherever it goes.

The seeds of many ferns and microscopic plants are so constructed as to be readily lifted and carried away by the wind, while some of considerable size are provided with an elaborate arrangement for aerial transportation. The common maple is an example of the last kind, for projecting from its large head is a membrane closely resembling in size, shape and general appearance the wing of the locust. When the seed is separated from the tree, even if the air be quite still, it does not fall directly to the earth, but, by its peculiar construction acquires in falling a spiral motion that takes it several feet from beneath the starting point, and when a brisk breeze is blowing one of these winged seeds has been known to twirl through the air for six miles before its journey came to an end and it sank to the ground, there to germinate and start a maple grove.—*From the St. Louis Globe-Democrat.*

RESIDENCES IN PALESTINE DURING ITS GREATEST PROSPERITY.

The town houses of Palestine varied in extent and splendor with the circumstances of their inhabitants, from the humble cottage to the larger dwellings of the patricians. The walls were built of bricks, of half-bricks, of dressed and undressed stones, and even of white marble, or large hewn stones. These stones were cemented together with mortar, gypsum, and even asphalt. Sometimes they were, besides, riveted together with iron or lead, but in such a manner as to be imperceptible. The walls were covered with a kind of whitewash, and palaces were painted in delicate colors. The woodwork was constructed generally of sycamore (the most common tree in Palestine), sometimes of olive and almond trees, now and then even of cedar, and adorned or inlaid with ivory or gold. Richer dwellings were distinguished by rows of pillars and other architectural ornaments. The houses of the better classes consisted generally of two or more stories, to which a stair, often costly, conducted from the outside. From the various uses made of the court, which also served as a kind of antechamber to visitors, it is clear that it was a most important part of the building. It varied in size with the circumstances of the tenant, being sometimes divided into an outer and inner court; at other times it was shared by several tenants. The inner court, whence the porter opened to callers on their names being mentioned, often led into a large and splendid reception room, from which other apartments led to the interior of the house. The upper rooms were not used for common purposes; inner rooms were inhabited chiefly in winter. The apartments were often richly decorated, sometimes painted, or covered with pictures. The reception room and inner court properly formed together but one apartment. It appears that the inner court was paved, was surrounded by galleries, and sometimes had fountains and baths. The roofs, although ostensibly flat, were, in fact, somewhat sloping, to allow the rain water to flow into the channels and cisterns, paved with stones or with earth beaten hard, and surrounded by a protecting balustrade. When great privacy was sought, as in prayer, the roof was used, especially when upper rooms were wanting, and, in the cool of the evening, the roof was the place of chief resort. It was also employed for domestic purposes, such as drying fruits, etc. The floors of the room were of gypsum, and even of marble; the doors were sometimes of stone, but more frequently of wood, and moved on hinges let into sockets above and below. They were barred by wooden bolts, which could be withdrawn by check keys from the outside. The dining apartment was very spacious and was often employed for assemblies. Instead of glass panes the windows had gratings or lattices. They mostly looked into the streets and were distinguished as Tyrian windows, probably large, or Egyptian, which are supposed to have been small, sometimes only two feet square. In the houses of the wealthy the window frames were carved, as in general was their furniture; the tables, couches, chairs, lamps, candlesticks, etc., were exceedingly costly. Among other articles of luxury may be mentioned soft cushions, destined to be placed under the head or arms.—*From a review of "History of the Jewish Nation After the Destruction of Jerusalem Under Titus," in N. Y. Sun.*

THE CAST OF A BELL.

The operation of casting a bell is a most interesting one. The flask whereon and wherein the mold is made consists of two parts constructed of boiler iron of a general bell form and plentifully perforated with holes for escaping gas while casting, one being so much less in size than its fellow as to give space for the loam forming around the mold between the two. No "pattern," as the term is generally used, is provided. The two parts of the mold are "swept" by "formers," accurately finished from thin iron to the form intended for the inner and outer surfaces of the bell. These "formers" are mounted and rotated over the applied loam. Five courses of loam and clay are successively applied, "swept" and baked, to complete each mold. Before this work is done, however, the inner flask is wound near the top with a rope made of hay. As the shrinkage is very great as the castings cool, difficulty would be met with in getting the flask and loam out of the nearly parallel inside top. This "pinch" is obviated by using this destructible base, which permits the collapse of the loam after the heat of the metal has consumed the hay.

The five courses laid on the flasks are: Loam, a mixture of loam, fire clay and manure; two successive coatings of powdered fire clay, and, lastly, a thin coating of brick and fire clay combined with foundry facing. Each of these coatings is baked in an oven before the succeeding one is applied. The coatings are "swept" by the formers, as applied, both in the inner and outer flasks, by careful adjustments as to thickness of materials, so that when the exterior mold is placed over the interior a space corresponding to the intended thickness and shape of the bell shall exist. Inscriptions or embellishments to be made upon the bell are provided for with the last coating by means of a "knurl," or wheel, having the desired motto raised upon its periphery, the wheel being carefully rolled around the soft surface and leaving its imprint in the clay. Other designs are impressed from dies of the required ornament, and the usual "beading" is accomplished by notches in the edge of the sweeps.

The two parts of the flask being placed together are firmly held in position by many clamps, the tendency of hot bell metal to squeeze through and force a separation of flasks being very great. As the mold nears completion a fire is started in a near by reverberatory furnace, in which is placed the desired charge of copper, and when the copper is melted the tin is added in its proportion. The melted metal being ready, the furnace is tapped, the bright stream caught in a huge ladle swung over the mold by a crane and poured into the open mouth of the mold until it is filled. After cooling and removal from the mold the bell is usually polished with sand and water in special revolving grinding machines. The tongue and clapper, the yoke and wheel are now attached and the whole suspended in its frame. In making a chime the bells are, after completion, temporarily set up and regularly tested by skilled bell ringers, from the permanent chiming stand of the foundry.—*Exchange.*

THE STRENGTH OF ICE.

The army rules are that two-inch ice will sustain a man or properly spaced infantry; four-inch ice will carry a man on horseback or cavalry or light guns; six-inch ice, heavy field guns, such as 80-pounders; eight-inch ice, a battery of artillery with carriages and horses, but not over 1,000 pounds per square foot on sledges; and ten-inch ice sustains an army, or an innumerable multitude. On fifteen inch ice railroad tracks are often laid and operated for months, and ice two feet thick withstood the impact of a loaded passenger car after a sixty-foot fall (or perhaps 1,500 foot-tons), but broke under that of the locomotive and tender (or perhaps 3,000 foot-tons.)

Trautwine gives the crushing strength of firm ice as 167-250 pounds per square inch. Col. Ludlow, in his experiments in 1881, on 6⅓-inch cubes, found 292-889 pounds for pure hard ice, and 222-820 pounds for inferior grades, and on the Delaware river 700 pounds for clear ice and 400 pounds or less for ice near the mouth, where it is more or less disintegrated by the action of salt water, &c. Experiments of Gasowski gave 208 pounds; those of others, 310-320 pounds. The tensile strength was found by German experiments to be 142-223 pounds per square inch. The shearing strength has been given as 75-109 pounds per square inch. The average specific gravity of ice is 0.92. In freezing ice increases in volume from 1.9 to 1.18, or an average of 1.11; when floating, 11-12 is immersed.—*From the Engineering Mechanic.*

SALUTING THE FLAG.

The respect of the navy for the flag—"Old Glory"—is partly expressed by a simple little ceremony which attends the hauling down of the ensign at sunset. One writer thus describes the saluting of the flag as it is taken in the moment the sun goes down.

The first time I ever saw it I was sitting on the quarter-deck of the United States steamer Yantic, conversing with three of her officers. We had been dining together, and were enjoying the cool evening breeze under the awning.

A few minutes before sundown a bugle-call sounded from the flag ship, and the call was immediately repeated by the buglers of the other ships of the squadron.

"What is that?" I asked.

"That's 'Stand by the colors,'" said one of the officers.

Two sailors came aft, cast off the ensign halyards, and stood by with their eyes on the flag ship. In a few moments we heard the bugles sounding again, for you must know that on board ship many of the commands are conveyed by a few musical notes upon the bugle. A marine came aft, and saluting, said:

"Haul down, sir."

"All right," said the officer of the deck, "sound off."

At that order the bugler of the Yantic blew the lovely call, "Evening colors."

The moment he sounded the first note the officers rose from their chairs, faced the colors, took off their caps, and stood silent, in respectful attitudes, while the two seamen slowly hauled down the colors, bringing them in over the rail as the call came to an end. When the colors reached the deck and were gathered in by the seamen, and the last note of the bugle died away, the officers put on their caps, resumed their seats, and went on with their conversation.

Removing the cap in honor of the colors is the common form of salute in the navy. When an officer comes up from below he always lifts his cap in the direction of the quarter-deck, and all the boys should remember, when visiting a man-of-war, that the proper thing to do when you go on board is to turn toward the stern of the ship where the ensign always flies at the taffrail staff, and raise the hat.

If the officer of the deck sees you he will return the salute, but whether any one is on the quarter-deck or not, always raise your hat when you go aboard. The salute is to the flag, not to any person, and surely every American ought to be proud to lift his hat to the flag of his country.—*From St. Nicholas.*

LATE SUPPERS.

The old tradition that to eat anything just before going to bed is sure to produce indigestion and render sleep impossible is now happily exploded. It is not good, as a matter of fact, to go to bed with the stomach so loaded that the undigested food will render one restless, but something of a light, palatable nature in the stomach is one of the best aids to quietude and rest. Some physicians have declared, indeed, that a good deal of the prevalent insomnia is the result of an unconscious craving of the stomach for food in persons who have been unduly frightened by the opinion that they must not eat before going to bed, or who have, like many nervous women, been keeping themselves in a state of semi-starvation. Nothing is more agreeable on retiring for the night than to take a bowl of hot broth, like oatmeal gruel or clam soup. It is a positive aid to nervous people, and induces peaceful slumbers. This is especially the case on cold winter nights, when the stomach craves warmth as much as any other part of the body. Even a glass of hot milk is grateful to the palate on such occasions, but a light, well-cooked gruel is better, and in our climate, during the cold months of winter, should be the retiring food of every woman who feels the need of food at night.—*From the Canada Lancet.*

TINY OXEN.

One of the greatest curiosities among the domestic animals of Ceylon is a breed of cattle known to the zoologists as the "sacred running oxen." They are the dwarfs of the whole ox family, the largest specimen of the species never exceeding thirty inches in height. One sent to the Marquis of Canterbury in the year 1891, which is still living, and is believed to be somewhere near ten years of age, is only twenty-two inches high, and weighs but 109½ pounds. In Ceylon they are used for quick trips across country with express matter and other light loads, and it is said that four of them can pull a driver of a two-wheeled cart and a 200-pound load of miscellaneous matter sixty to seventy miles a day. They keep up a constant swinging trot or run, and have been known to travel 100 miles in a day and night without either food or water. No one knows anything concerning the origin of this peculiar breed of miniature cattle. They have been known on the island of Ceylon and other Buddhistic countries for more than a thousand years.—*Tit-Bits.*

MAKING HOLES IN GLASS.

Strong glass plates are bored through by means of rotary brass tubes of the necessary diameter, which are filled with water during boring. To the water there is added finely-powdered emery. Thinner glass may be perforated with holes in an easier manner, by pressing a disk of wet clay upon the glass, and making a hole through the clay of the size required, so that the glass is laid bare. Molten lead is then poured into the hole, and lead and glass drop down at once. This method is based upon the quick, local heating of the glass, whereby a circular crack is produced, the outline of which corresponds to the hole made in the clay. When molten lead is poured upon clay so that steam is generated from the moisture, the lead is very apt to fly. Putty, although, of course, more expensive, is much to be preferred to clay for use in connection with molten lead.—*American Machinist.*

WHY AND HOW THREAD IS NUMBERED.

The question, "Why is spool cotton numbered as it is, and why are the figures not used in regular order?" is often asked. The explanation is this: The numbers on the spools express the number of "hanks" which are required to wind a pound. The very finest spinning rarely exceeds 300 hanks to the pound, while in the very coarsest there is about a half pound in each hank. The more common qualities, however, those from which sewing thread is usually made, run from ten to fifty hanks to the pound, and the spools on which it is wound are numbered from 10 to 50 in accordance.—*Boston Journal of Commerce.*

HORSE-POWER OF A LIGHTNING STROKE.

At Klausthal, in Germany, a lightning stroke struck the wooden post of a house and fused two nails four millimeters thick. Messrs. Siemens & Halske, of Berlin, afterward carried on a series of experiments to ascertain the force required to melt this quantity of iron. Assuming one second as the time standard, it required a current of 200 amperes and 20,000 volts, representing 7,000 horse-power. Assuming that the lightning occupied one-tenth of a second to fuse the two nails, the horse-power required would be 70,000.—*From Machinery.*

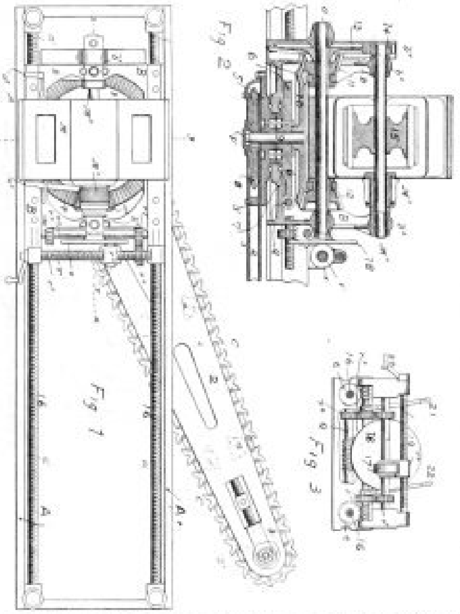
"This Indenture."

The phrase "this indenture" which is still frequently used in written contracts is probably unintelligible to most persons, since no one now "indents." Indenting a deed or contract consisted in cutting a zigzag line across the top of the document from one side to the other. All English deeds were formerly written in duplicate upon the same skin or parchment and separated by cutting them apart with a knife in the zigzag manner referred to. One of these instruments was given to each party named, and the fact that the two documents would exactly join each other was evidence of their genuineness.—*From the Albany Times-Union.*

NEW INVENTIONS.

MINING MACHINE.

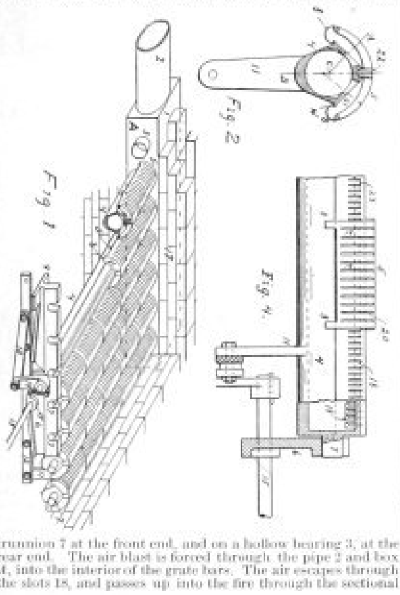
No. 555,832. ISLE A. STOREY, BOULDER, COLO. *Patented March 3rd, 1896.* Fig. 1 is a top view of the complete machine; Fig. 2 is a vertical section along the axis of the main shaft X X, and Fig. 3 is a front view of the feed gearing. The cutter chain is carried on an arm or boom 2, which is provided with suitable sprocket and guide sheaves 3 and 4. The boom is attached to center plates 5 and 6, which turn in a suitable bearing in the machine frame 7. The chain is driven by means of the sprocket 8, shaft 9, wheel 10 and pinions 11 and 12, shaft O, gear 13 and pinion 14, which is on the shaft of the armature 15. The pinions 11 and 12 are provided with levers by which they may be engaged so as to drive the wheel in either direction. The boom can be revolved around the shaft 9 by means of a worm Q, which engages teeth in the



edge of the wheel 6. The frame B, which carries all of the working parts, is moved along on the main frame A, by means of two worm wheels t, which turn upon the fixed screws 16, and act as nuts. Both of the wheels t and worm Q are rotated through suitable gears by the friction wheel 17, and the disc 18, which is attached to the end of the main shaft O. The rate of feed may be changed by shifting the friction wheel 17 across the face of the disc, by means of the screw 19 and handle 20. Thus the machine may be fed in either direction, or the boom may be swung around, together or separately as desired, by manipulating the feed levers, 21, 22. The cutter chain is provided with double faced cutters, which are designed to cut in either direction.

TUBULAR ROCKING GRATES.

No. 554,586. JAMES L. WHITE, WEST SUPERIOR, WIS. *Patented Feb. 11th, 1896.* Fig. 1 is a perspective view showing the general arrangement of the grate bars; Fig. 2 is a cross section of a grate bar; and Fig. 4 is a sectional side view of the same. Each grate bar is tubular, and is made to turn on a



trunnion 7 at the front end, and on a hollow bearing 3, at the rear end. The air blast is forced through the pipe 2 and box A, into the interior of the grate bars. The air escapes through the slots 18, and passes up into the fire through the sectional grates 5. These grates are made in small sections so as to be easily renewable, and they are provided with a rib 22, and hooks 8, which enable them to hold fast in position when the main bars are rocked. Each main bar is provided with an arm 11, by which it is connected to the raker shaft 15. The destructive action of the fire is limited to the grate sections 5, the main bars last a long time, not being exposed to the fire. The sections are easily removed through the furnace door, without taking down any part of the apparatus. The bars may be turned over far enough to remove ashes and clinker, or to dump the fire.

PUMP AND ENGINE VALVES.

No. 556,549. ARTHUR MARECHAL, BRUSSELS, BELGIUM. *Patented March 17th, 1896.* Fig. 1 is a cross section of a pump cylinder provided with these valves; and Fig. 2 is a lengthways section of the same. The valves E and D are made in pairs, and when in use, one forms a seat for the other. Both valves move, but in opposite directions; the necessary throw is thus one-half of that ordinarily required, and the opening or closing movement may be performed with great rapidity. These valves are especially valuable for blowing engines and

FIG. 1.

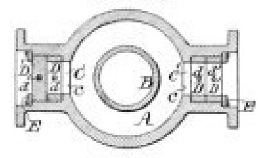


FIG. 2.

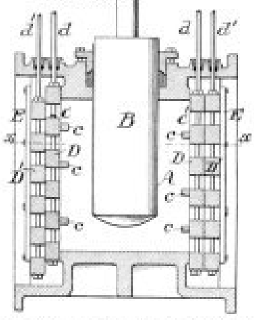
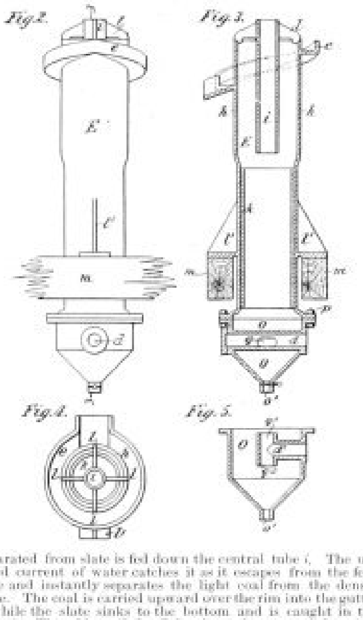


air compressors, and for use in triple expansion steam engines, etc. The drawing shows them, as used for inlet and discharge valves in a plunger pump. The bearing of the valves D upon the cylinder is only around the edges, and there are no ports or valve faces to be made on the water barrel or cylinder casting. Thus the construction of the castings is greatly simplified.

COAL WASHER.

No. 555,920. RUDOLPH BOERICKE, PHILADELPHIA, PA. *Patented March 10th, 1896.* Fig. 2 is a side view of the device; Fig. 3 is a vertical section, at right angles to Fig. 2; Fig. 4 is a top view, and Fig. 5 is a modified form of base or dirt catcher. A stream of water is introduced through the pipe d, and passes through the holes g into the base O, and upwards through the liner k and body E, to the top of the shell, where it overflows into the gutter e. The coal to be washed and

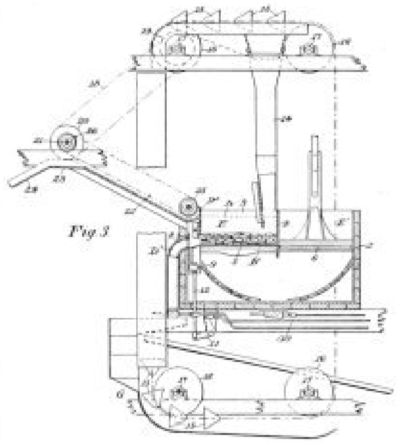


separated from slate is fed down the central tube i. The upward current of water catches it as it escapes from the feed tube and instantly separates the light coal from the denser slate. The coal is carried upward over the rim into the gutter e, while the slate sinks to the bottom and is caught in the base O. The object of the T head on the water inlet pipe, shown in Fig. 5, is to allow the force of the water current to be used to stir up and loosen the sediment which settles in the base, so that it can be readily discharged from the opening o'.

COAL JIG.

No. 556,739. ECKLEY B. COXE, DRIFTON, PA. *Patented March 24th, 1896.* The tank 2, is divided by a partition 4, into a working chamber E, and a pump chamber E'. The plunger 6 is moved up and down by suitable rods and cranks not shown, and the water which is beneath it is forced to surge up through the material in the working chamber, and back, at each stroke. The bottom is curved as shown to facilitate the movement of the water. The perforated plate 5 which forms the bottom of the working chamber, is covered with a layer B^1 of broken feldspar; the pieces being so

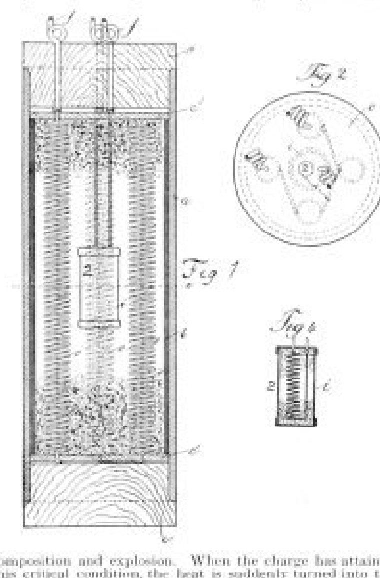
No. 556,739.



large that the water can flow through easily, and the refuse from the coal can make its way downward to the slate gate 8. The freshly broken coal is fed into the machine by the conveyor 15, through the chute 14, and the good coal is lifted by the pulsations of the water up to the tip of the discharge at D^2. Here it is taken up by the conveyor 22, and delivered to the chute 24. The slate and impure coal which is rejected by several of these jigs, is collected by a suitable conveyor and is treated in another jig of similar construction, and the little good coal still to be found among the refuse is thus finally removed.

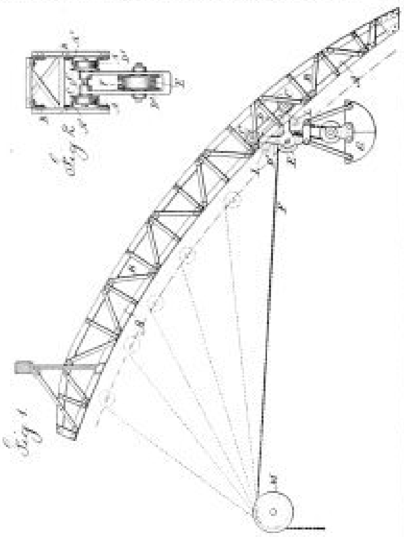
THERMO-EXPLOSIVE CARTRIDGE.

No. 556,901. CHARLES H. RUSH, CHICAGO, ILL. *Patented March 24th, 1896.* Fig. 1 is a lengthways section of a cartridge; Fig. 2 is an end view of the same; and Fig. 4 is a section through the igniter. The materials used for blasting by this process are non-explosive under all ordinary conditions, and the cartridges cannot be exploded by accident. They are filled with a mixture of about 15 parts by weight of chlorate of potash with one of paraffine oil. Other materials may be used, such as the nitrates of ammonia and potash, and manganese dioxide with powdered carbon instead of oil. The explosion is effected by heating the interior of the cartridge, after it is placed in the bore hole, to a temperature of about 400°. This weakens the chemical stability of the compounds and brings them to the verge of spontaneous decomposition and explosion. When the charge has attained this critical condition, the heat is suddenly turned into the igniter 2, which instantly detonates and precipitates the explosion of the charge. The time required for heating the cartridge may be varied from a part of a second to half an hour, to suit any variety of work, from artillery to slow blasting. The heating is done by means of electricity, which is sent through coils of German silver wire embedded in the material, and the igniter is fired in the same way. The material commonly used to charge the igniter is one part of soot mixed dry with five parts of chlorate of potash. This cartridge is well adapted to either simultaneous explosion in large numbers, or to single shot blasting. The materials are safe to handle both before and after they are made up into cartridges, and when cold, may be dug out of a drill hole with impunity.



COAL HANDLING APPARATUS.

No. 553,118. CHARLES W. HUNT, WEST NEW BRIGHTON, N. Y. *Patented Jan. 14th, 1896.* Fig. 1 is a side elevation showing the boom and hoisting apparatus, and Fig. 2 is a cross-section of the boom, upon a larger scale. The wheels of the trolley run between angle iron guides A, A^1, so that it cannot get out of place or become jammed on the boom. The



main sheave E is hung below the center of the trolley, and the bucket is thus underhung sufficiently to avoid striking the boom at any position. When the trolley reaches the lower end of the boom it is stopped, and the bucket descends vertically. In hoisting, the bucket rises until it strikes the trolley, after which both go up together. Thus the bucket is hoisted and carried horizontally to any desired distance, without a stoppage or pause of the hoisting engines.

MINING MACHINE.

No. 556,986. FREDERICK HURD, LONDON, ENGLAND. *Patented March 24th, 1896.* Fig. 1 is a top view, partly in section, of the machine at work, and Fig. 2 is a sectional end view of the same. The cutter bar employed in this machine is provided with a deep spiral groove throughout its whole length. The cutter bits are inserted in suitable sockets in the edge of the groove, and the end of the bar is armed with a pair of

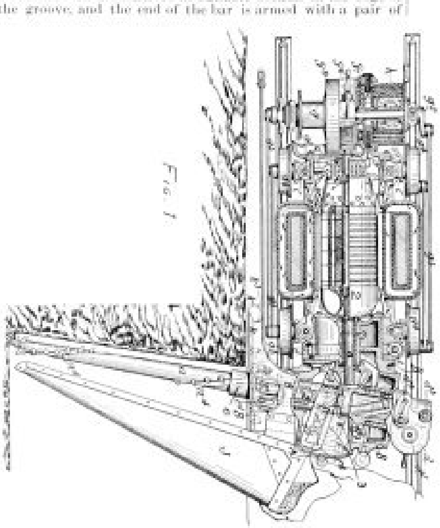


Fig. 1

Fig. 2

removable auger bits. The cutter bar passes through a rotating sleeve b, and is turned by means of a spiral rib, or feather, which engages the groove a^1. They are rotated by means of an electric motor 2, through the bevel gears b^1, c, and the shaft o. The head B, in which they are mounted, can be swiveled to any angle vertically by means of the worm i and worm gear i^1; or it can be turned over so as to reverse the machine from right to left hand, when desired. There is a feed pinion at d^1, which engages the circular teeth or grooves in the shank of the cutter bar, by which it may be fed into or withdrawn from the coal by hand feed. When the cutter bar has been entered to a proper depth, it is given a reciprocating movement in addition to its rotary motion, by engaging it with the chuck jaws e. These are reciprocated by means of the rods e^2 attached to the levers f^1, which are vibrated by means of cranks on the vertical shaft 3. This is turned by means of a worm wheel which engages a worm on the main sleeve b. Thus the cutters are given a shearing and rotary motion at the same time. The machine is drawn along on the tracks by means of rope and block, the rope being wound up by the drum g, which is slowly rotated by internal gearing g^3 and a worm g^4 on the forward end of the armature shaft. A quick motion, either way, is obtained by opening the clutch of the drum and coupling to the shaft, which drives the truck wheels by means of cranks g^5 and side connecting rods g^6. A scoop J having a conveyor inside of it follows close behind the cutter bar, and removes the chips.

MINING MACHINE.

No. 557,144. EDWARD S. MCKINLAY, DENVER, COLO. *Patented March 31st, 1896.* Fig. 1 is a top view of the machine; Fig. 2 is a vertical lengthways section, and Fig. 3 is a rear end view. The cutter bar H is of the ordinary revolving type which is armed with cutter points and is forced broadside into the coal. The shaft I carries suitable conveyer chains, not shown, which remove the chips made by the cutters. The shafts H and I are driven by chains W and X, from the shaft V, which is geared to the engine shaft T, by the wheels s, u, and t. The engines are back acting, the connecting rods passing backward along the side of the cylinders to the crank shaft at the rear. By this arrangement the cylinders and gearing are brought low down between the side frames, thus reducing the head room required to a small amount. The cutter bars and engines are attached to an inner frame composed of side bars D and cross girts P, O, N, and braces D^2. The engine frame can slide on this frame a few inches, and by adjusting the screws Q, the chains W and X can be kept taut as desired. The inner frame slides between flanges cast upon the sides of the tubular main frame A, and it together with the working parts, is fed forward into the work, or drawn back by means of pistons E in the cylinders A. The piston rods E are attached to the brackets F, which also support the shafts H and I. The pistons are driven forward by compressed air or steam admitted through the pipes J. The main frame is composed of the two cylinders A and the cross girts B, which are connected on the bottom by shoe bars B^1.

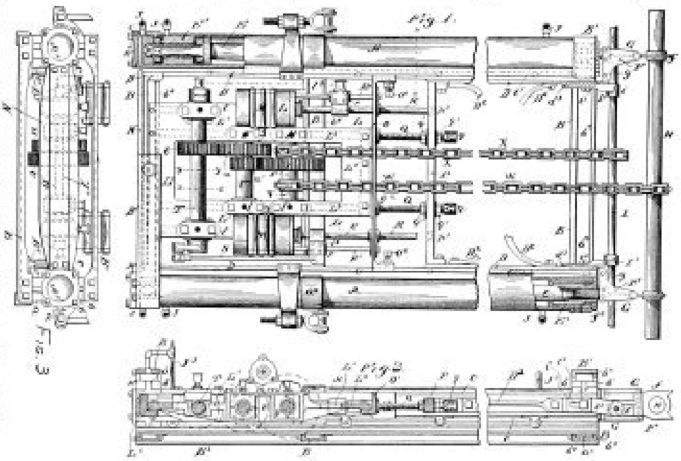

Fig. 3 — Fig. 1 — Fig. 2

GRATE.

No. 556,795. CHARLES YINGLING, METUCHEN, N. J. *Patented March 24th, 1896.* Fig. 1 is a top view of the complete grate; Fig. 2 is a sectional side view showing the grate bars in position for ordinary use; and Fig. 3 shows the positions assumed by the bars when rocked. Each bar rocks on trunnions which rest in pockets in the frame A, and the fingers of the alternate bars intermesh, as shown. The alternate bars are connected together by means of the links E, and the intermediate bars are rocked by means of

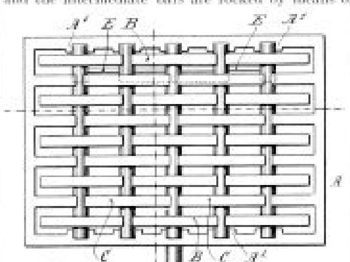

Fig. 1

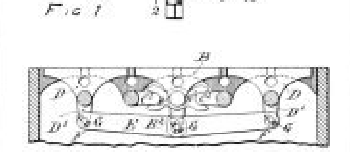

Fig. 2

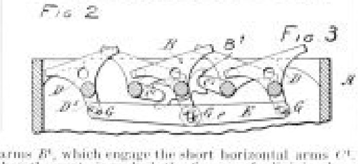

Fig. 3

forked arms B^1, which engage the short horizontal arms C^1. Thus when the grate is rocked, the fingers of adjoining bars are moved in opposite directions. The trunnions are located at a considerable depth below the normal surface of the grate, so that when the bars are rocked, the fingers have a horizontal motion, which tends to grind off the under side of the fire, in addition to the up and down motion. The bars at the side of the grate are tilted more than the middle bars; that is accomplished by making the arms D^1 a little shorter than the arms on the middle bars.

PLACING BLASTING FUSES.

No. 556,882. ROBERT H. ELLIOTT, BIRMINGHAM, ALA. *Patented March 24th, 1896.* Fig. 1 shows a fuse in position in a reamed powder chamber. Fig. 2 shows the device used to place the fuse in position. The wires are insulated for a short distance only back from the fuse H. The bare wires

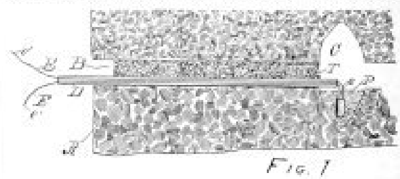

Fig. 1

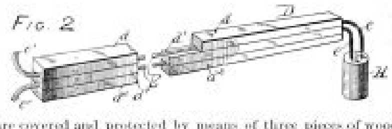

Fig. 2

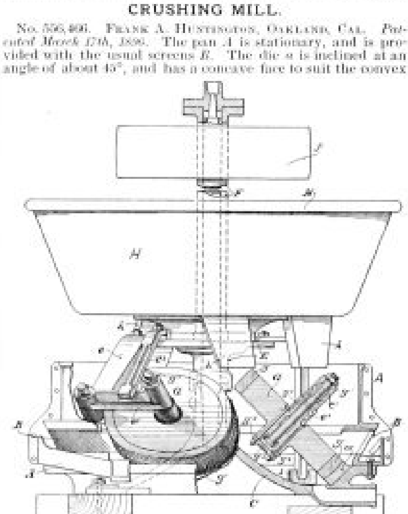
are covered and protected by means of three pieces of wood d, d^1 and d^2, which are suitably grooved and lightly bound together into a stiff rod D. In practice the rod D is pushed into the bore-hole until the fuse H hangs down in the powder-chamber, as shown in Fig. 1. Then the explosive material is put into place in the usual way, ordinarily burying the fuse therein. Then the tamping material T is rammed in and the apparatus is ready for the blast. It will be seen that the rod D, being stiff and lying straight along the bottom of the bore-hole, will not interfere with the ready insertion of the blasting charge nor with the placing of the tamping material, which may be conveniently rammed into place without disturbing the wires, whereas when the wires are simply insulated by the ordinary winding and are laid in the bottom of the bore-hole in the ordinary way, the tools used in inserting the blasting charge and the tamping material are very likely to catch in the wires, displacing the fuse and rendering it liable either to act poorly or to fail to act at all.

CRUSHING MILL.

No. 556,466. FRANK A. HUNTINGTON, OAKLAND, CAL. *Patented March 17th, 1896.* The pan A is stationary, and is provided with the usual screens B. The die a is inclined at an angle of about 45°, and has a concave face to suit the convex



rim of the grinding rolls. The rolls are hung by swing links to arms e, which project from the driver E. Thus they are free to rise sufficiently to run over lumps, etc., on the die, and to swing outward in obedience to centrifugal force. The driver, together with the hopper H, is fastened to the sleeve F and turns with it. There is a feed spout N in front of each roller, and a scraper I in the rear. The roller spindles are capped and well protected against the entrance of dust into the bearings.

The Colliery Engineer

AND

METAL MINER.

VOL. XVI.—NO. 12. SCRANTON, PA., JULY, 1896. With Which is Combined THE MINING HERALD.

IRON AND MANGANESE.

THE GREAT CEBOLLA RIVER DEPOSITS.

The Location, Geology, Topography and Development of the Greatest Beds of Iron and Manganese Known in the World.

Written for THE COLLIERY ENGINEER AND METAL MINER by Prof. Arthur Lakes.

During a recent trip to Gunnison county, in northwestern Colorado, we visited and examined what we believe to be by far the greatest deposits of iron and manganese at present known in the world. The locality, as well as the deposits, have been but little known hitherto to the outside world, owing to their distance from the railroad and their not being near any considerable market. The locality is on the banks of the Cebolla, about a mile below a number of cold and hot mineral springs, over which a rustic "resort" has been located. The hills on either bank of the Cebolla (pronounced Cevoya) are capped with a light colored rhyolite lava, and dykes of the same occur cutting up vertically through the river banks, indicating the original sources or fissures from which the lava issued.

About a mile below the hot springs the lava cap on the east bank terminates abruptly at three lofty and somewhat cone-shaped hills, from 600 to 1,000 feet in height, 2½ miles in length, about one-half a mile wide, and their bases covering about 800 acres.

These hills are mountains of solid iron and manganese, mingled with crystalline calcspar. Their prevailing color is a tawny red; the upper parts are covered with fir trees. Behind them, to the west, and bordering on them, is a still loftier hill composed mainly of titaniferous iron. This hill is greyer looking than the others, and the line where the titaniferous iron ends and the manganiferous begins is exceedingly clearly marked by a line of color.

We first examined a small quarry where the titanic iron came down close to the road. The grey massive iron was mingled with streaks of brown mica and a green, somewhat asbestiforous-looking mineral, which may be hornblende or pyroxene.

Then we drove to the foot of the first manganiferous and iron hill and studied a typical outcrop, exposing about 20 feet thickness of the ores near the roadside.

The appearance was that of horrible, rough, scraggy, black and rusty material like clinkers freshly thrown out from a slag furnace. Streaks of brown mica occasionally ran in and out of this, together with patches and veinlets of white crystalline calcspar.

The deposit was full of rough stalactitic cavities. Underneath some 20 feet of this "cap rock" the dark manganese proper begins, whose bottom, confines, or limits have not been reached or determined. Much the same typical formation continues to the top of the hill some 500 or 600 feet. Mr. Lewis, who owns these remarkable hills, and who is an old and experienced iron master from Missouri, and one of the pioneers of the iron and steel industry in that state accompanied us over the hills.

Passing around the corner of the mountain where it is separated from the next hill by Del Dorita creek, we climbed up to an opening made about 50 feet above the stream. Here the open quarry showed a face of 20 feet of solid ore without any ascertained limits. This was of manganese, yellow with rust from oxidation since the quarry was opened. Removing this crust we find beneath it the massive dark manganese. Numerous little cavities occurred in it lined with botryoidal or grape-like manganese, which on fracture, showed a radiating crystalline structure. Some crystallized lime or calcspar is also associated with the ore.

Mr. Lewis stated that in this quarry there was about the right natural combination of iron, lime and manganese to make spiegel iron used in steel making. A certain per cent. of phosphorus occurs. There is about 45 per cent. pure manganese. The ore could be mined at a cost of 15 cents per ton. A few hundred yards further up the creek along the base of the mountain we again climbed to an opening about 200 feet above the base where another open cut into the hill, 40 feet long showed a vertical face of 25 feet of solid ore without any definite limit. This is of iron and manganese, the greater portion being of solid steel-grey manganese of cavernous crackly nature, full of small irregular cavities sometimes lined with crystalline calcspar. At intervals of 50 feet above this are two other cuts in the same manganese showing at a glance 250 feet thickness of exposed ore and this practically continues to the top of the mountain, 500 feet.

Crossing the Del Dorita creek we ascended the next iron mountain passing up over similar iron and manganese deposits as in the preceding hill.

At the top of the hill, forming its crest, is an outcrop of brown cap rock calcspar. Crossing this and descending a few feet on the opposite slope we found quarries showing solid manganese and iron mixed with a fair amount of calcspar which would act well in fluxing. Iron, manganese and calcspar on this hill seem to lie in widely parallel zones. Mr. Lewis observed that of over 400,000 tons of manganese used in the United States, only 6,000 are produced in this country. The rest is imported from the Caucasian mountains and from the island of Cuba, where the leads are only four feet wide, and throughout the world all the manganese of commerce is from small leads in no way comparable with these vast deposits. The ore in these quarries, Mr. Lewis said, would net from 23 to 25 per cent. in manganese and 12 per cent. iron and 12 to 14 per cent. lime, another good combination for spiegel.

The lower part of this hill for some 200 feet to the base shows outcrops of calcspar standing up in little pinnacles mingled with deposits of iron and manganese.

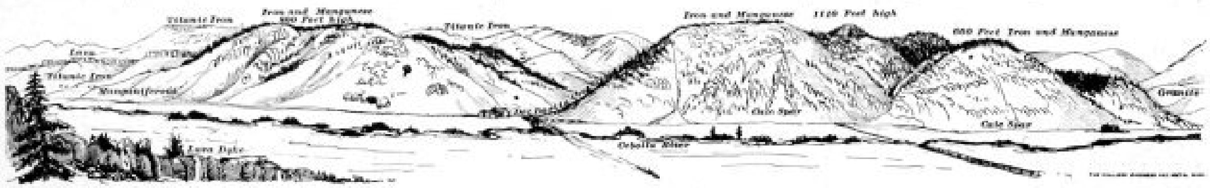
A deposit of brown jasper about 50 feet thick caps the top of this hill over an acre or so. South of this jasper is another remarkable body of ore shown in a cut which we called the "mountain rat quarry," as a colony of rats had made a nest in a crevice in the shaft. Here is an open cut showing a face of 20 feet of cap rock calcspar and iron mixed and below this a shaft 20 feet deep and 8 by 4 feet wide, all in solid grey iron, showing neither bottom nor lateral limits, in fact 40 feet of ore running 55 per cent. iron, the rest being silica and calcspar. Above the mine the outcrop of the cap rock on which they went down is seen. It looks like a brown sandstone traversed by thin seams of white calcspar and patches of iron and mica. Wherever this cap rock of calcspar vein outcrops, which it does very generally over the mountain, a heavy body of iron is sure to be found below it. This quarry was within 200 feet of the top of the hill and about 600 from the base. The maximum height of this hill above its base is 1,110 feet. Along the saddle joining this hill to the next, cap rock and prospect holes, all on solid manganese, occur for quite a distance.

These hills seem to have a sort of natural division of the ores. The eastern slope is one third manganese, the western two-thirds is of iron. Phosphorus in these openings on manganese, Mr. Lewis said, was not chemically combined with the ore but rather contained in the gangue the calcsparite and could be removed by reducing agencies.

Quarries also occur on the south slope of the end or last hill looking down into New Gulch, principally in unlimited bodies of remarkably pure iron, averaging, Mr. Lewis said, 60 per cent. iron. The lower portion of this hill shows the peculiar fringe of minarets and pinnacles of calcspar or travertine we have before alluded to.

ORIGIN AND HISTORY OF THE IRON AND MANGANESE MOUNTAINS.

The geological origin and history of these vast deposits of iron, manganese and calcspar we think is as follows:



THE CEBOLLA IRON AND MANGANESE MOUNTAINS, GUNNISON COUNTY, COLO.

In the first place we must remove a popular fallacy as to the supposed molten origin of iron deposits in general. These are not the direct results of igneous action or molten eruption. The ores are not the product of fire heat; they are not nor ever were in a molten condition like lava. They are the products of water and that in a heated state, in other words, hot mineral springs not unlike, perhaps, those still represented in miniature at the Cebolla resort, which are daily depositing both iron and manganese and calcspar, the same components as these great hills.

Though not the direct result of igneous eruption, the hills may have an indirect relation to such eruptive agencies. We have observed the prevalence of eruptive rhyolite (a lava closely allied to trachyte) in flows and dykes adjacent to the iron and manganese hills terminating at those hills.

Hot spring or solfataric or geyser action, together with a great variety of hot or cold mineral springs, are the natural and common accompaniments of the dying efforts of volcanic activity. It was such solfataric action that decomposed and leached out and redeposited the ores of Cripple Creek after the eruptions of andesite and phonolite had ceased and in fact most of our fissure veins and ore deposits have been formed in this way by solfataric or hot spring action.

AN INSTANCE OF ORE DEPOSIT BY GEYSER.

We had a remarkable instance of this on our trip through this same region not many miles distant, where the ore deposits of a mine called the Mammoth Chimney have evidently been deposited, in the form of opal and chalcedony rich in gold, along a line of fissure occupied by an ancient hot spring or geyser. One of the principal effects of the hot water and steam emanating from these hot springs is the decomposition and leaching out of soluble minerals and metals contained in the enclosing rocks from great depths even to near the surface. On reaching the surface the waters, laden with the solutions they have acquired in their upward course, deposit or precipitate it in solid oxidized form around their orifice. These deposits may be, as in the case of the Mammoth Chimney, silica, in the form of opal or chalcedony, but more commonly calcspar with iron and manganese. Hence the rusty mounds of calcspar built often to considerable height around the orifices of geysers and hot springs, as in the Yellowstone park, at Steamboat springs, Nevada, and even in a small way at the adjacent Cebolla hot springs.

What, then, these comparatively little hot springs are doing daily on a small scale where igneous activity has long ceased or become dormant, that, we conceive, on a vast scale and for a long period of time was carried on in the area where the iron, manganese and calcspar mountains now stand, when igneous forces were more energetic or had but a short time become latent.

It may seem an extravagant comparison between the little iron and calcspar mounds of modern living hot springs and the great mountains 1,000 feet high and 3 miles long; but allow vast periods of time, great igneous activity and powerful supply of hot mineral water, and we have a result by no means unparalleled in general geologic history.

We can fully endorse, from our own observations, Mr. Lewis' modest description of this great and unique property. He says:

"There are two hills or mountains of manganese and iron 800 and 1,000 feet high, their bases covering over 800 acres. From base to apex there are cuts, tunnels and shafts in solid ore, some of these more than forty feet in solid mineral, and in no place has the bottom or limit of the ore been reached. These openings are made at various distances for more than a mile in length by half a mile in width. So far as our experience goes, over this vast area it makes no difference where a hole is sunk, it goes into solid iron or manganese. It is generally found within a few inches of the surface, and in no case has it been necessary to go to a greater depth than 5 feet. Mining it could be open "quarry work," done at the minimum of cost. About one-third the area is manganese to itself entirely, or overlaying the iron to the depth of several hundred feet. On one hill, at its base, the manganese is opened up in mass between there and the summit. There are three large and several other smaller openings, all in manganese. So far as can be judged by the prospecting done, everything indicates that these immense deposits are as near solid as ores are ever found. The celebrated Cornwall ore banks in Pennsylvania are described as comprising three hills, 400, 200 and 160 feet high, covering an area of 105 acres, averaging 50 per cent. metallic iron. The area at Cebolla is 10 times that given of Cornwall, and averages 55 per cent. against Cornwall's 50, and besides, at Cebolla are the immense bodies of manganese ores, probably of greater value than the iron.

"The analyses show that the constituent elements in the ores average as follows:

Silica	3.15
Alumina	1.61
Lime	8.60
M. N. oxide	1.36
Iron protoxide	8.46
Iron peroxide	67.04
Sulphur	trace
Titanic acid	trace
Metallic iron	54.91
Phosphorus	1.53

"The last ranges from 0.02 to 2.43. Owing to the vast area these ores can be so mined as to give any per cent. of phosphorus desired."

As to the rocks that may at depth have supplied these elements. The two prevailing rocks visible at the surface near the deposits are rhyolite and granite. Both could supply the silica, alumina and lime.

The iron might come from the iron bearing minerals of the granite, or it is barely possible that sedimentary rocks limestones, etc., shown in other parts of Gunnison county but not visible here locally at the surface, might have contributed their quota.

These valuable deposits are within 20 miles of Gunnison City and the Rio Grande railway and there would be little difficulty in constructing a railroad up the Cebolla creek to these properties.

Quarry in Manganese Showing 25 Ft. Face Thickness of Solid Manganese.

HOT SPRING DEPOSITS.

How Vegetable Growths Assist Their Formation and Deposition.

Written for The Colliery Engineer and Metal Miner by Prof. Arthur Lakes.

In speaking of the origin of veins and ore deposits we have had frequent occasion in past articles to call attention to hot springs and their deposits, as at Cripple Creek, Steamboat Springs, and the Vulcan and Mammoth mine at Gunnison, and to the great importance of solfataric action.

In the Steamboat Springs region of Colorado, we described sometime since, the mounds and saucers of travertine or calcspar built up around the springs, and tried to describe the exquisite colors in some of the spring basins—delicate rose color, pink, yellow and dark green. The dark green we readily attributed to the gelatinous algæ or water weed, which comes up abundantly and floats on the surface above the orifices of springs even where their waters are over 100 degrees Fahrenheit. The other colors we thought might be from mineral tints, but according to Mr. Walter H. Weed (U. S. Geological Surveyor) all these tints are due to different kinds of algæ, often very minute. The same exquisite tints are seen in the geyser and hot spring basins of the Yellowstone Park, and are all due to the same cause. Nay, more than this, Mr. Weed shows us that the enormous bodies of travertine themselves, often covering many square acres and even square miles, are due to the precipitation of lime and silica through the medium of those singular plant forms. He says: "The travertine deposits of the mammoth hot springs in the Yellowstone Park, form one of the most interesting features of the region, covering two square miles and attaining a thickness in places of 250 feet. The deposits have few equals in size, while the beauty of the terraced basins, the brightly tinted slopes covered by the steaming waters, and the varied views presented cannot fail to impress every observer. In wandering about the springs one is sure to notice the brightly tinted basins surrounding the vents, with the red or orange colors of the slopes overflowed by the hot waters. These colors are due not to mineral matter but to the presence of algæ growing in the hot waters, and frequently so covered by carbonate of lime as to be scarcely recognizable. These plants take a most important part in the formation of the travertine deposits, and, in fact, it is their presence which has caused the great beauty of the deposits. The varied tints are due to a different color of the algæ at varying temperatures, examples of which are seen in the beautiful mosaic of basins about the vents of the Blue Springs, on the main terrace. The fact that these deposits of travertine are mainly due to plant life has been fully proven by a careful study of the old deposit and of those now forming. The plant life is the chief factor in the production of the many varieties of calc-sinter found about the springs. In the case of the fiberous tufa, forming the fan shaped masses found about many of the vents, an examination with the microscope shows that the fibres are simply encrusted algæ threads. The rippled surface of the algæ deposits covered by the overflow of the larger springs, shows a furry covering of orange colored algæ, the upright threads extending down into the mass. The algæ filaments serve as a nucleus for encrustation, besides absorbing carbon dioxide and thus causing the separation of lime carbonate. The masses of gelatinous algæ, often several inches thick, and forming mat-like coverings in the sluggish overflow channels, show the action of plant life most clearly. The successive layers of membrane-like material carry minute little crystals and stellate accretions scattered about in the plant tissue. These grow into small pellets that uniting together produce firm layers. Thin laminæ of carbonate of lime also form between the membranes and a compact deposit of travertine results from a combination of the two.

"The hot springs and geysers of the Yellowstone are surrounded by large areas of siliceous sinter (opaline quartz) that often entirely cover the floor of the geyser basin. About the spouting vents this material has been built up into mounds and cones of unique forms and great beauty. The more quiet pools have built up more or less regular mounds of white sinter which are in places as much as 20 feet in height above the surrounding level. Besides these deposits the alkaline waters of the geyser regions have left deposits of silica wherever they have flowed, and many square miles within the park are covered by white and glistening deposits of this material. Deposits of silica are formed about the geysers and margins of springs by evaporation, producing a true geyserite, and this silica is separated by plant life by the algæ that abound in the hot waters of the region, and by this agency by far the largest part of the sinter deposits of the region have been formed.

"This algous vegetation with its varied tints of pink, yellow, orange, red, brown and green, adorns the slopes of the geyser cones, flushes the white silica of the little basins with its tints and marks the waterways with its brilliant colors. It is ever present where the temperature does not exceed 185° F., often lining the great bowls of the cooler springs with leathery sheets of brown and green. Where a constant overflow prevails the channel is filled by a vigorous growth in which an algæ mat is formed having the consistency of a firm jelly, and most beautifully colored. In whatever form it is found, and no matter how brilliantly tinted, this algous material, if removed from the water and dried in the hot sun of the regions, rapidly loses its color, shrinks in size and becomes an opaque white mass of silica, whose weight is not one per cent. of its former state. Chemical analysis shows this dried material to be silica and water:

$S_i O_2$	93.37
$H_2 O$	4.17
Organic matter	1.50

"The growing algæ form a jelly of hydrous silica; of this the algæ filaments are formed and the algæ slime is a hydrous silica binding the threads together." In the case of siliceous sinter formation, algæ growing in the waters choke up the channel and cause the main supply to be diverted. Basins are formed by the algous growth and in them pillars grow up from the bottom, often a foot in height. These increasing in number finally fill up the pool, and their tops reaching the surface coalesce and roof over the basin until the waters becoming choked seek other outlets. The gradual lessening of this supply of water causes the final death of the algæ. In the cool waters that fill the space between the pillars the hydrous silica begins to harden. Aided by the acids of the decomposing vegetable matter this process is quite rapid and more silica is separated from the cold water to form a coral-like coating, and finally the former soft algous jelly becomes a hard firm rock. Eventually diversions of the hot waters build up another growth upon the old one and thus the channel, swinging around from side to side, successively forms new basins, new growths and new deposits of silica.

"The importance of these plant growths in building up sinter deposits may be realized when it is stated that in the walls of the great Excelsior geyser a section of 15 feet in thickness is exposed of which over 12 feet is recognized as clearly of algous formation and the remainder of cemented fragments of weathered sinter. Sinter is formed by evaporation very slowly. At Firehole geyser basin one-twentieth of an inch a year is the maximum. Sinter, however, formed by plant life may attain a thickness of 8 inches a year.

"Diatom beds occur in the park in cool marshes supplied by hot spring waters. The resulting diatom earth, beds of which are sometimes 6 feet thick, contains glassy silica separated from the waters by decomposing vegetable matter."

The manner in which these minute hot water plants secrete and deposit lime and quartz and so in time build up mighty structures is as wonderful as that by which the tiny coral polyp secretes lime from the seawater and builds up the great coral reef. *

The Dodge System of Coal Storage Chosen by the Erie.

The Erie Railroad Co., after careful investigation and the consideration of a number of plans, have contracted with the Dodge Coal Storage Co., of Philadelphia, Pa., for a 150,000-ton storage plant at East Buffalo, N. Y. The coal will be stocked in nine divisions or piles, each of about 17,000 tons capacity. The plant will be constructed under the patents of the well known Dodge system, with the latest improvements, including a complete haulage system for handling the cars. The efficiency of the Dodge system is demonstrated by the fact that every railroad using it has contracted for a second plant after more or less extended experience with the first.

Hoisting and Conveying Machinery.

Messrs. S. Flory & Co., of the Bangor Foundry and Engine Works, Bangor, Pa., report a flourishing business in cableways and hoisting machinery from various parts of the continent. They are now at work on an elaborate new catalogue, which will shortly be ready for distribution. Messrs. Flory & Co. have added to their engines an improved friction clutch, which has proven to be an effective and highly appreciated appliance. It is so constructed that all parts are of standard size and repairs can be easily and quickly made.

HOISTING MACHINERY.

Description of a Proposed Modification of the Koepe System.

Written for THE COLLIERY ENGINEER AND METAL MINER by WM. M. MORRIS, Pueblo, Colo.

In your February issue, page 166, you publish an article on methods of mining in Butte, Mont., in which there is given a description of the hoisting appliances at the Anaconda mine, and of new hoisting machinery about to be erected, which is designated as of the most modern type.

I do not wish to be considered too severe a critic, but I desire to compare the proposed Anaconda system with what I consider the most modern type of hoisting machinery, and I therefore introduce sketches, Figs. 1, 2, 3, 4 and 5, to illustrate my ideas.

Figs. 1, 2 and 3 show an old system patented in Europe and used with success in England and on the continent. Figs. 2 and 3 show the system known as the Koepe system of haulage, deriving its name from its inventor. It consists of one rope for the two cages, with a tail or balance rope attached underneath the cage, working around a wheel in the sump, as shown at *A*, Fig. 2. By this system a smaller engine with one coil of rope around the drum and with a friction brake on one or both sides of the drum wheel can be used. Records show that the rope never slips on the drum. The balance rope is of the same weight as the hoisting rope, and an old worn-out rope answers, as it has nothing but its own weight to lift. It effects a saving in power in hoisting the weight of the rope and a perfect balance at all points in the shaft, as against a variation of weight during different portions of the hoist under conditions existing in the old system.

Fig. 4 shows a system of hoisting that was designed by me. I designed the cage in 1886 or 1887, and gave it to a miner from Litchfield, Ill., who patented it. My arrangement with him was that I was to get half of the proceeds, but I have never heard from him since. On a trip to Leavenworth, Kan., in 1890, I recommended this system to the Messrs. Braidwood, who had a shaft 735 feet deep and did not have power enough to hoist. I met a man last summer at Belleville, Ill., who told me that the Messrs. Braidwood had patented this idea.

I have added to my old plans the chutes shown at *C C C C*, Fig. 4, thus making one of the most complete and economical hoists in use. I claim that with two men, one on each cage, three tons per minute can be hoisted from a depth of 2,500 feet. Fig. 4 shows a sectional view of a metal mine, but it is obvious that the system can be used as well in a coal mine.

I claim by this system of hoisting a saving of the work of eleven men, as follows: Five men on top and two men at each of the four landings or levels, as shown on Fig. 4, less the two men on cages. Assuming that these men are paid $2.00 per day, makes a total saving of $22.00. Next comes the saving in mine cars. As an example, we will take the proposed system of hoisting at Anaconda mine with double deck cages, three cars on a deck, making for the two cages, six cars on a cage, twelve cars. Then assume six cars on top and six at each level, making a total of 42 mine cars saved by my system. The price of these cars at the lowest estimate is $20 each, making $840.

Now, I can substitute in place of the two men to ride the cages one man on top to open the cage doors, which can be done by a system of levers, but I prefer a sure thing as against uncertainties, and therefore suggest a ratchet and pinion, as shown in the upper part of Fig. 5. A man can give one turn of the crank wheel and raise both cage doors in a second. The coal or ore will then slide out quickly into both chutes on either side. The doors can be lowered as soon as the material slides out and the cage is ready to descend into the shaft.

The upper deck *A*, Fig. 5, is intended for men, tools, props or mules. The steel box *B*, below, can be made to hold from four to six tons, in accordance with the capacity of the mine. A hoist can be made in, say, 1½ minutes, the loading and unloading of the cages can easily be done in half a minute. This gives, with a six ton box, three tons per minute, or 180 tons per hour hoisting from a 2,400′ shaft. This requires a velocity of

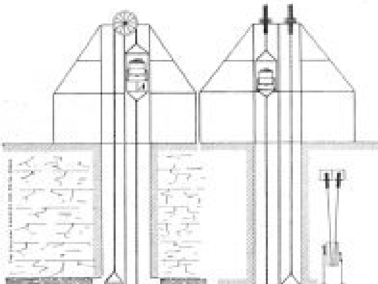

FIG. 1. FIG. 2. FIG. 3.

only 26⅔′ per second with a 10′ drum. I have had hoists which worked at a velocity of 35′ per second from a shaft only 350′ deep. Now, with a change in the arrangement of the men, say one man on top of the shaft and one man for each two levels, if they are opposite each other, in which case there should be a track around the shaft, so that coal or ore can be dropped into the chutes from either side, this man could attend to the dumping and signaling, as well as to the loading of the cages, and a total of three men is all that is required.

The cage with the steel box will not weigh any more than any other double deck cage, or at least will not be much more in weight.

To make my sketches clear, I would state that Fig. 1 is an old-fashioned balance pit used to hoist coal or ore when water is plenty and where the mineral can be elevated and the water run out at a lower level. A boiler iron tank *A A* is made to hold the weight of the load under the cage. The water is let into the tank from the top and let out at the bottom of the shaft; this is done while caging the cars. A powerful brake is placed on the pulley, or sheave wheel, which holds the cage at any point in the shaft, either with or without load. It must be understood that the water being emptied from the tank at the foot of the hoist must have an outlet some place to the surface. The chain underneath the cage is the same weight as the hoisting rope or chain. The Koepe system shown in Figs. 2 and 3 was no doubt taken from this idea. It is nearly the same as the system shown in Fig. 1, except that a rope is used under the cage with the wheel *A*, at the bottom of the shaft, to guide the rope and secure a perfect balance at any point in the shaft. Fig. 3 is the ground plan, showing the shaft, drum, brake wheels, pulleys and a pair of engines with one turn of the rope around the drum.

FIG. 4.

Fig. 4, which illustrates my plan, shows the engine, drum, hoisting tower and end view of the shaft with levels, dumping chutes and cars, also double deck cages. The upper deck *A* of the cage is for men only; the lower deck *B* is a steel boiler plate box, into which the coal or ore is dumped at each level by simply lifting the doors *C C C* with levers. The cage at the bottom is shown ready to load. The cage at the top is shown ready to unload into the chutes at each side by lifting the cage doors with the ratchet and pinion, the same as

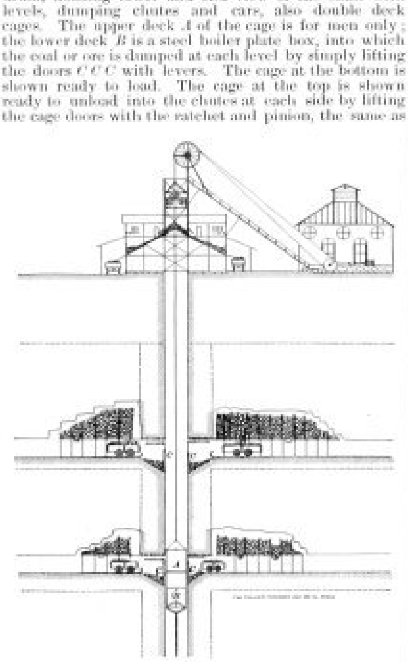

FIG. 5.

water gates are lifted. The bottom of the box pitches in both directions at the rate of seven inches to the foot. A man is required to ride on each cage to load and unload it.

Now, in regard to the comment on the proposed plant at Anaconda. In the first place, the expansion cylinders and Corliss valves in an engine running constantly are undoubtedly a great improvement over the old high-pressure engine, but in a hoisting engine that has so many stops and starts to make it is doubtful whether the same benefit can be secured. However, I do not want to be on record as opposing this plan until I have some definite information as to the results achieved, but the system of double deck cages and flat ropes is fifty years old and a nuisance. It requires too many men to do the decking, and there is too much time wasted in decking. Then, the great weight and cost of a flat rope and the quick destruction of the same by wear makes it very undesirable. A round, hammered or plough steel rope 1½″ in diameter whose safe load is 16 tons and breaking load 75 tons, with a weight per foot of 2½ pounds, is better than a flat rope ½″ x 8″ whose weight per foot will be about 6 pounds. The article from *The Mining World* says the two reels will wind up 5000′ of ½″ x 8″ cable. Allowing one reel 2,500′ and 100′ for pulley and reel, leaves 2,400′ of rope hanging in the shaft; this will weigh 2,400 × 6, or 14,400 lbs., equivalent to 7½ tons. This weight will have to be lifted in addition to the net load at each hoist. The 6 loaded cars weighing 6 tons, make a total of 13½ tons without the weight of the cars or cage, which are supposed to balance themselves. This weight will require an engine of 1,200 horse-power. By using the round rope, balanced as I suggest, a 600 horse-power engine would do, and by using the Morris cage system, the weight of 12 cars, say, 6 tons, plus the 7½ tons saved in weight of rope, makes 13½ tons, and if we add to this the weight of the round hoisting rope, 6,000 lbs., or 3 tons, and the weight of the tail or balance rope, making 6 tons, and subtract that from the 13½ tons, we have a saving in the weight hoisted of 7½ tons. Thus, by using my system and the Koepe system combined, there is a saving of 7½ tons at each hoist, and the same amount of material, 6 tons, is hoisted in each cage.

A 10′ drum making 80 revolutions in 1½ minutes makes a speed of 26⅔′ per second, which is not considered fast hoisting, and an engine, 24″ x 48″ cylinder, would furnish ample power with 80 pounds steam pressure. Let us see what this size engine with a 10′ drum will hoist from the bottom of the shaft. My rule is to multiply the area of the cylinder by the steam pressure and by the length of the crank in inches and divide it by the radius of the drum in inches, which will give the answer in pounds. Thus, the area of the cylinder is 452.39 x 24″, length of the crank in inches, x 80, the steam pressure, equals 888,588.80 lbs. Dividing this by the radius of the drum, 60″, gives the result of 14,810 lbs., nearly, or $7\frac{81}{200}$ tons. This is for one cylinder, the other to go for friction. The system is good for shafts running from 300 to 3,000 feet in depth.

A German Market for American Anthracite.

Mr. H. Barring, of Wilkes-Barre, Pa., who on the occasion of several visits to Europe, has given the question of the introduction of Pennsylvania anthracite into Germany considerable attention, writes us as follows:

"I enclose herewith a copy of a letter received from Brussels, which may be of some interest to you in view of the proposed attempt to compete with our anthracite coal in the European markets. Anything that you can do in furtherance of this scheme, in which I thoroughly believe, cannot fail to bear good fruits, if only as a matter of general satisfaction to you in having aided the settlement of the ever growing question of over production.

"In endeavoring to draw a conclusion from the within quotations of prices of German and Belgian anthracite, it should be borne in mind that Welsh anthracite, which is really the article against which we must expect to enter competition, costs from 6 to 7 marks, or $1.50 to $1.75 more at the ports than the much inferior anthracite mentioned above. Now, for instance, if German anthracite is worth at Amsterdam M. 24.80 a ton, which is equal to $6.20, Welsh coal would bring nearly $8 a ton, but even if it only brought $7 a ton, we could still beat them with our own coal even at full tide-water prices, and calculating on ocean freight rates at 11 shillings.

"The situation is not as favorable in some other places, as for instance, Cologne, where we meet German anthracite at 21 marks; this part of the country is in close proximity to the Westphalian mines. But we nevertheless can meet the competition of the Welsh coal there on equal terms. The same holds good in other places along the Rhine and the other large rivers of Germany."

The letter Mr. Barring refers to is from M. Hansen, of Brussels, Belgium, under date of April 27th, and is as follows:—

"Yours of the 19th inst. to hand. I shall forward to you small samples of Belgian and Westphalian anthracite. I have, however, no English (Welsh) anthracite at my disposal. Welsh is harder than Westphalian, and the latter harder than Belgian anthracite. Belgian is the quicker, German the slower burning coal, and for this reason the Belgian coal is preferred in Belgium, Holland, Southern Germany, Switzerland and France, the kitchen ranges in these countries requiring a free burning coal. English anthracite is the dearest of the three and its chief disadvantages are, irregular dimensions of nuts and not free enough from stones (slate).

"Anthracite must necessarily be *hard*, free from stones, and as much as possible not be smaller in diameter than 1½ inches, nor bigger than 2½ inches, and of course be smokeless.

"There is a good market for English anthracite in Holland, but its sale has diminished in Southern Germany. In Rotterdam, English anthracite has to be reshipped to go up the Rhine as far as Mannheim, from whence it goes to Southern Germany and Switzerland by rail. Westphalia and Belgium each produce annually about 300,000 tons of anthracite of the dimensions I named (about 25-50 mm.) and I am of the opinion that in a few years these countries will be unable to supply the ever increasing demand, and at suitable prices, large quantities of good foreign anthracite can be sold. The actual price is from M. 16 to M. 18 a ton on rail at the mine. Part of the Belgian mines are situated so as to load small vessels from 200 to 300 tons. Westphalian mines pay about M. 2.50 a ton for transportation to the Rhine." The medium price, 10 tons on rail is:

	German. Marks.	Belgian. Marks.
Brussels	224	190
Rotterdam	234	206
Amsterdam	248	231
Luxembourg	234	209
Cologne	210	217
Frankfort	257	266
Strasbourg	283	258
Freiburg	307	283
Ulm	315	308
Basel	309	284
Munich	350	348

Garlock Packing.

The Garlock Packing Co., of Palmyra, N. Y., report that the extensive additions to their factories are nearly completed. They are now manufacturing their water proof hydraulic and high pressure piston packings in both ring and spiral forms. They are receiving for both of these packings a constantly increasing trade and are crowded with orders for all kinds of their various packings, at both their Palmyra, N. Y., and Rome, Ga., factories. Mine managers who are not users of the Garlock packings should send in a small trial order which will most positively convince them of the superiority of Garlock packings over cheap inferior goods.

MINING SAFEGUARDS

TO INCREASE THE SECURITY OF MINERS.

Valuable Instructions From Bulletin No. 1, Colorado State Mining Bureau, by Harry A. Lee, Commissioner of Mines.

The act establishing the Bureau of Mines of Colorado provides that the officers of the department shall exercise practically the same functions as the mine inspectors in other states. In accordance with the spirit of the law, Commissioner Lee makes the following suggestions for ore mines in his Bulletin No. 1:

Explosives.—Explosives must be stored in a magazine provided for that purpose alone, and this magazine must be placed far enough from the working shaft, tunnel or incline to insure their remaining intact in case the whole stock exploded.

All explosives in excess of the amount required for a shift's work must be kept in the magazine. Under no conditions will the storage of powder in underground workings, where men are employed, be permitted. Each mine must have a suitable device for thawing powder and keeping it in condition for use. The water or steam bath is the only absolutely safe device. By a water bath is meant the surrounding of the vessel containing the powder with another vessel containing water which can be kept at the desired temperature. The thawing of powder with dry heat is unsafe. Dry heat under the most favorable conditions may exceed a temperature of safety. Miners should not be permitted to carry powder in their boot legs or elsewhere about their persons. A suitable place or places should be provided for preparing charges. At these points there should be a box or cupboard for caps and fuse. This should be securely fastened and so arranged that the caps cannot be jarred out or anything fall into the caps. A cap crimper should be attached to the side of the cupboard with a small chain.

Oils, Candles, Etc.—The storage of oils, candles and other inflammable substances demands the erection of a house for that purpose, and at a safe distance from the main buildings. They must not be stored with the explosives. Their removal for use, like the explosives, should be only in such quantities as are necessary to meet the requirements of a day.

Fire Protection.—All plants using steam—and especially small ones, where boiler, engine, blacksmith shop and shaft are all under one roof—must have a hose and hose connection to the injector or feed pump, and must keep the same ready for instant use. The line of hose should be sufficient to reach to the furthest point of the plant. As a rule the water supply at small plants is limited, and safety is largely dependent upon quick action. A few hand grenades hung about the plant in convenient places are great safeguards, and should be provided. Heating stoves placed in shaft houses should receive even more care in safety equipment than is common in dwelling houses.

Timbering.—Next to explosives, inadequate timbering causes more fatalities than anything about a mine. The general inclination is to use too frail and few timbers. No rule can be fixed for use of timber, the conditions must be met as they arise, and economy in timbering lies in doing well what is done. Strange as it may appear, taking districts as a whole, the best timbered mines are those most inaccessible and above the timber line, and the poorest timbered mines are those located in the woods. Temporary work which endangers life is criminal, and mine operators who supply their timbermen with material below the standard asked for assume very grave responsibilities.

Code of Signals.—1- Bell—Hoist (when not in motion).
1- Bell—Stop (when in motion).
1-1- Bell—Lower.
1-1-1-1 Bell—With care—Hoist (man on).
1-1-1-1-1 Bell—With care—Lower (man on).

Other signals to meet individual demands can be arranged, but the code in full must be plainly printed and placed in the engine room, at the collar of the shaft, and at each station or level, together with a notice and penalty for wrong or improper signals. Wrong or improper signals should be treated vigorously. An employe ascending upon one bell or descending upon two bells should be discharged. In mines working more than one level, signal gongs or speaking tubes should be placed from level to level. The danger of an employe signaling the engineer without first knowing the location of the cage or bucket is apparent. Where more than one level is being operated, special signals from lower to higher levels should be established; when established, the stopping of an up-going cage or bucket should be abolished. To illustrate this point: A. signals to hoist from the sixth to the second level; as the cage or bucket passes the fourth level B. stops it. The engineer is at a loss to understand; before executing one he has received another order. Let this be repeated several times and he becomes nervous. A rattled engineer is dangerous. It should be borne in mind that one bell does not mean "hoist until stopped," but "hoist to surface." Down-going buckets, or cages, are always "slowed down" at each level, and can be stopped with impunity; but on up-trips no one knows what signal is being obeyed, and therefore should not interfere.

The Bell Line.—The bell line should be so constructed that signals can be sounded clearly and easily from any station. This essential device is much neglected, and should receive more attention. A few iron sheave wheels or rollers, so placed that the line will stand clear of timbers, is often all that is required. At stations or levels where the line is used from both sides of the shaft, an attachment should be made so that reaching across the shaft for the line is unnecessary.

Hoisting and Lowering Men.—The hoisting or lowering of employes with a cage or bucket should be permitted or positively prohibited. If permitted, a notice must be posted near the head of the shaft, stating the maximum number who may use the cage or bucket at one time. This limit is not jeopardized when the men go "on shift," but, unless fixed, may be exceeded at the end of the day's work.

The handling of men with a bucket is very dangerous, and its use is discouraged by this department as much as possible. To issue an order stopping the use of the bucket for handling men would, at the present time, work a hardship in some districts upon both the miner and mine owner. But should the work of the bureau demonstrate the necessity, action will be taken and the practice stopped. It is to be hoped that the next legislature will enact a law compelling all new enterprises to use a cage in shafts two hundred feet deep and over. A strict compliance with the section of this bulletin entitled "Daily inspection," will be demanded of all mine operators hoisting and lowering employes.

Dump Guards.—At the end of each dump track, when a car is used, there should be a device to prevent the car going over, whether the load clears or not. It is generally supposed that a trammer can let go, but records show that while some do, the majority go over the dump with the car.

The Shaft Head.—The shaft head must be covered and so arranged that persons or foreign objects cannot fall in the shaft. When a cage is used, a bonnet which raises with the cage and falls back to place when the cage goes down, must be arranged. This bonnet or shaft cover need not be tight beyond what would stop a small animal from falling in, but the cage in turn must be supplied with a steel bonnet, oval in shape if solid, and if divided in the middle and hinged at the sides to admit sending down long timbers, the angles of the sides must not be less than forty-five degrees, nor the steel less than three-sixteenths of an inch thick. When a bucket and wooden doors are used, the shaft must be housed in and covered with doors which stand at an angle of not less than forty-five degrees pitch, hinged at the lower corners and opening upward or outward. These doors should not be less than four inches thick.

Stations.—All stations should have a passage-way around the shaft, so that crossing over the working department can be avoided. Where flat doors are used, a guard rail must be kept in place across the shaft and in front of the level, so that it will stop anyone walking or pushing a truck or car into the shaft. Across the track at some convenient distance an obstruction should be placed, so that cars or trucks cannot run by it and into the shaft, or trammers push cars by without removing the same.

Sinking Shafts.—Shafts equipped with mechanical appliances must be of at least two compartments, and the timbering must be kept well up with the work. When sinking, and work upon levels above are being prosecuted at the same time, especial care must be taken to protect men in the bottom of the shaft by placing close-fitting and strong doors in the working compartment, and by covering the ladder compartment with a plat, which will insure protection.

The Ladder Way.—All shafts over fifty feet in depth should be divided into at least two compartments, and one compartment set aside for a ladder way. The ladders should be sufficiently strong for the purpose demanded, and in vertical shafts should have landings at not more than twenty feet apart. The landings should be closely covered, except an opening large enough to permit the passage of a man, and the ladders should be so arranged that by no means could a person fall from one ladder through the opening to the next ladder. The ladders should be firmly fastened and kept in good repair. In incline shafts the landings should be put in as above described, but a straight ladder on the incline used.

The ladders in "upraises" or "winzes" from level to level should be likewise provided and kept in repair. Winzes or upraises are, after abandonment, very essential for ventilation, and, in case of accident, very essential as a means of escape. Just so long as they are necessary for the one cause and may be needed for the other, they should be kept in repair and ready for use if required.

Mill Holes and Winzes.—All winzes and mill holes running from level to level should be covered or surrounded with guard rails, so that persons walking along cannot step or fall in. Winzes, as a rule, are upon one side of the main drift and usually timbered a few sets above the drift level. Guard rails are easily placed about these. Mill holes, on the other hand, are often in the center of the drift. These must be securely covered with a door and kept covered.

Exits, Ventilation, Sanitary Condition.—As soon as practicable, all mines should have double or triple exits. Levels driven each way from the shaft must be connected by upraises or winzes, equipped with ladders and kept in good condition. These connections aid ventilation, and provide exits or means of escape in case of accident. Connections from first levels to the surface should also be made, unless underground connection is made with adjoining properties. Proper ventilation is of such vital importance to mine operators that it is well looked after, as a general rule. The sanitary condition about mines should receive careful attention. The use of abandoned stopes or drifts for closets should not be tolerated, and, where meals are eaten underground, the scattering of scraps and refuse matter about levels or stopes should not be permitted.

At the isolated mine boarding house, arrangements should be made for the disposal of slops and refuse matter. It should be the duty of the foreman in charge to look well to the sanitary condition of the bunk house and the cleanliness of his men. A large proportion of the miners are cleanly, but some are not; and a few filthy men in a bunk house soon infect the whole, or cause the cleanly men to quit rather than submit to the filthiness of their enforced associates. The condition of a bunk house is almost a sure index to the class of men employed. A cleanly and orderly condition predicts a thrifty, wide-awake and healthful crew, and *vice versa*.

The Indicator.—Upon all plants handling men, the engine should be supplied with a positive indicator. By a positive indicator is meant a device that is geared positively to the drum shaft and moves a target or indicator just as certain as the revolution of the drum raises or lowers the bucket or cage. Indicators arranged to move a target by the use of a string or wire cannot be depended upon, and are not as safe as marking the cable with a hemp wrapping or paint.

Mine Visiting.—The desire of persons, unaccustomed to mines and mining ways, to go underground should be discouraged. It is a novelty, an experience to relate to friends at home, but an experience in which the dangers are little appreciated, and of which it may be truly said, "ignorance is bliss." Were it within the province of this department to say who should and who should not enter mines, the line would be drawn sharply, and no one but employes or those having business would be admitted. Such a law would meet the hearty approval of all large mine operators, who appreciate the danger, trouble and expense to a company to be courteous; while the superintendents of smaller mines, whose better judgment is often overcome by a desire to please, would gladly take refuge and not assume the risks entailed.

Underground Surveys.—Each and every mine should keep an accurate plat of the underground workings, and have the same brought up to date at least once a month by competent engineers. No greater false economy can be practiced in mining than working upon the supposition that those in charge know just where drifts are. Where mines are adjacent, or working upon the same vein, and water is encountered, the necessity is apparent and imperative.

Boilers.—The bill creating the office of State Boiler Inspector makes mandatory provisions regarding the care of the boiler or boilers, and necessary reports to the inspector. It further provides severe penalties for failure to comply with requirements. Mine operators using steam or other pressure should familiarize themselves with this law and its mandates, and thereby insure the safety of all concerned.

The Mechanical Plant.—In the equipping of a mine with machinery, safety is too often sacrificed to false economy. When the expense of stops and repairs is taken into consideration, the very best machinery of a given capacity to be had, regardless of first cost, is the cheapest. It is well to bear in mind that competition in the mechanical line is so close that skilled labor, iron and steel, have a fixed market value, and that in accepting a plant of a given capacity from one firm, because its bid is $500 or $1,000 cheaper than another firm, the purchaser is simply buying that much less material or skill, and endangering the sucess of his enterprise.

The Mine Superintendent.—The duties and responsibilities of a mine superintendent cover a scope of requirements unequalled in any other professional calling. One of his most important duties is the formulating of a set of standing orders, the compliance with which will insure the safety of all under him. Fatal accidents can be too often traced to lack of mine discipline. Laws governing the employes about a mine should be as inexorable as in the regular army. Let the fact become established that failure to comply with regulations, however trivial, means loss of position, without recourse, and the safety of all concerned is almost assured.

The Mine Foreman.—The mine foreman is practically the working superintendent, and upon him devolves the detail of practical mining. The welfare of his employers and the safety of their employes is largely dependent upon his good judgment, and he must of necessity be a thorough miner, a good timberman, and a fair mechanic.

The Engineer.—Too much care cannot be exercised in the choice of this officer. His responsibilities are grave, and his work more wearing upon the nerves than the muscles. His cargo travels an invisible track, and must be guided by hearing and feeling. Safety demands that his whole senses be on the alert and concentrated on his work. His surroundings should be comfortable in a room by himself, and under no circumstances should he be permitted to converse with visitors while his engine is in motion. A law should be enacted compelling all engineers to undergo an examination, grading them by certificate accorning to ability. Engineers upon mines who handle men should all carry first grade certificates.

Daily Inspection.—All properties using mechanical appliances should be thoroughly inspected and reported upon daily. Some one man should be detailed to perform this duty at a given hour, and make a written report. These reports should be filed and show that that proper precautions are being taken. His duties should commence with the engineer, who will report the condition of the boiler, engine, cable, fire apparatus, &c. Then commencing at sheave wheel, he should test all bolts and nuts on boxes and gallows frame, the cable fastenings, and all things connected with the cage, bucket, doors or bonnets. Descending the shaft slowly, he should examine the bell line, timbers, lining boards, stulls, skids, rollers, guard rails at stations, doors, &c. He should also ascertain the amount of powder and the condition of the warmers. Ascending the shaft by ladders the same care as to detail should be exercised. Also the condition of winzes, upraises and ladder-ways, kept open for ventilation and exit in case of accident, should be examined.

The observance of this provision will prevent accidents and prove economical. It does not debar those in charge from "keeping their eyes open," but they are less apt to see danger than one whose especial duty it is and whose position is dependent upon not overlooking it. This inspection can be made in comparatively short time and at a time not to discommode the working of the mine.

In conclusion Mr. Lee says: To those who may feel the above recommendations to exacting, I desire to say there is nothing advised which is not in constant practice upon the older and best managed mines in the state. Because a mine is not paying is no excuse for jeopardizing human life by makeshift or temporary safety appliances. The common rule and the source of most all accidents is the desire to first "strike it rich and then make safe." The desire and duty of this department is to reverse the rule so it will read: "First make safe and then strike it rich."

ECONOMIES IN MINING

BY THE USE OF MECHANICAL APPLIANCES.

The Advantages Gained by Their Adoption, With Statements of Their Economy and the Conditions Suited to the Different Kinds.

By Cyrus Robinson, M. E., Columbus, Ohio. (Transactions Am. Inst. Min. Engineers.)

It has long since ceased to be necessary to urge coal operators and mining engineers to adopt power machinery in connection with some or all branches of their operations in mining, either at the face of the coal, in the entries, or at the tipple. The use of such machinery has become an accepted fact, and instead of having to consider whether we shall adopt power machinery or not, we simply accept it and consider what kind of machinery is best adapted for our requirements. And it will be the object of the writer to outline in this paper briefly, what points and methods are best to follow in considering any change of system or operation, in and about the mines, for the purpose of effecting the greatest economy.

First it is necessary to find out whether it is possible to effect an economy by making a change in the particular branch of operation to be considered. We will take first the haulage.

Assuming that we have decided an economy can be effected by installing a system of power haulage, the next point to be considered is the system best adapted to our conditions.

It is generally agreed and accepted by engineers that where the grades exceed 3 per cent. against the loads, traction haulage is not as efficient as rope haulage; therefore, where such conditions exist, we can eliminate all forms of traction haulage and simply consider rope haulage. As this in itself is a subject worthy of a separate paper, I will not stop to discuss it. If the grades are below 3 per cent. I believe that the best system to adopt is traction haulage. The next point to be considered would be the presence of gas and the nature of the coal dust in the mine. If there is explosive gas, even in small quantities, to be found in the pockets of the roof or crevices, it would not be safe to install electric or steam haulage and we are brought again to consider rope haulage or compressed air locomotives. If there is plenty of room in the entries and the curves are of large radii, a very efficient compressed air system can be installed, especially where there is any pumping to be done and where the coal is adapted to be worked by machines, but where the entries are low and crooked and the curves sharp, I do not think that, as the present compressed air locomotive is designed and built, it would prove successful. This narrows us down to some form of a rope plant or continuing with mules.

If the mine is free from gas and the grades against the load are below 3 per cent., I believe that no better system of haulage can be found than the electric system with traction locomotives, using the overhead trolley wire and a track return. During the past eight years between fifty and sixty of these plants have been installed and in many instances they have taken the place of endless and tail rope systems. The principal advantages of the electric system are its flexibility and simplicity, and in the writer's experience he has found that wherever electricity has been adopted as a means for the transmission of power in the mine, its use has been gradually extended to all parts where power is required, every addition increasing the economy by decreasing the fixed charges on the balance of the operations. In plants where an electric system of haulage has been installed, I have noticed that by degrees the system has been extended for the purpose of running the fans, pumps, screens and coal cutting machines from the same plant. It is not necessary to give any figures on this, as the reduction of the cost of fixed charges, by this extension, is self-evident. With the electric system in general use for haulage, coal cutting, pumping, etc., the greatest total economy is effected, the only labor expense in the mine being the locomotive man and the trip runner. The expense on the outside, of the engineer and fireman in the power station, being divided up amongst a number of different operations, makes a very small charge against the haulage, whereas with the tail rope system we have to have a trip runner and coupler, and with the endless rope system the gripman and the trip runner on the inside, as well as an engineer and fireman on the outside, and as the power can be used for no other operation, the whole of the expense of the engineer and the major portion of the expense of the fireman is chargeable against the haulage.

The cost of extending electric haulage is very small compared with other systems. The trolley line with all the necessary fittings, bonding of the track, erecting, etc., can be extended 500 feet for $50. A rope could not be extended this distance for less than $200, and it would be necessary to shut down for a period while this change was being made, while with electric haulage the extension could be made while the plant was in operation.

Another great advantage the electric haulage has over the rope systems is the ability to go into any part of the mine, and if necessary the locomotive can do switching, delivering any car irrespective of its place on the trip on any branch off the entry.

Another economy peculiar to the electric locomotive is the light track that can be used. It is claimed by many that it is necessary to put down just as heavy a rail for an electric locomotive as for a steam or compressed air locomotive. This is not the case. A ten ton electric locomotive will run on a thirty pound rail with an ordinary road bed with a minimum of track repairs, whereas a steam locomotive of this same weight would very soon pound a track of this weight to pieces; the difference between the two locomotives is that the electric locomotive has a true rotary motion and that, if designed and built properly, the entire weight, except the wheels and axles, rests on good spiral springs, so entirely doing away with the hammering of the track. The steam locomotive necessarily has connecting rods and a rigid wheel base, a large portion of the weight also resting dead on the axles. The action of the connecting rod and this weight is to hammer the track at every joint; the action of the steam cylinders, set at 90° as they are, tends to vibrate the locomotive crosswise and so continually spread the track. For a ten ton steam or compress air locomotive it is necessary to use not less than forty pound track to ensure the same minimum repairs as with a ten ton electric locomotive on thirty pound track. The difference in the cost of the two road beds would more than be enough to buy the electric locomotive in the average plant.

In this connection I wish to cite the experience of the Red Run Coal Company of Ralston, Pa. This company has a very long outside haul of about two miles. Some three years ago they purchased a steam locomotive and commenced to run it on twenty pound rails. In about six months they changed this to twenty-five pounds; six months later they changed it to thirty pounds and even now it is necessary to keep one man constantly at work on this track. The writer's company* recently made a contract with them for installing an electric plant for operating locomotives, machines and fans in the mine, the locomotive to haul the coal to the outside where the steam locomotive would take it. As the weight of the rails in use in the mine was twenty pounds, the superintendent was very desirous of having a locomotive that would weigh not more than four and one-half tons. The writer was of the opinion that this would not be of sufficient capacity to do his work and therefore furnished him a six and one-half ton locomotive. In view of the experience that this company had had with the steam locomotive, it was a difficult matter to convince them that the twenty pound rail would be all right for the six and one-half ton locomotive; and it was only on our company's guarantee, that they would try it. Since that time we have been receiving letters advising us how well the locomotive is working and how superior it is to the steam, as well as how little trouble they are having with the track.

COAL CUTTING.

Probably the greatest single economy that can be effected in and about a coal operation is in the substitution of machinery for hand labor in under-cutting the coal. With the present mining rates in Pennsylvania, Ohio and West Virginia, it is possible to obtain a saving of from fifteen to eighteen cents per ton where the breast form of machine can be used, and from six to eight cents per ton where the pick or punching machine is used. In no other branch of operating a coal mine is it possible to accomplish so much as in this one, and consequently this branch is receiving, and will continue to receive, for some time, the major portion of the attention of coal operators and engineers.

In considering this question, it is not difficult to decide whether it will pay to install a plant or not, as there are practically no coal mines in this country where machines will not pay. In this district alone the writer's company has installed machines which, all working, have a united capacity of some twenty-five thousand tons per day, while in the state of Ohio this is doubled. Even in the very thin veins (30″) of Alabama, machines of this make are found to make a reduction of from eighteen to twenty-five cents per ton, while out in Missouri and the Indian Territory, where the price of labor is much higher, the saving obtained is much greater. During the past few years we have installed numbers of machines in England, France, Austria, India and Chili. Reports from them and duplicate orders speak for the economy effected.

The question of advisability of introducing machines is no problem; the main and practically the only points to be considered are: What form of machine and power are best adapted to the existing conditions at the particular mine? Every mine presents new conditions, and the meeting of same requires intelligent and careful consideration. I believe that the first and most important question should be: Is there any explosive gas in the mine? If there is, or even if there are only traces at intervals, I should strike out from further consideration the use of electricity for transmitting the power. It has been urged by the manufacturers of electric machinery that a motor that does not spark at the commutator, or one that does not have any commutator, cannot fire gas, and consequently they advise the use of electric machinery for operating the coal cutters in a gaseous mine. The danger of an explosion does not arise from sparking at the motor, for the average spark from a well designed motor will not fire gas or dust, as it is not of long enough duration. It has been proved by experiments that to ignite fire-damp it is necessary to decompose it into its component parts with evolution of hydrogen, which becomes ignited, and the heat from the flame so caused eventually raises the temperature of the fire-damp to the point of ignition. This temperature, as everyone knows, is very high, so that it is perfectly safe to state that there is no danger from the motor itself, consequently, for this work we may conclude that a commutatorless motor has no advantages. The dangers arise from ruptured cables and wires, semi-short circuits caused by falls of roof, etc. Such a condition of affairs generally forms an electric arc of intense heat, and as same is not apt to be discovered, we will say, for the period of thirty seconds, sufficient time has elapsed to allow of the action described above taking place, and where gas is explosive by direct contact with a lamp, as is the case in the coal veins in the Pittsburg district lying below the bed of the rivers, it would be suicidal to install an electric plant.

*The Jeffrey Mfg. Co., Columbus, Ohio.

If gas is present in a mine, we have left for consideration only the form of machine to be used, breast machine or punching machine. If the roof and coal are ordinarily good, it would not pay, in the writer's opinion, to consider any form of machine except the breast machine, where the system of mining is room and pillar, and locomotive longwall machine where the system followed is long walls. As this latter system is not followed in this district, we will not consider it further. My reasons for making the above broad statement in favor of using the breast machines under the conditions mentioned are as follows:

1st. The coal can be undercut for about eight cents per ton less than with any other form of machine.

2nd. The coal is in better condition after it is mined.

3rd. Not so much territory is required for the same output, and consequently there is reduction of fixed charges and dead work.

4th. Ease of obtaining labor to operate such machines.

5th. The ability to cut in the fire-clay next to the coal in the thin veins where it is desirous to save as much of the coal as possible.

6th. Larger yield of coal per acre and consequent increased value of the lease and property, etc.

Where the roof is very bad and it is necessary to post close to the face, the punching machine will do good work. Although I have seen numbers of mines where at first glance it would have seemed impossible to work the breast machine, due to bad roof, the introduction of them has proved to be a success, the roof and conditions being very materially improved by the systematic process of machine mining, reduction of territory opened, and rapidity of advancement of the face, same generally being undercut twice in twenty-four hours from five to seven feet deep.

Where the mine is free from gas and the roof ordinarily good, it does not require a very extended investigation to prove the advantage and economy of electricity over all other systems of power transmission for your coal mine. The following table giving the cost of wire and pipe installed, based on the present market price of material and labor, shows very conclusively the superiority and economy of the electric system of transmission as compared with the pneumatic:

Horse Power Delivered.	Distance in Feet.	System of Transmission.	Total Loss in the Line.	Cost of Line Installed.
100	5,000	Compressed air	10 per cent.	$2,150.00
100	5,000	Electric 250 v.	10 per cent.	837.50
100	5,000	Electric 550 v.	10 per cent.	280.00

Guided by the above figures the inclination would be to decide in favor of the electric five hundred and fifty volt transmission and if the vein of coal had an average thickness of not less than five feet, the decision would be correct. In thinner veins, unless the distance from the power station to the point where the power is to be used exceeded ten thousand feet, I would not recommend the use of a current of a higher voltage than two hundred and fifty; if five hundred and fifty volts were used in a vein of this thickness it would be advisable to insulate the wires, and if this were done properly the cost of five thousand feet would be about the same as two hundred and fifty volts, so that nothing would be gained. Contact with a wire carrying a current of five hundred volts pressure is not productive of bad results if the person's system is in normal condition, but if he has a heart or nervous trouble it is apt to render him insensible and in some cases the contact would be fatal. The same proportionate conditions would obtain with a current at two hundred and fifty volts, so that we may say that the only safe thing to do is to keep men with such troubles away from electric currents. In veins exceeding five feet thick the writer's company has installed quite a number of plants using the high voltage system. The most notable among these being,

Youghiogheny River Coal Co., Scott Haven, Pa., No. 1 mine, 5 machines.

Youghiogheny River Coal Co., Scott Haven, Pa., No. 2 mine, 6 machines.

Knob Coal Co., Brownsville, Pa., 5 machines.

Crozer Coal & Coke Co, Elkhorn, W. Va., 5 machines.

Upland Coal & Coke Co., Upland, W. Va., 5 machines.

No trouble has been experienced at these plants from the use of this system and it is the writer's opinion that the majority of the plants installed in the future will employ the five hundred and fifty volt system.

If the first cost of the electric system is so much less, the extensions and maintenance give a still more favorable comparison, more particularly in the rooms from the cross entries to the face. When the electric system was first applied to coal cutting it was the custom to wire each room separately, running branch wires from the cross entry feeders in the same manner that the pipe branches are put in for compressed air transmission. The writer estimated that it would reduce the first cost to furnish an insulated concentric cable with each machine having a length equal to the length of the room and so do away with room wiring altogether. This system is now in general use and has been found very economical, not only doing away with the large investment in wire but also with the man required to keep up the room wiring.

It is not necessary for me to enlarge on the great advantages and economy of operation of the true and continuous rotary motion of the electric motor as compared with the reciprocating engines for transforming the power on the machine, and as I have already taken up more than my share of space and time, I will close this paper and hope at some other meeting to present another one, dealing with many other branches of this very important subject.

THE PROGRESS IN MINING

Abstracts From the Proceedings of the Mining Societies

And Journals of Europe and America, Illustrating the More Modern Developments in all Branches of the Mining Industry.

A THEORY IN MINE VENTILATION.—The following is copied from the *Colliery Guardian:*

In the case of bratticed workings in a coal mine, current theory teaches that the intake air-current should enter by the smaller side of the partition; for, as the current expands in traversing the mine workings, it is supposed to be evident that the larger volume should be assigned the larger section of passage. That is theory. But practice has demonstrated that it is sometimes better to ignore current theory, and give the larger volume the lesser passage. And thus we have to-day mining engineers who hold strictly to current theory and regard dubiously any supposed contradiction by experience, while we have many others who rely on the lessons of their own experience and reject such theory as may be contrary thereto. But while they thus reject the theory just referred to, they have no theory by which they can explain their own experience.

No doubt theories have been suggested to account for the heretical fact. The first time the writer had his faith in the orthodox theory shaken was seven years ago. The third edition of Mr. Wardle's work fell into his hands, and he was greatly struck by the instances quoted to show that the expanded volume oft-times chose the smaller passage. Mr. Wardle enunciated a theory to account for this, but this theory did not commend itself to the present writer. Some time afterward, the writer was sent to overlook a small sinking in Yorkshire. This shaft was divided by a canvas brattice, which divided the shaft circumference into two arcs, about 90° and 270° respectively. The ventilation was purely natural. On the morning of the writer's arrival, he found that owing to "stythe" (CO_2) the men were unable to get into the shaft. And he observed that they had slung a brazier of burning coal into the shaft from the jack roll. Of course, this brazier hung in the wide section of the shaft. The men's idea was that this brazier would act as a furnace and set up an upcast current on the wide side of the brattice. It was difficult to see what effective motive column they were likely to obtain from a brazier within three or four fathoms of the surface. However, the writer went to the narrow opening formed by the chord of brattice, and lighting a wisp of paper, held it over the aperture to see if there was any appreciable down draught. To his surprise he found an upward current actually proceeding from the supposed downcast. Some months later he had considerable trouble with a pair of winning headings giving off much gas. A brisk ventilation passed into these through air tubes. But at 24 or 25 yards the gas usually got the mastery, and holings at irregular points had to be made to cope with this state of things. It was originally intended that these holings should be made every 40 yards, but the pressure of the gas *in situ* obliged the management to make them much oftener. It was at last decided, as an experiment, to make the air-tubes the return instead of the intake. The result was that all the difficulty vanished, and thenceforth the headings went their proper distances without further trouble. Subsequently, the writer drove a stone drift. This drift was ventilated by boxes 15 inches square carrying the intake current. Coal was got at 110 yards, but the coal hewers had to drive a further distance of 120 yards to get a holing. Before this was accomplished the ventilation became so feeble that some alteration was deemed necessary. The boxes were then made the return, but in this case success refused to be wooed in any such manner. The result was absolute failure, and the writer got more puzzled than ever. He had seen the facts contradict the theory, and now here was fact apparently contradicting fact. The writer related these apparently contradictory experiences to a friend—a colliery manager—who remarked, "Well, it is difficult to form an opinion either way, and therefore we brattice our places on whichever side happens to be most convenient, but," he continued, "I have noticed that those places where the air goes in by the smaller passage invariably foul first, and this where all the places form a 'sheth' of bords ventilated continuously by the same current of air."

Now, such a statement concerning "a sheth of bords all ventilated by the same continuous current" is highly suggestive. The significant thing is that the place which fouls first, and that which fouls last have no point of difference in the matter of quantity, seeing that both are ventilated by the same current. Hence, when we ask this question as to which side should be the intake and which the return in a bratticed place, we may cancel this factor of quantity from our problem, for if it were only a matter of quantity, the "sheth" of bords all ventilated by the same current would alike foul, or all alike be cleansed, other things being equal. And it will be seen as we proceed that the question is solved, not so much by considerations that affect the quantity, as by those which affect the purification of the air at the face. It is not here positively and dogmatically asserted that quantity cannot positively be affected by the determination of which side of the brattice shall be the intake. The writer merely affirms that he cannot see what fluctuation in volume can result from a mere reversal of the current. The various resistances to the circulation of a given volume through a bratticed drift would appear to be much the same whether the current enter by the narrow or by the wide side. In either case the resistances of both sides must be attacked in turn; and it is difficult to imagine how the order of attack can affect the volume in the sense of increasing or diminishing it. One thing is certain, this constant examination of the question, only with reference to quantity, has for long obscured the true theory of a very important phase of colliery ventilation, viz., the rapid removal of deleterious fumes and gases from the working faces. And it is time colliery managers and engineers recognized that there are other factors in an efficient ventilation than mere volume; while the ventilating pressure as shown by a water-gauge is no record of the subtle gains, losses, restitutions and differential influences of the pressure *en route.*

Let us then accompany the ventilating current into the bratticed place, and observe its phenomena. The place may be a coal heading, or a mine tunnel through siliceous rock. In this communication we will assume that the deleterious gases in the face are, either by reason of their molecular weight or their expansion by heat, lighter, bulk for bulk, than air. For distinction, we will call all these gases other than air, vapor. We know, then, that if two gases of different density be thrown together, and if in the immediate vicinity there be a region of lower pressure, both gases will forthwith begin to flow, or expand in that direction. But the velocity of the lighter gas will be greater than that of the denser fluid. A volume of smoke visibly ascends when there is no appreciable upward current of the air. The smoke from a cigar travels from the center of the room to the chimney with a greater velocity than the air amongst which it moves. It is immaterial whether the regions of differential pressure are separated by a vertical or by a horizontal distance, the lighter vapor will travel quicker to, and sooner arrive at, the region of lower pressure. Translating these remarks into the language of mechanics, we affirm that:—The force (or pressure) acting on a particle of the denser fluid is equal to the force acting on a particle of the lighter fluid. Therefore, the quantity of motion in each particle is the same.

But, the quantity of motion = the mass × the velocity. Hence if the mass be less, the velocity will be greater. From which we conclude that the gas of lower density will expand into the region of low pressure with greater velocity. In the light of this incontrovertible law, let us examine the two cases under review. Let us first take the case of a drift with a brattice consisting of air-tubes by way of which the current returns from the face. In this case the air has come into the face by the larger passage. Hence it has lost little of its pressure. And hence by bringing in the current by the large side, we get the greatest possible pressure on the face of the drift. Then at the end of the tubes (*i. e.*, the entrance to them) we get at once the desiderated region of pronouncedly lower pressure due to the velocity imparted to the current as it enters the narrow opening. Yet further, the air having leisurely entered by the wide passage, is in a state of steady rest in comparison with another state to be described presently. Here then, we have a set of simple phenomena remarkably easy to understand. The force acting on the vaporous impurities and the air itself is the same. It is the difference of pressure obtaining between the face and the entrance to the tubes. In obedience to this force the air and vapor make for the return tubes. But the vaporous particles, being lighter, are more easily affected by the force; velocity is more easily and rapidly impressed upon them, and they continually beat the heavier air particles as all race together for the region of lower pressure at the entrance to the tubular return. Owing to their lighter mass, the vaporous particles are, as it were, strained out of the air at the face. Thus the quantity of air passing into the drift is not in any wise increased in volume; it is simply purified with the greatest possible rapidity at the face.

Let us now take the opposite case where the tubes carry the intake current to the face. Here, the current, after having overcome the great frictional resistances of the small air tubes, rushes into the face at a high velocity. This work is accomplished at the expense of its pressure. Therefore, having spent our pressure in the tubes, we cannot put it on the face, and so get a tremendously reduced pressure just where we want it greatest. But some will say: Look at the kinetic energy of the current thus put on the face; surely that will be a great factor in sweeping out the impure vapors! But this is just where current theory blunders. The kinetic energy at this point is a positive marplot. For the air rushing from the tubes into the face finds the vapor at relative rest. It pierces the vapor, rebounds from the face, again cleaves its way through the vapor, and heads for the return by the large passage, leaving the vapor behind in the unequal contest. If both started from rest, or from comparative rest, the natural properties of the vapor would enable it to beat the air in the race for the region of low pressure, but the kinetic energy accumulated by the air in the tubes gives it a flying start of the vapor. The result is the we get quite as much air around the drift, but that we fail to obtain the same purifying effect at the face as when the current goes in by the wide side. We get the air in, but we do not get the vapor out. We lose our pressure on the face by spending it in the boxes, and we nullify the natural tendency of the vapor to first escape by endowing the air, its competitor, with an undesirable kinetic energy. But that is not all. Not only do we minimize our pressure at the face, but we raise our pressure at the entrance of the wide return to a maximum. And thus we obtain a difference of pressure at these points absolutely in the wrong direction. For when the air is discharged from the tubes into the face, it eddies and whirls about until its velocity becomes readjusted to the requirements of the wider passage of return. And when this readjustment is affected, what is the result? No one who is familiar with the phenomena of fluids will dispute that we have now to reckon with a restitution of pressure at the very entrance to the wide return. Hence there is no immediate region of lower pressure to which the vapor can escape. True, there is such a region in the tubes, but the vapor can hardly be expected to go out of the drift by way of the intake. And as for the wide return, the entrance is blocked by the greatest pressure of all.

Let no one imagine that the ventilation of the drift would be impossible while such a distribution of pressures obtained. For a power other than fluid pressure is at work here—the power of kinetic energy. The drift, considered as a whole, is ventilated by its superiority of the fluid pressure at the entrance to its intake; but the face of the drift, considered by itself, is ventilated by the kinetic energy of the air from the tubes. But while the air comes into the face charged with a kinetic energy that enables it ultimately to overcome the restored pressure at the entrance to the wide return, we must remember that the deleterious vapor in the face has received no such endowment. It is knocked aside and scattered about by the air; it is caught and imprisoned in the vortices of the aerial whirlpools, but the restitution of pressure at the entrance to the wide return forbids its egress until its diffusion with the air is throughly complete. No doubt the air particles do drive out many vapor particles by sheer concussion, but in the race for a return which is of larger section than the intake, the natural properties and environment of the vapor unite to handicap it most severely. We get rid of all these difficulties by making the smaller passage the return. The natural properties of the vapor then assist it to escape with expedition. The pressures are then distributed with the best possible effect. And the air coming slowly in by the wide side gains no undue advantage of the vapor in the matter of accumulated kinetic energy. But it must be noted that this theory rests on factors pertaining rather to distribution of pressure than to distribution of quantity, or volume. The writer does not affirm that by making the smaller section of a bratticed placed the return you will get an increased volume of air, but he affirms that by this method you will sooner purify and more effectively cleanse the atmosphere at the face of the drift.

* * *

COKE, GAS AND AMMONIA.—The following is taken from *Kuhlow's German Trade Review:*

By-products of distillation.—As being of particular interest in connection with the subject of by-product coke manufacture, we give an abstract translation of the paper read by Dr. Knublauch at the last meeting of the German Association of Gas and Water Engineers held at Cologne.

The behavior of the carbon and hydrogen of coal on distillation is the chief point of interest in gas or coke manufacture. At the coke ovens, the aim is to obtain the greatest quantity of carbon as solid residue; in the gas works, it is to hold as much carbon as possible in combination with hydrogen—and especially in those combinations which form the best illuminating hydrocarbons. The choice of coal and the conditions of production—more particularly the temperature of distillation—are the most important factors in producing the best illuminating gas. It has been shown that benzol and a small quantity of toluol are chiefly responsible for the illuminating power of gas; but exposure to a somewhat higher temperature will partially destroy them, with formation of graphitic carbon and so-called diluents. But besides the constituents of coal which on its distillation yield gases suitable for producing light and heat, there are certain other constituents, occuring in considerable quantities, which claim attention. These are sulphur and nitrogen, of which the latter is the more important, since certain of its products have a very high market value. The nitrogenous products of distillation were regarded for some time as very troublesome, and even to-day in gas works are often considered of secondary importance, though costly ammonia recovery apparatus is attached to coke ovens. The importance of the nitrogen products from coal will be sufficient justification for the publication of the following results of experiments and observations, made during a number of years at the Cologne Gas Works, and subsequently in the author's laboratory:

Nitrogen in Coal.—The amount of nitrogen is very variable in different sorts of coal, and even in the same kind. There is from 1.3 to 1.6 per cent. in Westphalian coal. The proportion that is converted to valuable compounds is, however, very small; forming only from 0.2 to 0.25 of the weight of Westphalian coal. The enormous amount of coal distilled daily in gas works and coke ovens makes the total quantity of these easily obtained compounds very large indeed. The daily demand of a million tons of coal over the whole globe, corresponds to a yield of ammonium sulphate of about 10,000 tons daily, taking the nitrogen recovered as ammonia at 0.2 per cent. of the coal. The coal used at Cologne puts yearly into the gas retorts alone about 1,000 tons of nitrogen, of which 200 tons is recovered as ammonia and cyanogen; and these, reckoned as sulphate, may be valued at £12,500. It may appear remarkable that 10 years ago we knew nothing of the remainder of the nitrogen; and only quite recently the matter of its disposition has been solved, in the course of a determination of the proportion which is converted to cyanogen.

We have seen that no certain relation exists between the nitrogen content of coal and the yield of nitrogen products; but until recently it was deemed correct to calculate the one from the other. This ignorance had two causes. On the one hand, too little value was attached to chemistry in the gas industry (and this remains the case); and, also, until the nitrogen question was better understood, probably there was no gas works at which the products could be so separated as to enable any molecule of the coal distilled to be traced in any form in the products obtained. When this had been effected very well in Cologne, after the chemical bearings of the subject had been properly worked out, the nitrogen question again came to the front. The defects in wet purification and in the liquor works having been disposed of by chemical guidance, experiments showed that the ammonia completely extracted from the gas in the gas liquor yielded only 9.6 to 10 parts of sulphate per 1,000 parts of coal—corresponding to a percentage of nitrogen in the coal of nearly 0.2 only. Estimations of the nitrogen in the coal carried out at the same time, showed seven to eight times that quantity—corresponding to 70 to 80 parts of sulphate per 1,000 parts of coal. Attempts to convert more nitrogen into ammonia were so far successful; but, on the other hand, disadvantages accrued, and the new processes were put on one side. The most memorable were the addition of lime to the coal before distillation, and the passage of steam over the incandescent coal and coke.

What Becomes of Lost Nitrogen.—What becomes of the 86 to 88 per cent. of the nitrogen of the coal unaccounted for hitherto? A very small quantity occurs as cyanogen in the gas and nitrogen bases in the tar; and there are only the coke and the gas where the residue may possibly be found. Actually, analyses showed a great quantity of nitrogen in the coke. The nitrogen content of the coke may even be higher than that of the coal, especially when the volatile nitrogen is small in relation to the total volatile matter of the coal. Nitrogen is not, like sulphur, detrimental to the use of the coke; and estimations of it were not, therefore, carried out for the valuation of the coke. Without entering closely into the question, we gain the impression that, with a higher temperature in the retorts, the nitrogen will not remain in the coke. After estimating in addition the nitrogen in the tar and the nitrogen as cyanogen in the gas, no other nitrogen compounds are in the products; and the surplus nitrogen must be free in the gas.

Exact results are scarcely obtainable in large scale working, or only after long continued trials; and therefore a laboratory apparatus was devised for distilling the coal. By this it was found that the generally possible yield of ammonia could be determined for various coals, and variations made dependent only on the choice of the coal. The results of experiments proved: (1) That the nitrogen content of the coal and its distribution among the different products are not in any degree proportional. For example, the yield of ammonia may be much greater from a coal of low than from one of high nitrogen content. This statement is also true of the other nitrogen products. Thus, a sample of coal containing 1.176 per cent. of nitrogen yielded 0.1874 as ammonia, and one containing 1.555 per cent. yielded 0.1850 and one containing 1.479 per cent. yield 0.2086. (2) These variations are frequently very great with coal of different origin, and often small with same kind, though even then they are sometimes very considerable. Foster has investigated the question as far as English coals are concerned; and Schilling has made some experiments with various kinds. The yield of ammonia found is confirmed in the three series of observations. The yield for different kinds of coal in coke ovens working on a large scale has been also determined; and a series of coal distillations has been made in which the ammonia has been completely extracted from the gas and liquor. Though more recently introduced at the coke ovens, ammonia recovery is often better carried out there than in many gas works. A large number of distillations of many kinds of coal have been made by the author to ascertain the yield in the various products. The average yield of sulphate of ammonia for coal from 15 different sources is shown in the following table:

EXPERIMENTS ON THE DISTILLATION OF COAL.

Source of Coal.	Number of Tests Made.	Average Yield of Sulphate per 1,000 Parts of Coal. Parts.
Westphalia (a) gas coal	6	10.4
" (b) cannel (so called)	3	7.7
" (c) coke oven coal	9	11.0
Upper Silesia (a) gas coal	1	13.5
" " (b) coke oven coal	8	
Lower Silesia (a) gas coal	2	7.7
" " (b) coke oven coal	3	8.4
Saar	6	8.2
England, gas coal	3	16.4
Belgium	1	6.8
Moravia, coke oven coal	3	10.6
Russia	1	11.8
North America	10	9.4
South America	1	13.3
Italy, lignite-like coal	2	28.9
Bohemia	2	7.4
Scotland, cannel	2	7.9
Spain	1	2.3
Australia	2	1.9

In choosing coal for gas making, it is desirable to ascertain the yield of tar, ammonia, and sulphuretted hydrogen, as well as that of coke and gas. The difference in yield of ammonia varies in importance according to the current prices of ammonia compounds. The difference between 8 and 12 parts per 1,000 parts of coal, would mean, to a works like Cologne, the difference beetween 700 and 1,050 tons of sulphate per year—that is so say, about £4,000 value. It is also of considerable importance to know the yield of sulphuretted hydrogen from a coal, especially in cases where the purifiers have occasionally to be worked to their utmost capacity. This yield also is in no degree proportional to the amount of sulphur in the coal. It is easy to choose coal which shall not throw a great burden on the purifying plant.

***

FIRE-DAMP, THE FORMENOPHONE AND THE INDICATING SAFETY LAMP.—From the *Colliery Guardian.* The members of the French Fire-damp Commission are carrying out a series of tests on the Hardy formenophone at the Paris Conservatoire des Arts et Metiers; and at a recent meeting of the Societe des Ingenieurs Civils de France, M. Molinos presiding, the inventor, M. Ernest Hardy, director of the Thivencelles et Fresnes-Midi Collieries, Nord, made a communication as to the application of sonorous vibrations for analyzing two gases of different density by means of his apparatus, incidentally remarking that the communication as to this apparatus lately made to the Societe de l'Industrie Minerale, without his knowledge, was very incomplete.

M. Hardy began by recalling the fact that, *cæteris paribus*, the sharpness of sound given by a sonorous tube depends on the density of the gas which causes it to vibrate, so that if two organ pipes, tuned in pure air, be made to sound through being blown with pure air by two distinct bellows, they will be in unison; but if one of them be blown by a mixture of pure air and a quantity, even insignificant, of an extraneous gas, such as formene or carbonic acid, the sound of that pipe will be modified, and the two pipes sounding together will produce a discord, the number of vibrations in a given space of time being proportional to the quantity of foreign gas mixed with the air.

In the apparatus that he had devised, one of the blowers is always fed with the same pure air enclosed in a tight chamber, while the other is supplied with the surrounding atmosphere, which is drawn through a scrubber containing a concentrated solution of potash, for freeing the gaseous mixture from any carbonic acid which it might contain. On leaving the blowers, and before entering the sonorous tubes, the two gases pass through a regulator which reduces them to the same temperature, after which they are both saturated with water vapor, so that all causes of error are eliminated, leaving no correction to be made. A microphone is inserted in each of the sonorous tubes; and an electric current traverses the two microphones in succession, and also a telephone receiver, which repeats, while accentuating them, either the pure sound of the sonorous pipes or the discord which they may produce.

For registering the quantity of extraneous gas in the air, two speaking tubes connect the sonorous tubes with a sound-board, closed by a membrane, which reproduces the vibrations of the two sonorous tubes. When the latter sound in unison the membrane vibrates regularly and with the same amplitude; but, when there is discord, the difference of amplitude is utilized for interrupting an electric circuit, which passes through a telegraph translator. A wide paper band is continually unrolled by clockwork, a movement of which makes contact every five minutes for the space of exactly 20 seconds; and the current of a battery, controlled by the translator, passes through this 20-second contact, and then through an electro-magnet, which becomes active at each beat that takes place during the twenty seconds of observation, and which causes a ratchet wheel to revolve to the extent of one tooth. The ratchet wheel communicates its motion to another wheel, the spindle of which carries a hand provided with an inked disc. The hand starts from zero at each observation; and its disc traces the arc of a circle on the paper band, making a point at each discord. When the 20-second contact terminates, the hand stops, and, a few seconds afterwards, disengaging gear actuated by the clockwork brings back the hand and its disc to zero, ready for a fresh observation.

According to the observations of the French Fire-damp Commission, the density of fire-damp may vary from 0.5802 to 0.966; and it must be acknowledged that the density of this gas may be affected by the presence, in a mine atmosphere, of carbonic acid and water vapor. It is the former of these two substances which, on account of its great density, viz., 1.529, will chiefly vitiate the results registered by the apparatus; and calculation shows that 1 per cent. of carbonic acid may counterbalance 1.2 per cent. of fire-damp in the mine, or, what comes to the same thing, that 6 per cent. of carbonic acid may mask as much as 7.2 per cent. of fire-damp. If it be borne in mind that fire-damp ignites when present in the proportion of 7 per cent., and explodes in that of 8 per cent., it will be seen that this proportion of 6 per cent. of carbonic acid—which, it is true, has been met with but rarely in fire-damp—may prevent detection in the mine of an inflammable mixture very near the explosive point.

The proportion of 2.72 per cent. of carbonic acid, which has sometimes been met with in return airways, would mask 3.26 per cent. of fire-damp, a proportion vastly higher than the 0.5 per cent. which is tolerated as a maximum by the regulations in some coalfields. Carbonic acid appears also to greatly affect the precision of the indications furnished by the safety lamp, which is ordinarily used in collieries for the detection of fire-damp; but it certainly does not so affect them in the same proportion.

The influence exerted by water vapor (density 0.622) on the indications of the formenophone would be exerted in the contrary direction, by diminishing the density of the air passing through the apparatus. Calculation shows that 1 per cent. of water vapor will produce the same effect in the formenophone as 0.85 per cent. of fire-damp. This amounts to saying that 2 per cent. of water vapor—a proportion which is met with in return airways, owing to the respiration of men and horses, the combustion of lamps and the sprinkling of dusty mines where dust explosions (*coups de poussiere*) are to be feared—would convey the impression that fire-damp is present to the extent of 1.7 per cent., while the atmosphere might be perfectly free from this gas. It is therefore indispensable to only use the formenophone with an absolutely pure gas; and such a gas fire-damp certainly is not.

Nor is the density of air impregnated with fire-damp modified merely by the presence of extraneous gases in the fire-damp; on the contrary, it is also modified by the influence exerted by the temperature, because, for the apparatus to work properly, the gaseous currents traversing the two sonorous tubes must have absolutely the same temperature.

Now it must not be expected that the outer air, introduced into a mine as a standard of comparison, will be of exactly the same temperature as the air impregnated with fire-damp, which air, especially when stagnant in roof cavities, takes from the rocks their temperature increasing with the depth; and here comes in the importantance of the regulator of temperature for obtaining isothermic conditions in the two gases that it is proposed to analyse by the acoustic method. Great care must, however, be taken to secure the thorough efficiency of this temperature regulator, which is traversed very rapidly by the two gases to be compared. Here again a difference of only 1 deg. Cent., in the temperature of the two currents, modifying their density, will correspond with 0.0075 of fire-damp; a difference of 10 degs. Cent. between the mine atmosphere and that on the surface taken as a standard of comparison, will correspond with 0.075 or 7.5 per cent. of fire-damp, leading to the supposition that the atmosphere is inflammable, while all the time its expansion only has given rise to such an indication.

Other methods for indicating the percentage of fire-damp in the atmosphere of colliery workings were then passed in review by M. Coriot, who remarked that the safety lamp, which is in the hands of every miner, gives very valuable and correct indications, so much so that a practiced observer is able, with the Mueseler lamp, to detect eight one-thousandth parts of fire-damp in a mine atmosphere. It has also become possible, he added, with the last form of Fumat lamp (which has, behind the flame, a reflector that may receive a graduated scale), to measure the elongation of the flame very correctly, and to obtain indications corresponding with a half division of the scale—that is to say, with four one-thousandth parts of fire-damp. These very slight contents, far slighter than that of 0.07, which corresponds with the ignition of fire-damp, are thus revealed by a portable appliance, in the hands of all the men, simple, strong and sufficiently correct. If, however, a still greater exactitude be required, recourse must be had to lamps with an alcohol flame, the slight brilliancy of which permits of the rings caused by combustion of the fire-damp to be seen more clearly; and the Chesneau grisoumetric lamp is now giving very precise indications of one to two thousandth parts of fire-damp in the air. The speaker considered that such minute proportions of fire-damp as these can hardly be arrived at by the formenophone, which depends for its use upon the sense of hearing.

***

THE SPONTANEOUS IGNITION OF COAL.—The following interesting extract is taken from *Kuhlow's German Trade Review*, and it is interesting to notice that Professor Dr. Medem traces spontaneous ignition to the oxidation of iron pyrites, and as no coal is entirely free from this sulphide of iron, the cases the doctor brings under notice become all the more interesting.

Professor Dr. Medem, in the course of a treatise on the spontaneous combustion of hay and coal, gives the following account of the causes of this phenomenon and methods that have been proposed for its prevention and suppression.

The simplest form of spontaneous ignition is exhibited by dry spongy platinum, and is due to the absorption and condensation of oxygen in the pores of the metal. When exposed to a current of hydrogen gas, chemical combination immediately sets in, raising the temperature sufficiently to ignite the stream of hydrogen.

In the case of charcoal, a pyrophoric tendency is only manifested when some of the volatile hydrocarbons have been left behind in the distillation process and enter into combination with absorbed oxygen. If, however, such charcoal be freely exposed to air, the external portions speedily lose this property, owing to the pores becoming saturated with air, but it will regain its pyrophoric character if powdered so that the internal layers are enabled to absorb oxygen. As the process of chemical combination only goes on in the interior of a heap, the best way to arrest it is to spread the charcoal out, since attempts at ventilation by blowing or drawing air through the mass will only result in increasing the combustion. Every time the charcoal is broken up the danger of ignition will recur, down to the time it is ground to powder, but powdered charcoal once "killed" by exposure to air never regains its pyrophoric properties.

Hard coals, brown coals, and the like are subject to two dangers, explosion and ignition, each having a separate cause. Explosion is due to the liberation of fire-damp following on a decrease in atmospheric pressure, whereas ignition results from the oxidation of the iron pyrites contained in the coal, when exposed to the action of oxygen and moisture. The danger is the greater the finer the state of division of the coal, and coal stacked above ground is particularly liable. Attempts made to reduce the danger by ventilating the stacks have failed in this case also, on account of the increased amount of oxygen thereby introduced into the interior of the mass, and accordingly the coal is stacked as tightly as possible in order to exclude air. Strangely enough, the practice of ventilating the coal bunkers of ships has not been altogether abandoned, notwithstanding Liebig's impressive warning given as far back as 1866, and neglect in this particular has frequently led to lamentable fatalities. Since 1865 no less than ninety-seven coal-laden vessels have been destroyed, and the lives of some 2,000 seamen sacrificed through spontaneous ignition of the cargo.

Mining Machinery.

We are in receipt of a copy of the 1896 catalogue of the Nelsonville Foundry and Machine Co., of Nelsonville, Ohio, a first-class plant under the superintendency of Mr. L. D. Howard, a gentleman of many years' experience in the manufacture of mining and conveying machinery. The company announces through its advertisement in this journal its ability to furnish first-class mining machinery of latest design for hoisting, haulage, ventilation, cleaning, sizing, conveying, etc., etc. The catalogue just mentioned consists of 170 pages of illustrations and text descriptive of the products of the Nelsonville shops, together with a number of pages of useful tables, formulae and data. It should be in the office of every mine manager.

THE COLLIERY ENGINEER

......AND......

METAL MINER.

WITH WHICH IS COMBINED THE MINING HERALD.

Established 1881. Incorporated 1890.

PUBLISHED MONTHLY AT SCRANTON, PA.

Entered at the Post-Office at Scranton, Pa., as second-class matter.

THOS. J. FOSTER, RUFUS J. FOSTER, MINING ENGINEER, } EDITORS.
WILLIAM TATE, ASSISTANT EDITOR.

THE COLLIERY ENGINEER COMPANY, PUBLISHERS.

DENVER OFFICE, 502 Boston Building.
PROF. ARTHUR LAKES, Assist. Editor in Charge.
POTTSVILLE, PA., OFFICE, 12, Morris Building.
BAIRD HALBERSTADT, E. M., Special Representative.

TERMS.

Subscription, (Postage in the U. S., Canada, or Mexico, prepaid.) **$2.00 a Year.**

To Foreign Countries in the Universal Postal Union, $2.50.

THE COLLIERY ENGINEER AND METAL MINER and HOME STUDY, $3.00 per year.

Remit by P. O. Order, Express Money Order, Bank Check or Draft or Registered Letter.

P. O. Orders.—You can buy a Money Order at your Post-Office payable at the Scranton Post-Office.

Express Money Orders can be obtained at any office of the American Express Company, the United States Express Company, and the Wells, Fargo & Co.'s Express Company.

Registered Letters.—If a Money Order Post-Office, or an Express Office is not within your reach, your Postmaster will register the letter you wish to send us on payment of eight cents.

We Cannot Be Responsible for money sent in letters in any other way than by one of the four ways mentioned above.

EXPIRATION OF SUBSCRIPTION.

The date after your name on the wrapper of THE COLLIERY ENGINEER AND METAL MINER shows to what time your subscription has been paid.

RENEWALS, ETC.

If you do not want THE COLLIERY ENGINEER AND METAL MINER continued for another year after your subscription has run out, notify us by postal card to discontinue it. The courts have decided that subscribers to newspapers who do not order their paper discontinued at the expiration of the time for which it has been paid, are held liable for the payment of their subscriptions up to the date when they order the paper discontinued.

NOTICE OF DISCONTINUANCE.

THE COLLIERY ENGINEER AND METAL MINER is sent to subscribers until an explicit order for its discontinuance is received by us, and all payment of arrearages is made, as required by law. *Papers returned are no notice of discontinuance, as we cannot tell where they are from.*

CHANGES OF ADDRESS.

A subscriber wishing to have his address changed should be careful to give his *former* as well as his present address; otherwise we cannot find his name on our mailing list.

All communications should be addressed,

THE COLLIERY ENGINEER COMPANY,
Coal Exchange,
Cable Address—"Retsof, Scranton." Scranton, Pa.

DAVY LAMPS.

THAT the Davy lamp is an unsafe lamp for miners has been proven time and time again to the satisfaction of all intelligent mining engineers and superintendents. That, when first invented by Sir Humphrey Davy, the Davy lamp was far in advance of any other means of lighting gaseous mines, we cheerfully admit, and join with the mining fraternity generally in honoring the memory of the great inventor. That it was the foundation on which all subsequent lamps, including the best now on the market, were built, is a matter that cannot be disputed. But *why* miners will insist on using the most primitive lamp made and will ignore the discoveries and inventions of late years, is something we cannot understand.

The Davy lamp is not only behind the times, but is absolutely unsafe under the conditions existing in coal mines to-day. When it was invented the velocities of air currents were much below those of to-day, and a velocity of six feet per second was an exceptionally high one, if ever attained. Under such conditions the "Davy" was comparatively safe. Miners, to-day, who would protest most vigorously, and rightly, against a sluggish air current, demand Davy lamps and refuse to use better and safer types.

We have personal knowledge of instances where mine managers have tried to introduce a safer type of lamp, and have failed on account of the miners refusing to use any but the "Davy." The unreliability of the Davy lamp was very forcibly impressed on the writer on the first ultimo. On that day he was in State Mine Inspector Brennan's office at Shamokin, Pa., when a telegram was handed to the inspector announcing that five men had been burned by an explosion of gas at Buck Ridge colliery. The inspector immediately ordered out his carriage and invited the writer to accompany him to the colliery. On arrival there it was found that two of the five men were fatally injured, and the other three seriously.

Investigation showed that in a group of three breasts or chambers, worked on a pitch of 65 or 70 degrees, the inside breast, which was driven up only 23 feet above the first heading, or aircourse, was full of practically pure fire-damp. The two breasts outside had been swept clear of gas by a vigorous current of air, but the men working them were not allowed to begin work until the gas was dislodged from the inside breast. These men, rather than lose time, tendered their services to assist in changing the location of a hand fan and in putting up a couple of lengths of small box piping up the breast. Five men were in the heading at the inside rib or manway of the breast containing the gas. All of them had Davy lamps, and, as a good current of air was flowing through the heading and past the body of gas, they felt safe. The pushing of a length of pipe up the breast dislodged a small quantity of gas, which was naturally forced down to the heading, where it mixed with such a quantity of air as to make it inflammable. The men had their lamps swung from their belts and as they moved around they naturally swung so that the flame passed through the gauze and ignited the gas. There was a burst of flame which scorched them and set their dry clothing on fire, and the burning clothing caused the most serious injuries. The main body of gas in the breast was too pure to ignite. The gas that ignited did not explode, it merely flashed. An examination of the lamps used by the men showed that all were in perfect condition. Thus, we have undoubted evidence of a serious and fatal accident directly due to a Davy lamp passing the flame in an atmosphere charged with inflammable gas.

There are improved safety lamps on the market, which have been severely tested, both experimentally and practically, and which have demonstrated their perfect safety by automatic extinguishment under such conditions, and which will not pass the flame under any velocity existing in mines. These lamps are known to intelligent mining men. Most operators are willing to supply them if the miners will use them, as they desire to protect their employes and property. In most cases the continuance of the use of the Davy lamp is due to the prejudices of the miners, and the sooner the more intelligent miners convince their obstinate brethren of the foolishness of refusing to accept the better and safer lamps, the better it will be for them.

The bituminous miners of Pennsylvania do not use the Davy lamp. They united with the operators and inspectors in having their use condemned by law. In this they showed themselves in advance of the anthracite miners, and they profit by this advance in securing greater safety.

UTILIZING NATURAL FORCES IN MINING.

IN a paper read before the Engineering Association of the South, Mr. Tyler Calhoun describes how the forces of nature are utilized by the Tennessee Coal, Iron and Railroad Co., at the Thomas mines.

The output of the mines, from a three ft. seam which outcrops on the mountain side, is from 800 to 1,000 tons per day. The inside haulage is effected by mules, but from the mine mouth to the chutes the loaded cars are moved by gravity, and the empties are returned by the same means. The arrangements for dumping the cars and opening the end gates are also automatic. Nos. 1 and 2 mines are practically self-draining, by gravity. No. 3 and part of No. 2 mine are largely in a depression into which considerable water runs during wet seasons. There is a large sump arranged at the lowest point in this basin in which is accumulated the water from over fifty acres of worked out territory. This water is taken out through two siphons, each 1,200 ft. long, one of which is 2 in. in diameter, and the other 3 in. The summit over which the water is run is only about six feet above the ordinary level of the water in the sump, but it is 600 ft. distant from the sump.

Even in mining the coal, advantage is taken of natural forces. Mr. Calhoun states that the more intelligent miners will, when conditions are favorable, undermine their coal three or four feet and let it stand in that condition over night, when it is found that the pressure of the overlying strata has broken down the coal, or has loosened it so that it is easily wedged down, thus saving the miner about five cents per ton in getting the coal and ensuring a much smaller percentage of slack.

To get the coal from the chutes to the railroad, 1,035 feet lower in the valley, a self-acting incline is used, over which two cars, holding eleven tons of coal, are run in a trip. These cars are set on a slope so that their tops are level when on the average grade of the incline. They are hopper bottomed, and the bottoms each consist of two swinging doors held in place by chains wound on a two-inch rod extending through the car and controlled by a ratchet, like those used on an ordinary railroad drop-bottom car.

A description of the incline is as follows: Its steepest grade, at the top, is 46 per cent., falling to 14 per cent. at the bottom, the average throughout the whole incline being 22 per cent. Its horizontal length is 4,700 ft. The rope used is a patent locked steel rope, 1¼ in. in diameter, and 4,900 feet long. Its tensile strength is placed at 67 tons, and safe working load at 13.4 tons. It is worked at about 7 tons direct strain on the steepest part of the incline. The rope carriers are 8 in. cast iron rollers placed 40 ft. apart. The drums are 7 ft. in diameter, and the guide sheaves, leading the rope on and off the drums, are of the same diameter. The movement of the trips is controlled by a combination of levers and a powerful screw, by means of which one man can stop the machinery, from full speed, so quickly that the rope, which is wrapped around the drums three and one-half times, can be made to slip in the grooves. The drums are set vertically, and in line with the incline tracks; and the brake bands, one on each drum, have their bearings on two cast iron rims that are bolted to the top of the drums, the bolt holes being slotted to allow for expansion of the brake rim without injury to the drum.

The shafts of the drums are coupled with extension shafts, which extend about nine feet above the drums, at which elevation they carry two spur wheels; these gear with two pinions, on two other shafts known as the fan shafts, in the ratio of 31 to 7. The fan shafts are carried in cup bearings that rest on girders just above the drums; these shafts have also two other bearings, one just below the pinions and one at the top. Between the pinions and the tops of the shafts are the fans, eight feet in diameter, with four wooden blades each; these fans act as regulators of the speed of the incline machinery. The regulation is practically perfect, the runners simply letting off the brakes gradually at the start, until the resistance of the atmosphere on the fans balances with the motive power of the incline, after which the fans regulate the speed to a nicety, until it becomes necessary to put on brakes at the end of the trip.

The incline track is laid with 30 pound steel rails, to a guage of 4 feet. It is a three rail track, except at the center, where the trips pass on a double track, and at the lower end, where they run on a single track, through an automatic switch, which each descending trip throws open for the following ascending trip.

From the foot of the incline the loaded incline cars run out to the railroad chutes by gravity, and return empty by the same means.

The coal is screened in the chutes by gravitating over a series screen composed of four separate screens each five feet in length, with a drop of from two to six inches from each screen to the one below it. This turns the lumps over and shakes up the coal so as to ensure very thorough cleaning. The slope of the screens is adjustable by means of threaded rods by which they are suspended from the track stringers above. The screen bars used are of the diamond top pattern, which have been found to be very efficient. From the time of dumping until loaded in railroad cars or into charging cars for the coke ovens, the coal is moved only by gravity. The charging cars, loaded with slack, run by gravity to the coke ovens, and are hauled back, empty, by mules.

The railroad tracks in the yard below the chutes are also arranged so that after the locomotive places the cars on the storage tracks, they are handled under the chutes, through the yard and over the track scales entirely by gravity.

In concluding his paper, of which we publish only a synopsis, Mr. Calhoun says:

"Thus it may be perceived that gravitation plays no unimportant part in the handling of coal at Thomas mines. This accommodating force stands ready to do many other money saving jobs for us at this place, when sufficiently urged. The regulating fans at the drum house consume forty or fifty horse power, which could at least be made to ventilate the mines.

"The outflow of water from the three mines, at the dryest time we have had for several years, was twenty-five gallons per minute. A few days since, after several days' rain, the flow was 350 gallons per minute, and a regular flow of 100 gallons may be depended upon in all ordinary weather. A hundred gallons per minute, led down the mountain in a pipe alongside the incline to the ovens, would easily give fifteen effective horse-power, with which a washing machine or a haulage plant on the ovens could be operated.

"These suggested utilizations of force may be more or less chimerical, on account of practical difficulties, but they serve to show that, to an engineer at least, many interesting problems will present themselves in connection with mining work."

THE GAS ENGINE FOR MINING WORK.

THE gas or gasolene engine for mining work is a mechanism that, as a rule, is not appreciated by mine managers.

We do not believe that for general use or heavy service it will ever approach the steam engine in point of efficiency or economy. But there are many instances in mining operations where it can be used to decided advantage.

For instance, there may be a fan located on an outlet some distance from the main plant, and the question of conveying steam to the engine through pipes has been settled as impracticable. The erection of a steam plant near the fan may be impracticable or too expensive in first cost and maintenance, and either electricity or the gas engine must be adopted. Electricity may not be advisable for local reasons. Then the gas engine is the motor. It is self-contained, and can be safely run by any intelligent man. The entire ventilating plant can be isolated, and as the gas for propelling the piston is generated in the cylinder, one man can manage the plant.

Again, for temporary use in running a pump in dip workings that will not last long enough to warrant the introduction of compressed air or electric power, the gas engine is a success. In fact, wherever a comparatively small power is needed at isolated points, a portable gas engine is an excellent motor. There is no doubt that the mining industry, with its numerous instances where from five to twenty horse power is temporarily required at isolated points, will in the near future employ hundreds of gas engines, particularly if their cost can be brought down to figures that will enable them to compete with other motors. We understand that gas engines are now on the market at reasonable prices, and if this is the case, we predict a demand for them, at mines, which will grow in proportion to the efforts of the manufacturers in introducing them to the mine managers.

MINE VISITING.

THE visiting of the interior of mines by men and women, to gratify idle curiosity, is a practice that cannot be too harshly condemned. They learn nothing from such visits, interfere with the work, and frequently run into great danger through their ignorance and unfamiliarity with mines. All they gain by such visits is an unpleasant sensation if they descend a shaft, and what to them is a novel experience in "darkness made visible." They can get the same unpleasant sensation by riding on a fast elevator from the upper floor of a sky scraping building, and can see just as much by going into a damp dark cellar on a dark night with no other illuminant than a small candle. Both of these trips can be made safely and without ruining clothing. Mine visitors who are inspired merely with idle curiosity and a desire for a novel experience are a nuisance to mine managers, and are frequently a source of danger not only to themselves, but to the employes. In his bulletin on Mining Safeguards (published on another page) Mr. Harry A. Lee, Commissioner of Mines of Colorado, denounces the practice of mine visiting by persons unaccustomed to mines, and suggests the enactment of a law prohibiting all persons but employes and those having business in a mine from entering. This is a good suggestion, and is one that will meet the approval of mine managers generally. Such a law would not prohibit mining engineers and mine officials visiting mines, because they have business in them. The mining engineer or mine official who visits a mine learns something, and is able to note peculiarities in the seam or vein and strata, in the methods of timbering, mining, drainage, haulage, ventilation, etc., etc., which would be entirely unnoticed by the novelty seeking visitor. The visiting of mines by mining engineers and mine officials cannot be too highly commended, but the reverse is the case when non-mining people indulge in the practice.

Catalogues, Etc., Received.

The Boston Belting Co., 256 to 260 Devonshire St., Boston, Mass., has just issued a convenient and handsome catalogue of first class mechanical rubber goods. It is a model of convenience and typography.

The Jeffrey Mfg Co.'s new catalogue of coal mining machines and mine equipments has just been received. It is an artistic illustrated publication of such a high grade as will ensure its being appreciated and saved by those fortunate enough to secure a copy.

The Norwalk Iron Works Co.'s new publication descriptive of the well known Norwalk air and gas compressor is a handsome illustrated pamphlet, which, besides describing the products of the company, contains considerable matter on the use of compressed air that is of value to all mine officials.

"Lidgerwood Cableways" and "The Lidgerwood Rapid Unloader" are the titles of two interesting and convenient pamphlets published in the usual excellent style of the Lidgerwood Mfg. Co. They are well illustrated and very interesting.

The Knowles Steam Pump Works' new catalogue of electric power pumps illustrates and describes "up to date" pumping machinery and contains some valuable rules and tables for the use of mine managers.

"An Era in Boiler Performance" is the title of a new publication of the Stirling Co., of Chicago, Ill. It contains a report on an evaporative test on three Stirling boilers at the Waltham Bleachery and Dye Works, Waltham, Mass., made on April 7th, by Dean & Main and D. P. Jones, engineers.

The General Electric Co.'s new catalogue of electric haulage, power and mining machinery is the handsomest catalogue yet issued by that enterprising company. It is something more than a mere illustrated catalogue. It is in fact a bound volume of illustrated articles on electrical mining machinery reprinted from THE COLLIERY ENGINEER AND METAL MINER, and other periodicals, together with a large amount of other matter. Typographically it is very fine and is well worthy a careful reading and preservation.

"Manilla Rope for Transmission and Hoisting" is the title of an artistic and interesting publication issued by the C. W. Hunt Co. of 45 Broadway, N. Y. It is a unique publication and one that is of more than passing interest.

Taken all through the publications mentioned above are the finest of their kind ever received at our office during any one month.

BOOK REVIEW.

THE STORY OF A PIECE OF COAL, by Edward A. Martin, F. G. S. This is a small volume of 168 pages, bound in flexible cloth, and uniform with other books published by the Messrs. D. Appleton & Co., in the series known as "The Library of Useful Stories." It is on the whole a very meritorious production, and we heartily recommend it to students and others dsirous of knowing something more of coal than the fact that they pay retail dealers a high price for a short ton of it. The department on the Fauna and Flora of the coal measures is especially good for so small a work, and those portions on the composition of coal, and the safety lamp are well worth reading. The chapter on "The Coal Supplies of the World," makes the grievous error of stating that Pennsylvania anthracite is "in inexhaustible quantity." We wish it was. Again, in speaking of the bituminous seams, it is stated that "a remarkable seam of coal has given the town of Pittsburg its name." This should be reversed. Pittsburg was a town under its present name long before the coal seam was named, and it derived its name from the author's distinguished countryman, Wm. Pitt, and the Pittsburgh seam is indirectly named after him. Otherwise the chapter is very good, and judging from the preface the author is not responsible for these two errors, which do not affect the value of the book to any marked extent. It is a remarkably cheap book, being sold by the publishers for forty cents.

SLOVAK GRAMMAR. FOR ENGLISH-SPEAKING STUDENTS. By Charlton Dixon, Philipsburg, Pa. Paper cover, 134 pages. Price, $1.25.

This book is the production of a mine foreman who has recognized the necessity of a knowledge of the Slovak language. On his endeavoring to get books treating on the subject, he found that he could only get German works. Being a good German scholar, he purchased the best text-books on the subject in that language, and translated the necessary matter into English, compiling and arranging it in the most convenient manner. Besides, he added a considerable amount of information that came to him in the course of his researches, which tends to make the book complete. The book was published and endorsed by the publishers, *American-Slavonic Gazette*, the leading Slovak paper in America. It is for sale by the author.

TAXATION. We have received from Mr. Geo. A. Schilling, Secretary of the Bureau of Labor Statistics of Illinois, copies of the advance sheets of the introduction and supplemental chapter of the second edition of the Eighth Biennial Report. These sheets take up the question of the present mode of assessments, and show that great injustice is done, particularly in large cities, by unequal taxation by which progressive business men, manufacturers, etc., as well as small property holders are unjustly discriminated against. The pages sent us are very strong, and the reforms proposed therein are endorsed by many of Chicago's most responsible business men.

FIFTH ANNUAL REPORT OF THE BUREAU OF LABOR STATISTICS AND MINES OF THE STATE OF TENNESSEE, FOR THE YEAR 1895, issued by Mr. F. P. Clute, Commissioner of Labor and Inspector of Mines, is a very complete report when the difficulties under which Mr. Clute labors are taken into consideration. It would be a much more valuable statistical document if the laws of Tennessee compelled all mine operators to furnish the mine inspector with the same statistics as the Pennsylvania inspectors receive. These statistics are of a nature that we can see no reason for some of the operators withholding.

DEPARTMENT OF GEOLOGY AND NATURAL RESOURCES OF INDIANA. TWENTIETH ANNUAL REPORT, 1895. This report, issued by Mr. W. S. Blatchley, State Geologist, is mainly a geological report, to which are added the reports of the Inspectors of Mines, and the reports of the State Supervisors of Oil Inspection for the years 1894 and 1895, and a paper on The Crawfishes of Indiana, by W. P. Hay, zoologist. It is an octavo, cloth bound volume, of over 500 pages.

IOWA GEOLOGICAL SURVEY, VOL. V. ANNUAL REPORT FOR THE YEAR 1895. This is a handsome volume of over 400 quarto pages, issued by Prof. Samuel Calvin, A. M., Ph. D., State Geologist, and H. Foster Bain, Assistant State Geologist. It is profusely and well illustrated, and as a whole is one of a series of reports that will eventually prove of great value to the state of Iowa.

Resignation of Inspector J. E. Roderick.

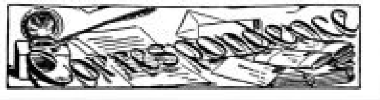
Mr. James E. Roderick of Hazleton, Pa., who was appointed mine inspector of the Fifth Anthracite District of Pennsylvania, last fall, has tendered his resignation, to take effect as soon as his successor can be selected. Mr. Roderick has resigned to accept the position of general superintendent of Mr. A. S. Van Wickle's collieries. His resignation at this time occasioned considerable surprise among his friends and acquaintances throughout the region, as this is the second time he has resigned as inspector to accept a position with private parties. Some years ago he resigned the inspectorship to accept the superintendency of Messrs. Linderman & Skeer's collieries, a position which he filled with signal success up till last fall. During his first incumbency of the inspectorship he made a record as one of the ablest and most conscientious of the state's officials. His ability as a mining man and his evident fitness for an important executive position soon attracted the attention of Messrs. Linderman & Skeer, who offered him a handsome increase over the salary the state paid him, and naturally he accepted the offer. Last fall, being aware that the Stockton collieries would probably be abandoned in a few months, he became a candidate for the position he had formerly resigned, and after a hard fought competive examination, he was recommended by the board of examiners for appointment. He had only served a few months of the term for which he was appointed, when Mr. Van Wickle, who is thoroughly familiar with his ability as a mine manager made him an offer which he wisely accepted. In this change, the state loses the services of an inspector who ranks in ability and general mining knowledge with any inspector of mines in the world, and Mr. Van Wickle secures one of the most competent mine managers in America.

Mr. Cyrus Robinson has resigned as engineer and manager of the mining department of the Jeffrey Mfg. Co., of Columbus, Ohio, and accepted the position of manager of the J. H. McEwen Co., with headquarters in New York city.

"A Few Facts and Figures of Interest to Mining Men" is the title of a leaflet issued by Charles Henry Davis, C. E., and T. W. Sprague, S. B., of 99 Cedar St., New York, who are consulting and supervising engineers making a specialty of the thorough examination of mines, mining properties and water powers and reporting on the best and most economical means for power transmission.

At the commencement exercises of the graduating class of '96 from the Steven's Institute of Technology, Hoboken, N. J., held June 18th, 1896, the degree of Doctor of Engineering was conferred by the faculty and trustees of Steven's Institute, upon Commodore George W. Melville, Engineer-in-Chief of the United States Navy, in appreciation of the excellent engineering work performed by Commodore Melville for his country and the advancement of the science of steam engineering, well illustrated in the world wide famed "White Squadron." Only once before in the twenty-five years' history of the Steven's Institute has the degree of Doctor of Engineering been conferred, and then upon Professor R. H. Thurston of Rhode Island, who formerly occupied the chair of Mechanical Engineer in Steven's Institute, and is now director of Sibley College, Cornell University.

The Garlock Packing Co., of Palmyra, N. Y. and Rome, Ga., have closed their office at Omaha, Neb. and opened a new office and salesroom at 1713 Wazee St., Denver, Col. Mr. Chas. B. Whitman, who is manager of the same, is well and favorably known by the trade and needs no introduction at our hands. The principal salesrooms of the company are at New York, Chicago, Philadelphia, Denver, St. Louis, Pittsburg and Boston. The Garlock Packing Co. are manufacturers of high grade packings for steam, water, gas, ammonia, etc. They manufacture water proof hydraulic packing, also high pressure packing which is especially adapted for high pressure work on locomotives, stationary and marine engines, and is designed to insure long service. Samples, catalogue and prices will be mailed on application. Address the nearest office.



This department is intended for the use of those who wish to express their views, or ask, or answer, questions on any subject relating to mining. Correspondents need not hesitate to write for supposed want of ability. If the ideas are expressed, we will cheerfully make any correction in composition that may be required. Communications should not be too lengthy, and personal reflections should be carefully avoided.

All communications should be accompanied with the proper name and address of the writer—not necessarily for publication, but as a guarantee of good faith.

The Editor is not responsible for views expressed in this Department.

☞ Correspondence should be in as simple language, and as free of technical terms and formulæ as possible, consistent with clear solution.

Questions on subjects not directly connected with mining will not be published.

Ventilation.

Editor Colliery Engineer and Metal Miner:

SIR:—Please insert the following question in your valuable journal for answer by some of your correspondents:

The upcast and downcast of a mine are each 1′x12′x 400′, connected by three airways, each 6′x8′x750′. The water gauge is 1 inch. A fall occurs in one of the airways, closing off the current, the horse-power remaining constant. What change will take place in the quantity passing and in the water gauge? Yours, etc.,

STUDENT, Uniontown, Pa.

June 3d, 1896.

Methods of Working.

Editor Colliery Engineer and Metal Miner:

SIR:—I would be glad to hear from your correspondents as to the methods they would adopt for working a coal seam where conditions are as follows: Dip, about 20 to 25 degrees, regular, with no basin. Seam, cut off by fault 2,500 feet from outcrop. Coal, 6 feet thick. Character of coal, hard bituminous. Bottom bench of 12 inches, rather soft. Roof, 18 inches of draw slate, hard to hold; above that, a slippy shale, treacherous. Fire-damp given off. Considerable water. Product to enter domestic coal market, as it will not coke. Yours, etc.,

R. M. S. B., Henry Ellen, Ala.

May 20, 1896.

Explosives.

Editor Colliery Engineer and Metal Miner:

SIR:—I would be pleased if some of your able contributors would give me some reason why dynamite will not explode under the following circumstances: I have a well 5 inches in diameter and 139 feet deep, with 120 feet of water, at the bottom of which I tried to explode a stick of dynamite with a magnetic battery. The cap exploded, but the dynamite did not. I then took the dynamite out and tried it on the surface, and it ex-exploded all right. I then put two caps in one stick and put it in the well with the same result as before; the caps exploded, but the dynamite did not. I also tried it on the surface, and it exploded all right. I then fixed up a cartridge of powder, put it in the well without any dynamite, and it exploded all right. Now, the question is, why would the dynamite not explode, while the powder and caps would? W. A. GRAY,

May 23, 1896. Horse Creek, Ala.

A Question of Methods.

Editor Colliery Engineer and Metal Miner:

SIR:—In your May issue there are three solutions to the "tree" problem, a geometrical, an algebraic, and an arithmetical solution. The geometrical and algebraic solutions were perfectly clear, succinct and comprehensible, except that Mr. McTaggart might have simplified his solution by eliminating the unknown quantity y and proceeded with x, as it is solvable very easily with x as the only unknown quantity. The difficulty is with the last solution submitted by Mr. Duncan, of Dunbar, Pa. Will you or Mr. Duncan kindly explain the arithmetical reason for dividing the difference of the squares of the perpendicular and base by twice the perpendicular? What mathematical authority is there for solving the question this way? I think the formulas are:

1. $\sqrt{\text{Base}^2 + \text{perpendicular}^2} = \text{hypothenuse}$.
2. $\sqrt{\text{Hypothenuse}^2 - \text{Base}^2} = \text{perpendicular}$.
3. $\sqrt{\text{Hypothenuse}^2 - \text{perpendicular}^2} = \text{base}$.

By what rule of arithmetical reasoning does Mr. Duncan solve this problem? His formula is:

$$[(120^2) - 100^2)] \div 2 \times 120 = \text{ans.}$$

Why does he divide the result of the brackets by 2×120, which is twice the perpendicular? An explanation will be gratefully appreciated by many of your readers. Yours, sincerely, J. E. WATKINS,

May 27, 1896. Taylor, Pa.

Broken Shaft.

Editor Colliery Engineer and Metal Miner:

SIR:—Please publish the following as my solution of Mr. Noll's question regarding the broken shaft, in March issue:

QUES.—At Kangley Mine we have an endless rope system of haulage with 2½ miles of ¾″ crucible steel wire rope worked with an engine of the Litchfield pattern with 12″x20″ cylinders and a 7 foot cog-wheel, to which is attached a 4 foot drum. Placed 3 feet behind this drum is another drum which is equipped with Walker's slide rings. This drum is not connected with the engine, but is worked by the rope passing from the forward drum back to the Walker drum with five laps, thence to the tension wheel, and on to the inside. The shaft, which is a six-inch one, has broken at two different times within four months. What would cause the breakage of such a large shaft, it being only 4 feet long? Could the variations in the grooves of the drum made by the wear of the rope cause the fracture?

If the drums were not set true with each other, would that cause the break?

ANS.—The rope that pulls the loads has the greater strain, and will groove the drums deeper than the rope on the end that leaves the drums, thereby making the circumference of the drums smaller on the end that receives the ropes than they are on the other end (especially is this so if the drums are wood lagged). This forms a gigantic differential pulley, and the ropes must either slip or the shaft must break. There are five laps on the drums, making ten ¾″ steel ropes, whose combined breaking strain would be 220 tons for 7 strand rope. Hence, the shaft must break before the rope.

J. S. CHEW, What Cheer, Ia.

May 22, 1896.

Algebra.

Editor Colliery Engineer and Metal Miner:

SIR:—Please publish the following in your next issue in reply to J. P. Wolfe, Big Stone Gap, Va.

A and B dig a ditch 100 feet long for $100. Each receives $50.00; but A receives 25 cents per foot more than B; how many feet does each dig?

ANS.—As A receives 25 cents per foot more than B, it follows that A will dig ½ of ¼ of 100 feet less than B. Therefore, if we take ½ of ¼ of 100 feet from 50 feet (which is half the length of the ditch), we will then have the amount of feet to be dug by A, which will be 50 — (½ of ¼ of 100) = 43.975 feet. The amount per foot will be found by dividing fifty dollars by the amount in feet of the ditch dug. Therefore, the amount per foot that A will receive will be $50.00 ÷ 43.975 = $1.13[illegible] per foot. Now, as B receives 25 cents per square foot less than A, it follows that he will dig ½ of ¼ of 100 feet more ditch than A. Therefore, the length of ditch in feet dug by B will be 50 + (½ of ¼ of 100) = 56.025 feet. The amount per foot will be found as in case "A." Thus, 50 ÷ 56.025 = 89[illegible] cents per foot. C. R. SCUBBAH,

June 12, 1896. Braceville, Ill.

Let x = number feet A digs.

$100 - x$ = number feet B digs.

$\frac{50}{x}$ = dollars per foot A receives.

$\frac{50}{100 - x}$ = dollars per foot B receives.

Then, since A receives 25 cents more than B, the equation becomes

$$\frac{50}{x} - \frac{50}{100 - x} = \tfrac{1}{4}.$$

Clearing of fractions,

$$20{,}000 - 200x - 200x = 100x - x^2.$$

Transposing and collecting, $x^2 - 500x = -20{,}000$.

Whence, $x = 250 \pm \sqrt{62{,}500 - 20{,}000}$.

$x = 250 \pm \sqrt{42{,}500}$.

$x = 250 \pm 206.15 +$.

$x = 456.15$ ft., or 43.85 ft.

The first is visibly not right; therefore,

$x = 43.85$ ft.

$100 - x = 56.15$ ft.

$\left.\begin{array}{l}\text{A digs } 43.85 + \text{ ft.}\\ \text{B digs } 56.15 + \text{ ft.}\end{array}\right\}$ Answer.

Respectfully yours,

JOHN G. SMYTH,

June 8, 1896. Wilkes-Barre, Pa.

[We have also received a solution similar to the latter from W. S. Cope, McDowell, W. Va.—ED.]

The Fifth and Higher Roots.

Editor Colliery Engineer and Metal Miner:

SIR:—To afford a comparison of the practical value of the different methods of extracting the fifth root, permit me to find, by the method I proposed in your March number, the fifth root of 21035.8, which root has already been found by the methods proposed by Ajax and Mr. Hannah. Let $b = 7^5$ = the fifth power of the trial root. Then,

$$K = 2\left[\frac{21035.8 - 7^5}{21035.8 + 7^5} + \tfrac{1}{3}\left(\frac{21035.8 - 7^5}{21035.8 + 7^5}\right)^3 + \tfrac{1}{5}\left(\frac{21035.8 - 7^5}{21035.8 + 7^5}\right)^5 + \right] = .2244302 +.$$

Substituting this value of K in the following equation, we have

$$x = 1 + \frac{K}{5} + \frac{K^2}{1 \times 2 \times 5^2} + \frac{K^3}{1 \times 2 \times 3 \times 5^3} + = 1.0459086 +.$$

$$\sqrt[5]{21035.8} = 7 \times 1.0459086 + = 7.321360 +.$$

Again to find the 10th root of 1,000. Let $b = 2^{10}$. Then,

$$K = 2\left[\frac{1{,}000 - 2^{10}}{1{,}000 + 2^{10}} + \tfrac{1}{3}\left(\frac{1{,}000 - 2^{10}}{1{,}000 + 2^{10}}\right)^3 + \tfrac{1}{5}\left(\frac{1{,}000 - 2^{10}}{1{,}000 + 2^{10}}\right)^5 + \right] = -.0237165266731 +.$$

Substituting this value of K in the following, we have

$$x = 1 + \frac{K}{10} + \frac{K^2}{1 \times 2 \times 10^2} + \frac{K^3}{1 \times 2 \times 3 \times 10^3} + \frac{K^4}{1 \times 2 \times 3 \times 4 \times 10^4} = .9976311574963 +.$$

Multiplying this value of x by 2,

$$\sqrt[10]{1{,}000} = 1.9952623149926 +.$$

It will be seen that the degree of accuracy attainable by the foregoing method is much greater than can be had by the use of a table of 6 figure logarithms.

Yours, etc., S. A. COREY,

June 10, 1896. Hiteman, Ia.

PRIZE CONTEST.

Prizes Given for the Best Answers to Questions Relating to Mining.

For the best answer to each of the following questions, the value of $1.00 in any of the books in our book catalogue, or six months' subscription to THE COLLIERY ENGINEER AND METAL MINER.

For the second best answer to each question, the value of 50 cents in any of the books in our book catalogue or three months subscription to THE COLLIERY ENGINEER AND METAL MINER.

Both prizes for answers to the same question will not be awarded to any one person.

Conditions.

First—Competitors must be subscribers to THE COLLIERY ENGINEER AND METAL MINER.

Second—The name and address in full of the contestant must be signed to each answer, and each answer must be on a separate paper.

Third—Answers must be written in ink on one side of the paper only.

Fourth—"Competition contest" must be written on the envelope in which the answers are sent to us.

Fifth—One person may compete in all the questions.

Sixth—Our decision as to the merits of the answers shall be final.

Seventh—Answers must be mailed us not later than one month after publication.

Eighth—The publication of the answers and names of persons to whom the prizes are awarded shall be considered sufficient notification. Successful competitors are requested to notify us as soon as possible as to what disposal they wish to make of their prizes.

Competition Questions for July.

QUES. 235. Can you suggest some new and improved arrangement by which we can dispense with the wire gauze cylinder in our new safety lamp? Do you think we could substitute for the meshes of the gauze an annular space between two short tubes? and if you do, show how a flame passing through a relatively long space of annular section would more effectively quench a flame than the fine wires of a mesh.

QUES. 236. Please look at a map of the North American continent and find for me the longitude of St. John's, situated on the easternmost coast of Newfoundland, and the longitude of Cape Flatte, situated on the westernmost coast of the United States; and having found the two longitudes, show what would be the time of day at St. John's when it was 12 o'clock, noon, at Cape Flatte. Please also explain how you calculate the time for St. John's.

QUES. 237. We have contracted to work a large royalty of 1,000 acres of very fine coking coal, and the whole of it, except a small patch where we have sunk the shafts, lies under a lake. The seam is 5 feet thick and pitches from the shafts in the direction of its greatest length at the rate of one foot vertical for every 20 feet horizontal. The rock above the seam is a soft slaty limestone, and admits much water, and on this account I hope you will repeat your former acts of kindness and explain to me with the help of a diagram how you think I should work this coal to keep the working face dry and avoid much expense in the general drainage.

QUES. 238. What system of pumping would you adopt, in working the seam mentioned in the former question, to discharge the water feeders of the mine into the sump at the bottom of the pumping shaft?

QUES. 239. It has been repeatedly observed that in a rectangular hoisting shaft where the cages are nearly as long as the shaft is wide, the horse power of the hoisting engines has to be increased in the proportion of the square root of the cubes of the velocities, instead of as you would think, directly as the velocities; as for example let v be the velocity, then the power required is in the proportion of $\sqrt{v^3}$. Can you give me a good reason for this singular increasing resistance that occurs in hoisting with large cages in rectangular shafts?

QUES. 240. A pound of coal, when burnt, develops 11,000 heat units, English. At what velocity, then, would this piece of coal have to move through space to store up as much mechanical energy in its mass as would be exactly equal to the mechanical equivalent of the heat units due to its combustion. State the result in miles per hour.

Answers to Questions which Appeared in the May Issue and for which Prizes Have Been Awarded.

QUES. 215.—In surveying around the bottom of a mountain, we made all the necessary levels and insets to determine the correct figure of a truly horizontal base that was just touched by the western side of an outcropping coal seam. From the plat we found the figure to be practically that of an ellipse, with its major axis coursing from south to north 6,012 feet, and the minor axis coursing from east to west for 2,842 feet. The mountain is 1,800 feet high. The coal seam is 4 feet thick, and is overlaid with a strong sandstone. We levelled our transit at a distance of 64 feet eastward of the eastern end of the minor axis, and with the center of the telescope at an elevation of 4 feet 1 inch above the calculated level of the base, the bottom of the coal seam here made an angle of elevation of 38° 26′, and the distance, measured in a straight line from the plumb point on the ground to the bottom of the coal seam, was found to be 1,025 feet. Now, I wish to know three things that I am sure you will calculate for me.

First—What is the pitch of the seam?

Second—What is the area of the seam?

Third—What percentage of this seam could be reasonably worked? Show with a sketch how you find the pitch.

We are sorry to say this question has again been attempted and all have failed. One gentleman sent in a good solution but he took the minor axis at 2,482 instead of 2,842. Another gave the contents instead of the area for the second request.—EDITOR.

QUES. 222.—In a mine shaft in course of being sunk an iron kettle full of water was hoisted from the bottom at a mean velocity of 6 feet per second. The kettle was cylindrical in shape and 3.5 feet in diameter and 3.5 feet deep, and by some unknown cause a round hole had been cut through the bottom, and it had a mean diameter of 3 inches. The result was that the kettle left the sump in the shaft bottom full of water and arrived at the top of the shaft empty, and by coincidence the discharge of water just ceased at the moment the kettle reached the surface. Now, I will be obliged if you will deduce for me, out of these facts, the depth to which the sinking has advanced.

ANS.—The contents of the kettle in cylindrical feet are $3.5^3 = 42.875$. The contents of the kettle in cylinders 3 inches in diameter and 12 inches in length are $42.875 \times 16 = 686$. The mean velocity of discharge is

$$\sqrt{\frac{3.5 \times 64.4}{2}} \times .62 = 6.5819 \text{ feet per second.}$$

The time of discharge is

$$\frac{686}{\sqrt{3.5 \div 2 \times 64.4} \times .62} = 104.2246 \text{ seconds.}$$

The height to which the kettle would rise to empty, or the depth of the sinking, is $104.2246 \times 6 = 625.3476$ feet.

P. J. WALSH, Lemont Furnace, Pa.

Second Prize, MORGAN D. ROSSER, Kingston, Pa.

QUES. 223.—In trying to find out the combustible substance that would give the best results in generating the flame in our new safety lamp, I have fallen across the following facts that completely puzzle me, and as I am afraid that any further attempts to solve the riddle would drive me to distraction, I will be obliged to you if you will show to me how it occurs that when two volumes of pure hydrogen combine with one volume of oxygen, more heat is given off than when one volume of marsh gas combines with two volumes of oxygen. One thing I have noticed that may help you to find an answer, and that is, the hydrogen and oxygen produce water that is a liquid, whereas the marsh gas and oxygen produce liquid water and a permanent gas, and, strange to say, coal gas that contains a high percentage of $C_2 H_4$ gives off less heat than $C H_4$, and oils, such as are burned in lamps, give off less heat per unit of weight than any of the gases under notice, and yet we know that a large percentage of energy is concealed somehow in burning these hydro-carbons, but it is not given off as heat, but I have no doubt you can tell me something that will remove the mystery.

ANS.—The calorific power of hydrogen is 34,462 and 2 parts of H unite with 8 times its weight of oxygen in burning to steam whose specific heat is 0.4805. Hence the maximum temperature of combustion or "heat given out" will be

$$\frac{34,462 - (8+1)(51.95 + 537)}{(8+1) \times 0.4805} = 6,743° \text{ C.} \quad (1).$$

In this a correction for the latent heat of steam 537° C., and for the difference between the specific heats of water and steam, 51.95 is made.

The calorific power of $C H_4$ is $\frac{(3 \times 8080) + 34,462}{4} = 14,678$ $\left(C = \frac{16}{16+4} ; H = \frac{4}{16+4}\right)$ and 1 part of $C H_4$ unites with 3.2 parts of 2 O_2 ($= 4 \times 16 = 64$) to form $2 H_2 O + C O_2$ in the relative weights of $(3.2 + 1) \times \frac{36}{80} = 2.01$, and $4.2 - 2.01 = 2.19$, whose specific heats are 0.4805 and 0.2164.

Hence,

$$T = \frac{14,678 - [2.01 \times (51.95 + 537)]}{2 \times [(2.01 \times .4805) + (2.19 \times .2164)]} = 4,685° \text{C.} \quad (2)$$

Hence we see from (1) and (2) that hydrogen develops the greater heat as stated.

CHAS. ED. BOWRON, Tracy City, Tenn.

QUES. 224.—All the plants in the vegetable kingdom of life are grouped under four distinct divisions, as Thallogens, Acrogens, Endogens, and Exogens. Will you, therefore, name for me a single example in each division that flourished during the Carboniferous period, and also a single example in each division of plants that are living now in your state or country?

ANS.—The four great divisions of the vegetable kingdom to which the question refers were represented during the Carboniferous period by such examples as are here given:

Sub Kingdoms.	*Representative Plants.*
Thallogens.	Lichens.
Acrogens.	Calamites.
Endogens.	Grasses.
Exogens.	Coniferae.

The sub-kingdoms in the vegetable world are now the same as they were during the Carboniferous period, and the four representative examples required for this state (Pennsylvania) are:—

Sub Kingdoms.	*Representative Plants.*
Thallogens.	Mushroom.
Acrogens.	Horse Tails.
Endogens.	Grasses.
Exogens.	Pines.

JOSEPH VIRGIN,
Mine Superintendent, Hosopple, Pa.

Second Prize, CHAS. E. BOWRON, Tracy City, Tenn.

QUES. 225.—A mine shaft is 3,000 feet deep, and I wish to know what weight a first-class steel rope, $1\frac{1}{2}$ inches in diameter, will safely carry in hoisting coal up this shaft.

ANS.—Weight of 19-wire strand plow steel hoisting rope, $1\frac{1}{2}$ inches in diameter, with hemp center, is 3.65 pounds per foot.

$$\frac{3,000 \times 3.65}{2,000} = 5.475 \text{ tons' weight of rope.}$$

Breaking load is 110 tons and safe working load with factor of safety $= 5$ is $\frac{110}{5} = 22$ tons.

$22 - 5.475 = 16.525$ tons gross weight cage and load.

CHAS. ED. BOWRON, Tracy City, Tenn.

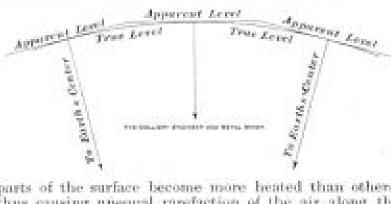
Second Prize, A. W. EVANS, Petros, Tenn.

QUES. 226.—Will you explain to me, with a neat drawing, how it occurs that the horizontal planes at the two ends of a perfectly straight line of sight are never parallel, although the telescope is set truly level at the ends in question? Again, while you are busy, you might show me how it is that we cannot get a "perfectly straight" line of sight, and the longer that line is, the greater is the divergence. Further, make a bold finish by showing the reason why a sight made over a surface heated with the rays of the sun can never be trusted for accuracy.

ANS.—A line is said to be level (apparently), when it forms a right angle with the earth's radius or is tangent thereto. That the planes at the end of the line are not parallel is due to the spherical shape of the earth. The divergence of the planes from the apparent level depends upon the distance between them. When this distance is small, the angle of divergence will deflect so little from the apparent level that the planes seem to be parallel, but as a matter of fact, they are not.

The cause why a perfectly straight line of sight cannot be obtained is due to the rays of light passing through the air being curved downward. This downward curvature makes the point sighted to appear at a higher level than it actually occupies and the result is a broken line that will be somewhat longer than the true line, and the longer the line of sight the greater the difference.

The reason why a sight made over a surface heated with the rays of the sun cannot be trusted is that some



parts of the surface become more heated than others, thus causing unequal rarefaction of the air along the line of sight and consequently irregular refraction, that makes correct calculation impossible.

JOHN VERNER, Lucas, Iowa.

Second Prize, A. W. EVANS, Petros, Tenn.

QUES. 227.—To work a valuable coal seam, we must deliver onto the nearest railway with a branch road of our own, and as the surface is very uneven, and the possible duration of the seam does not warrant the making of cuttings and embankments, we will deem it a favor if you will advise us about the haulage we should make to be cheap in construction and efficient in action; and, if possible, please support your conclusions by reference to actual cases; and be careful to note that we have decided against every kind of locomotive traction.

ANS.—In this case, where the surface of the ground is very rugged in contour, I would for cheapness of construction and efficiency in action advise the construction of a wire rope tramway, on the double rope system. One of the chief advantages of this system is its capability of surmounting any grade. By using the Bleichert system you have a regular service and few stoppages for repairs and no interruptions due to atmospheric influences or any interferences on account of surface traffic. The expenses of operating are very low. Terminals can be established at the places most convenient for receiving and delivering. These facts just noticed prove the advantages of wire rope tramways where the grading is very irregular. The Bi-Metallic Mining Co. of Granite, Montana, has a tramway 9,750 feet in length, with a fall of 1,225 feet. The descending load develops 14 horsepower, which is used to run the crusher and elevator, capacity 250 tons in 10 hours. Cost of transportation 5 cents per ton per mile.

The Granite Mountain Mining Co. line at Rumsey, Montana, is 8,750 feet long, with a fall of 1,297 feet and develops over 14 horse-power. There is a span of 600 feet and from Fred Burr hill down to the mill at Rumsey, the grade is usually so steep as to fall 1' in 2'.

The Split Rock Cable Road Co. of Syracuse, N. Y., has in operation a line 16,500 feet long. Daily capacity 750 tons.

There exists in nature hardly a supposable difficulty, which would bar the introduction of this system of transportation. I would advise the owner of this valuable property to inaugurate a correspondence with the Trenton Iron Co., Trenton, N. J., and the Lidgerwood Mfg. Co., New York City.

A.W. EVANS, Petros, Tenn.

Second Prize, CHAS. E. BOWRON, Tracy City, Tenn.

QUES. 228.—Sometimes in mining, where the seam is situated above the drainage level of the district, water can be collected at the surface and conveyed down the shaft in pipes to do the work required in pumping, hauling and ventilating. This great water power is applied through the medium of hydraulic engines, in which a stream of high pressed water is projected onto reaction blades, whose surfaces are curved to secure total reflection instead of simple deflection. Now, to make sure that we all understand the explanation given, will you still further assist us by answering two questions?

First—What are the curves that are given to the inside surfaces of the reflecting cups, of the reflex water wheel?

Second—Show by a sketch and the necessary explanation, that with total reflection more power is obtained than could be secured with a deflection of 90° from the plane of the wheel's rotation?

ANS.—To obtain the highest efficiency the water must (1) enter and pass through the wheel without loss by friction and foam and (2) must reach the tail-race without absolute velocity. With cups which are merely radial vanes as in the California "Hurdy-gurdy" shown at A, the impinging jet of water N is deflected 90° to B and passes away with considerable velocity while with properly curved vanes shown at c, c', the jet is reflected 180°, thus producing as much energy from its reaction as from its action or double that of the radial straight vanes, their relative efficiencies being as 40 to 80% of the theoretical water power. For complete reflection the inside surfaces of the reflecting cups are parabolic.

Tracy City, Tenn.

The Care of Mine Mules.

Every mine manager and operator knows that notwithstanding the mule is a hardy and tough animal, he is afflicted with certain diseases, and is either incapacitated for a time at least, or dies, entailing considerable loss. Besides, many mine mules are totally incapacitated by injuries that if properly handled would result only in temporary disablement.

It is a recognized fact that in man, the highest order of animal life, the stomach is the most important factor in determining the degree of health enjoyed, and that if the stomach and digestive organs are in perfect condition, the bodily health of a man is good and he is physically able to do a large amount of labor. This same condition exists in mules and horses. The leading stock breeders of the world recognize this fact and profit by it.

We do not believe in advertising in this journal any preparation or appliance that has not received unqualified endorsement from some mine manager or other official in whom we have confidence, as we believe it is our province to not only publish such articles as are practical and useful to mining men, but to keep our advertising columns free from advertisements of a doubtful character. Before accepting an advertisement of "Nutriotone," we found that it had been used with excellent results for several years by the Lackawanna Coal Co., the Mt. Jessup Coal Co., the New York and Scranton Coal Co., and the Sterrick Creek Coal Co., all operating mines in close proximity to Scranton. Each of these companies unqualifiedly endorse the preparation.

Nutriotone is just what its name implies. It is a restorative and nutritive tonic,—a perfect food auxilliary. It is intended to supply the restorative elements generally wanting in ordinary feed in proper proportion to satisfy all the demands of the animal system. It thus improves the appetite, aids digestion, promotes assimilation, and increases the activity of all the functions of the animal economy, so that the tone of the system is maintained in normal condition, and possibilities of growth and development intensified. It is a natural remedy for the petty ills of the animal system in its restorative action, and prevents the graver ills and diseases by keeping the system in condition whereby attacks may be thrown off. It contains no mineral or organic poisons, but it consists of purely vegetable and mineral substances, which are so combined as to furnish the elements most needed to meet the demands of Nature. Its effect is such, that besides curing the diseases of mules and horses, it tones up their systems so that wounds and injuries heal up in remarkably short time. It may be administered in almost any quantity, and its use may be entrusted to any stableman of average intelligence. It is not intended for a food, but it should be used as a supplement, or in addition to ordinary foods.

Nutriotone is manufactured by the Thorley Food Co., of 40-42 Franklin Street, Chicago, Ill., and 312-313 Kirk Building, Syracuse, N. Y. In the Northern Anthracite Field, it is handled at present by the Weston Mill Co., of Scranton and Carbondale, Pa., and J. T. Nyhart, Peckville, Pa. It is a preparation that merits the attention of mine managers generally.

A Large Shipment of Electrical Mining Apparatus.

One of the largest single shipments of electrical apparatus was shipped recently by the Westinghouse Electric and Manufacturing Company to Great Falls, Montana. The shipment filled eight freight cars and the freight of that cargo to its destination amounted to $8,000.

The machinery will be used by the Boston and Montana Consolidated Copper and Silver Mining Company in the refining of copper and silver, and it is the largest machinery of its kind ever constructed for electrical refining purposes. The Boston and Montana Company is one of the largest copper mining concerns in the northwest.

Until a few years ago the copper produced in that country was not refined, but the copper matte was sent east, some of it to England, and then refined. Since the introduction of electricity into the refining process, the companies are in a position to compete with the East.

The Anaconda Mining Company purchased from Westinghouse some time ago seven 360 horse-power generators, of an output of 3,600 amperes each at 75 volts. Since these machines have been in operation the electrical process of refining has proved a great success. The machinery of the Boston Company will be driven by turbines from the waters of Great Falls.

The generators will be directly connected with the turbines. There are two of them, the largest ever made, each one of 1,100 horse power, at an output of 4,500 amperes and 180 volts. These machines were shipped in four freight cars, while the others were filled with detail apparatus, such as switchboard appliances, etc.

LEGAL DECISIONS ON MINING QUESTIONS.

Purchase by Cotenant of Mining Claims.—A tenant in common in a junior mining claim cannot buy in the title of a senior conflicting mining location, and assert it against his cotenant in the junior claim.

Franklin Mining Co. v. O'Brien (Supreme Ct., Colo.) 43 Pacific Reporter, 1,016.

Who are Not Fellow Servants.—The foreman of a stone quarry (or similar business) owned by a corporation, whose duties require him to exercise a general superintendence over the men, and to make and abrogate rules for their guidance, is not a fellow servant with one of the men.

Richmond Granite Co. v. Bailey (Sup. Ct., App. Va.) 24 S. E. Rep. 232.

Foreign Corporations May Buy and Sell Mining Lands in North Carolina.—A foreign corporation created for the purpose of mining and milling gold and other minerals in the state may, if not prevented by its charter, acquire and dispose of real property in the furtherance of the objects of its creation.

Barcello v. Hapgood, (Supreme Ct. N. C.) 24 S. E. Reporter, 124.

Measure of Compensation for Taking Mineral Lands for Public Uses.—Where, in proceedings to condemn a right of way across land, the evidence shows that part of the land is underlaid with mineral limestone, the extent to which that fact would tend to increase its market value is for the determination of the jury.

Sanitary Dist., Chic. v. Loughran (Supreme Ct. Ills.) 43, N. E. R. 359.

Trespass by Agent of Mining Company.—That the agent of a mining corporation, in mining coal in certain land, acted under the belief that the coal was owned by the company, when in fact it did not have even color of title, there being no mistake in the identity of the land, does not prevent trespass from being an intentional one.

Sunnyside Coal & Coke Co. v. Reitz (App. Ct. Ind.) 43 N. E. Rep. 47.

When Punitive Damages Will Not Be Allowed.—In the absence of evidence, in a personal damage suit against a coal company, of malice or reckless conduct on the part of the company indicating a purpose to have the employe injured, or of a reckless disregard of the safety of the person of the employe, the jury should be confined, in case they return a verdict against the company, to compensatory damages only.

McHenry Coal Co. v. Sneddon (Ct. App. Ky.) 34 S.W. Rep. 228.

Non-Liability of Coal Company for Injury to Employe.—An employer was not liable for the death of an employe by his falling after having been caught by a rope, part of a hoisting apparatus, which commenced to tighten up just as he was stepping over it, where the employe was fully acquainted with the apparatus, and it was working as usual on the day of the accident, and the employe had been forbidden, and his duties did not require that he should cross the rope.

O'Brien v. Staples Coal Co. (Sup. Jud. Ct., Mass.) 43 N. E. Reporter, 181.

Injunction: Mining Claim.—Where the showing made by a party desiring a preliminary injunction tended to prove that the other party, as lessee of the owners of an interest in certain mining claims, in which the complainant owns the largest interest, was working such claims without the consent and against the wishes of the complainant, and not dividing the proceeds in good faith, such showing is sufficient to justify the injunction, in the discretion of the trial court, on the ground that the acts of the other party constituted an exercising of exclusive ownership by one tenant in common.

Red Mt. Consol. Min. Co. v. Essler (Supreme Ct. Montana) 44 Pacific Reporter, 523.

Engineer and Excavation Contract.—A contract for the excavation of ground, for the erection of an inclined plane, provided that the work should be done "according to the directions and under the supervision of the engineer in charge of the construction of the incline" and the work was to be paid for at a certain rate per cubic yard. The Supreme Court of Pennsylvania held that, the contractor had no right of action, when the planes in the incline were so changed as to leave no earth excavation to be done, on account of the loss of possible profits, unless such excavation was directed by the engineer in charge.

Huckestine v. Nunnery Hill Incline Plane Co. 35 Atlantic Reporter, 1,108.

Location of Mining Claims in Town Limits.—The fact that land on which discovery and location of a mining claim are made is within the patent limits of a town will not affect the title of a locator, where it was known prior to the patent of the town that valuable mineral veins existed where the discovery and location were made afterwards.

In ejectment for a mining claim, where it appears that the discovery shafts of both parties are identical, evidence that the discoveries were made on lands patented prior to the dates of discovery of either party should be admitted, and the jury instructed if that fact were found, neither party could recover.

Moyle v. Bullene (Ct. App. Col.) 44 Pacific Reporter, 69.

Construction of Contract of Guaranty.—A party made a contract with another by which he gave the latter the sole agency of the sale of the output of a colliery, "at all points along the line of the N. R. Co., its branches and connections," and agreed to fill all orders for coal sold by such party to any persons at such points. The court held that coal delivered at one of the termini of the road on coal docks leased by it and under its control was within the contract, and therefore within a guaranty by a third party of payment by the second party of money becoming due thereunder. Also, that such contract could not be limited by parol to a particular kind of coal from said colliery.

Hutchinson v. Root (Sup. Ct. App. Div. 1st Dept.) 38 N. Y. S. Reporter, 16.

Deed of Trust on Mining Property.—Where the deed of trust on the property of a mining company does not cover the profits arising from the business, the profits accruing before the commencement of an action cannot be intercepted by the appointment of a receiver, and applied upon the mortgage debt, either directly or indirectly, through the use of same in the operation of the business. Where the deed covered all the "personal property of every kind, now owned or hereafter to be acquired and owned and used, in connection with and for use in developing and operating its said coal mines"; authorizing the grantor to take and use the rents and income until default, such mortgage did not cover the profits or proceeds of the business of mining, such as coal, coke, and iron mined and manufactured, and accounts from the sale of same.

Ala. Nat. Bank v. Mary Lee Coal & Ry. Co. (Sup. Ct. Ala.) 19 So. Reporter, 404.

Illegal Combinations.—A statute denouncing as void and prohibiting the enforcement at law or in equity of every contract whereby a combination of capital, skill, or arts is formed to create or carry out restrictions in "trade," or prevent competition in the sale or purchase of "commodities," renders void a lease by a coal company of a saloon on its property, in which the lessor covenants not to permit the sale of liquor, to any one else on its lands, and to issue to its employes checks in payment of wages, and to redeem all checks which the lessee might take in payment for liquors in consideration of the payment as rent of two-thirds of the profits of the business.

Texas & P. Coal Co. v. Lawson (Supreme Ct. Tex.) 34 S. W. Rep. 919.

Fire in Mine: Contributory Negligence of Miner.—Where a miner after having been notified of the outbreak of a fire in a mine in time to permit him to reach the shaft in safety, unnecessarily lingered in the mine, without notifying the men on the surface of his intention to do so, and it appears it would have been proper to stop a fan, which caused a circulation of air in the mine, or keep it running according to the location of the fire, a nonsuit, on the ground of contributory negligence should be granted in an action to recover for his death, as said miner had no right to assume that those in charge of the fan knew the location of the fire, though the jury also find that the negligence of the mining company in stopping the fan was one of the concurrent causes resulting in the death of such miner.

Pugh v. Oregon Imp. Co. (Supreme Ct. Wash.) 44 Pacific Rep. 547.

Assignment of Lease of Coal Mine.—A lease of a coal mine obligated the lessor not to lease to any other party any coal land to be operated during the life of the lease, and prevented the lessee from dividing his time or attention with any other mine for the reason that the rent depended upon the number of bushels mined. The lessee assigned his interests in the lease, and the assignees sought to restrain him from operating another mine, on the ground that he was still bound by the original lease. The Supreme court of Iowa held that no right to insist on the obligation between the lessor and the lessee was transferred to the assignees, but that they acquired only such rights as their assignor had under the lease, and were bound in his stead by the obligations. An assignment of a lease of a coal mine, with the good will of the trade, does not carry with it an obligation that the assignor will not again engage in the same business in the vicinity.

Fidlay v. Carson, 66 N. W. Reporter, 759.

Mining Claim—Failure to do Assessment Work, etc.—The owner of a placer mineral claim does not forfeit his right to same, so as to render it subject to relocation, by failure to perform the required annual assessment work during a time when adverse possession is held by another, when he commences an action for its recovery within the statutory time.

Where the owner of such a claim, which was erroneously included in a sale under a decree of court, moved his effects from the claim, and absented himself for two years, allowing the purchasers to work it without objection, while he knew that their title was invalid, and intending to claim it only in case their development rendered it profitable to do so, his acts will constitute an abandonment.

Trevaskis v. Peard (Supreme Ct. Cal.) 44 Pacific Reporter, 246.

Hydraulic Mining.—An injunction, says the Supreme Court of California, will not be granted against the use by a mining company of a ditch, across the land of another, for carrying detritus from an hydraulic mine, on the ground of an improper and injurious exercise of the easement, where it appears that the water in the ditch caused a slight caving in of the land of the complainant, but did not cause or threaten any appreciable danger. Also, that in an action to abate, as a nuisance, such ditch, evidence of a custom of using such ditch in all hydraulic mining is admissible. And further that, under the laws of the United States, a patentee of mining land, over which an adjoining owner had for several years, by local custom, and from necessity, maintained such ditch to a river, took subject to the easement, or right of the mining company to use the ditch for such purpose across the patented lands of the other.

Jacob v. Day, 44 Pacific Reporter, 243.

Responsibility for Injuries in Coke Yard.—Where a party was employed in a coke yard, and was directed to clean the sprocket wheel of a slack elevator by the foreman of the company, it being the duty of the foreman to control, employ and discharge such men, and to look after and keep the machinery in repair and running order, and such party was injured on account of the negligence of this foreman in failing to delay the starting of the machinery, and also in failing to detach the chain by which the elevator was operated, the Appellate Court of Indiana says that such employe cannot recover for the injury, unless he shows that the foreman's negligence was the omission of a duty owing by the company to the employe, the discharge of which duty was intrusted by the company to the foreman.

New Pittsburg Coal & Coke Co. v. Peterson, 43 N. E. Rep. 270.

Coal Lands—Agreement to Sell, Adverse Possession, etc.—The effect of the record of articles of agreement, showing the purchase of the coal on certain land from the equitable owner, as notice to all the world, is not affected by the fact that the legal owner of the premises subsequently gives to the former vendor a deed vesting in him a complete title to the premises.

The possession of the surface of the land is in no way adverse to the right of possession of coal beneath the surface by another under an agreement for the sale of such coal. And, the purchaser of coal beneath the surface is not bound to take actual possession in order to preserve his title to it.

A recorded contract for the sale of a tract of land, and also of coal beneath the surface of an adjoining tract, by the equitable owner of such properties, is not merged in a subsequent deed of the latter tract by the legal owner to the purchaser.

Lulay v. Barnes (Supreme Ct. Penna.) 34 Atlantic Reporter, 52.

Apportioning Interests in Mining Claims.—The owners of a certain mining claim and the owners of sundry adjacent claims, between whom and the owners of the first claim there had been disputes as to their respective rights in certain locations, organized a mining company, and conveyed to it their various rights in the disputed locations. One half of the stock was assigned to the owners of the first claim. The other half was placed in trust for the owners of other claims, who could not agree upon a division of the stock, with an understanding that account should be taken of the ore from the several locations, and the proceeds, after deducting one-half for the owners of the first claim, should be paid to the grantors of the several claims. Subsequently, in a suit brought by third parties against the assumed owners of a mine on one of the disputed claims, it was adjudged that an interest in the location belonged to such third parties. The court held that in the absence of some of the parties interested in the stock of said mining company, held in trust, the court could not, in such suit apportion the stock so held, and direct a transfer of the shares, but that the most that could be done was to adjudge that the assumed owners of the disputed mine should transfer a proportion of such interest as they had in such stock to the parties found to have an interest in the location.

Wheeler v. Billings (U. S. Cir. Ct. App.) 72 Federal Reporter, 301.

Coal Production of the United States in 1895.

Mr. E. W. Parker, statistician of the United States geological survey, has completed the compilation of the statistics of coal produced in the United States during the calendar year 1895. The total output from all mines was 171,804,742 long tons, or 192,420,411 short tons, having a total value at the mines of $197,572,477. This shows an increase over the production in 1894 of about 19,350,000 long tons, and an increase in value of about $11,500,000. The output of anthracite coal in Pennsylvania increased from 46,358,144 long tons in 1894 to 51,785,122 long tons in 1895, a gain of over 5,400,000 long tons. The value increased only about $3,500,000, from $78,488,063 to $82,019,272, showing that anthracite coal was cheaper in 1895 than in 1894.

The product of bituminous coal increased from 118,820,405 short tons of 2,000 pounds in 1894 to 134,421,974 short tons in 1895, a gain of over 15,500,000 tons. The value increased about $8,000,000. There was an increased production in all but five of the twenty-nine coal producing states. Alabama and Pennsylvania showed phenomenal gains of more than 25 per cent., Alabama increasing from 4,397,178 short tons in 1894 to 5,679,775 tons in 1895, with a valuation of $5,348,796, and Pennsylvania from 39,912,463 short tons to 50,017,446 short tons, valued at $35,902,678. The states in which a decreased product was shown were Georgia, Kansas, North Dakota, West Virginia and Wyoming. The principal loser was Kansas.

The following table gives the production of the several states:

States.	Short Tons. 1895.	Value. 1895.
Alabama	5,679,775	$ 5,348,796
Arkansas	598,322	752,156
California	75,453	155,778
Colorado	3,056,000	3,666,828
Georgia	260,998	215,863
Illinois	17,735,864	14,239,157
Indiana	4,090,554	3,651,883
Indian Territory	1,350,965	1,733,454
Iowa	4,192,659	5,036,289
Kansas	2,334,356	3,112,306
Kentucky	3,207,770	2,702,747
Maryland	3,915,585	3,160,592
Michigan	112,322	180,016
Missouri	2,360,350	2,703,675
Montana	1,489,193	2,815,906
New Mexico	718,554	1,070,320
North Carolina	24,900	42,350
North and South Dakota	39,197	42,046
Ohio	13,376,137	10,627,533
Oregon	73,685	247,901
Pennsylvania	50,017,446	35,902,678
Tennessee	2,333,304	2,348,182
Texas	484,959	921,138
Utah	459,136	590,649
Virginia	1,340,576	870,465
Washington	1,191,410	2,577,858
West Virginia	11,421,863	7,287,129
Wyoming	2,277,323	3,025,631
Total bituminous	134,421,074	$115,553,205
Pennsylvania anthracite	57,999,337	82,019,272
Grand total	192,420,411	$197,572,477

DOORS IN MINES.

THEIR EFFECT ON THE AIR CURRENTS.

Their Use, Abuse, and the Extent to Which They May be Avoided.

By James Blick, Inspector of Mines.

(Read before a joint meeting of the Western Penna. Central Mining Institute and the Ohio Institute of Mining Engineers).

We have no definite knowledge of the time or place where mine doors were first used, but in all probability they were introduced away back in the early history of mining operations, when the people were groping along in the dark, seeking knowledge the best way they could, to enable them to ventilate their mines; also to find out some method or appliance whereby they could procure a light for use in the underground workings that would not ignite the explosive gas, which was and had been the miners' most deadly enemy from the earliest period of coal mining, an enemy which they were unable to combat, having no means at hand wherewith to expel it from the mines or to detect its presence in the mines until its deadly blasts were upon them. Doubtless the person who introduced the first door into the mines considered (and rightly so) that he had performed an achievement far superior to any previous accomplishment in mine ventilation, and that his newly invented apparatus was the one thing needful, as by its application the mine manager could conduct the air current through every part of the mine and sweep away the deadly gas, thereby removing the danger of explosions which the miners so much dreaded, and which oftentimes suddenly came upon them, like a thief in the night, without the least warning. Probably the mine door, the Davy lamp, and the ventilating furnace were introduced at about the same time, closely followed by the steam jet, all of which were vast improvements upon the most primitive methods of ventilating and lighting of the mines, the first of which consisted of the vigorous shaking of a canvas cloth at the entrance of the mine by some strong, lusty person employed for that purpose; the second consisting of nothing better than a few bright sparks guaranteed by the use of the flint mill; but a brighter day had at last dawned, the mists of ignorance were being pushed aside by intelligent action; the old pioneer miners were now enabled to prosecute their calling with a degree of safety never before experienced. This gave them confidence in their own ability to overcome and remove the many obstacles which had previously blocked their way to progress and prosperity, and had prevented them from extending their operations to such an extent that would satisfy the growing demands for their commodity; and however little value we may place upon the mine door, Davy lamp, furnace, and steam jet at the present day, yet we are compelled to admit and to testify to the fact that the success of the old pioneer operators and miners was in a very large measure due to the introduction of the devices and apparatus before mentioned, and immediately following their introduction the business of coal mining made rapid strides forward; therefore we affirm that the mine door as a means of conducting the air current around

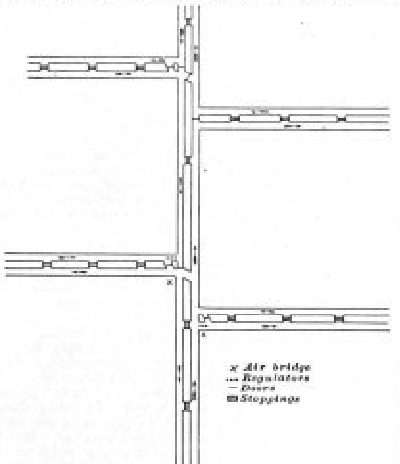

FIG. 1.

and through the various ramifications of the mines was a great improvement upon what had gone before, and was a useful invention which did valuable service in its early history, and it was doubtless the means of preventing the destruction of many valuable lives and much property in those early days. At that time the mine workings were not extensive, and the employes in each mine were few, but since the mines have become deeper, more gaseous, and very extensive, in very many cases employing large numbers of men, it is found that primitive methods and appliances which were useful and beneficial in their day, are no longer satisfactory, efficient, or safe, and instead of being safeguards, they have for some time past been looked upon as man-traps, hence, the name of mine door has been changed to that of trap door.

Who gave it its new name and when and where it received it I know not, but I suppose the change of name was due to its merits, and I feel no inclination to attempt to controvert the assertion often made to the effect that the cause of many explosions can be traced to the use of the trap door. It is impossible to arrive at a close estimate of the number of lives sacrificed and the value of property destroyed by gas explosions in mines by reason of the doors being left standing open, for in nearly all large explosions the destruction is so complete as to render it impossible to ascertain to a certainty, whether open or broken doors were the direct cause of the mischief or not; but there is good reason to believe that were the evidence not so completely obliterated, the source of the trouble in many cases could have been traced to the ever present trap door. By reviewing the history of mine disasters we find that in 1857 an explosion occurred in a mine located in England by which 190 lives were lost and the mine left a complete wreck, several months having elapsed before the bodies were recovered; we are also informed that in this mine at the time of the explosion there were no less than 52 doors

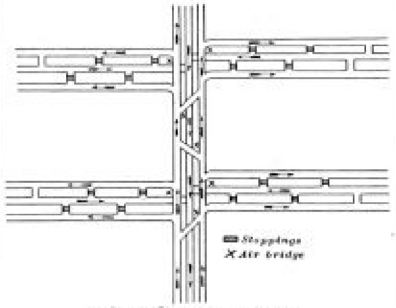

FIG. 2.

in use, and the presumption is very strong, indicating that one or perhaps several of those doors were left open at the same time, which cut off the ventilation for a sufficient length of time to permit the accumulation of a large body of gas, which was supposed to have been ignited some distance from where it was generated, it having been moved thither by the air current after it was again directed through its proper channels by the closing of the doors. I can recall four instances in Western Pennsylvania where loss of life has occurred through the doors having been left open, two cases in Fayette county, in 1884, whereby 15 lives were lost; one case in Westmoreland, in 1887, whereby one man lost his life; and the fourth case in Washington county, in 1893, where one man was killed and another seriously injured, and probably there are parties present who can recall other instances of a similar nature. Explosions are not the only evil effects resulting from the use of doors, for if we go into any mine where they are used to excess we invariably find that the men are compelled to work in a stagnant, impure atmosphere to a greater or less extent, and I venture to assert that the fact of a multitude of doors being in use at any mine is a sure indication that such a mine is not, and cannot at all times be properly ventilated. No matter what the power of the ventilation or how great the volume of air produced, it is next to impossible to maintain a steady, constant flow of air through the workings, for some one or more of the doors in different parts of the mine must of necessity be open much of the time during working hours, and in many cases the effects of even one door being open for a short time only, will result in the disarrangement of the ventilating current throughout a considerable portion of the mine. I am aware that this could be avoided to a certain extent by the use of double sets of doors, so that the one would always be closed before opening the other, but this method entails a considerable item of expense and is only adopted in rare cases.

In view of the evil effects of trap doors in the past we may do well to pause and ask ourselves the question whether we have done our full duty in seeking ways and means to supersede it with something better, or whether we have been careless, resting satisfied with things as handed down to us, when we might have adopted methods more becoming of the advanced age in which we live. I fear our answer to such a question must be somewhat unsatisfactory; for while it is true that our systems of mining of late years have been on the ascendant, still any person with an extensive knowledge and acquaintance of the mining districts of our own and other states at the present time, will observe that the devices introduced by our ancestors, though crude, inefficient, and unreliable, largely preponderate at this late date, and in many cases at mines which are managed by skillful, efficient managers from whom we have a right to expect better things. Reverting again to the subject of trap doors, I may say that I regard them not only as being a source of danger, but likewise a useless, unnecessary expense. Some managers and interested parties have for some time past been seeking ways and means to ventilate their mines on scientific principles, without the use of doors; and with our present knowledge of the science of mining (with past experience for our guide) I see no reason why we should not abolish the much favored trap door wherever it is possible to do so, and I think it can and has been fully demonstrated that new openings and some of our old mines, can be developed, operated and ventilated much more satisfactorily and at less cost without them (especially in the Pittsburg coal bed). Up until the present time our mines, with few exceptions, have been opened and developed upon a system, or systems, requiring a very liberal use of trap doors, consequently we must recognize the fact that in many cases under the best management it will be impracticable to dispense with trap doors altogether, but in such cases we must accept them as a necessary evil, which must be tolerated for an indefinite period of time, and their presence will be a standing rebuke to remind us of our past shortsightedness and imperfect acquaintance with proper scientific methods of mining and ventilation of coal fields, which nature has so abundantly deposited for our benefit and well being. In Fig. 1 is shown one of the prevailing double entry systems of mining and ventilating with room turned on each entry, wherein a liberal use of doors is necessary to conduct the air current forward to the face of the workings, and you will observe that when one or more of those doors are open the ventilation is entirely disarranged for the time being, and, as they are all open many times during the day, it can be readily seen that constant flow of air through the workings is next to impossible, for no sooner is the current re-established by the closing of one door than it is again interrupted by the opening of another one. There is also another system of ventilation in vogue in some localities much less satisfactory even than the one before mentioned; in this case single entries are driven and rooms are opened on each side of the entry, doors being placed on every room neck on one side of entry. The evil effects of this system are so apparent as to need no comment at this time, but this system is now almost unknown in the Pittsburg region. Fig. 2 represents a plan of ventilation on the treble entry system, rooms being worked on the two outside entries only; by this method a large number of men can be employed and an abundant and constant supply of fresh air can be furnished to all working parts, without the use of any door whatever and in case of an emergency occurring in any section of the mine, such as a sudden inflow of gas, an additional amount of air direct from the inlet can be diverted at will to any section where required. This system has been adopted in several mines in Allegheny county and will in all probability be introduced at other mines in the near future. The sketch itself will show the merits of this mode of operation and ventilation. I think it can and has been clearly demonstrated that, by the adoption of this method of development, the expense to the operator is considerably reduced, the miners work in a pure atmosphere and the mine manager need have no anxiety for fear of the evil consequences which may result from trap doors being left open or broken down. I may further say that I incline to the opinion that the treble entry system can be profitably applied in almost any territory (with the possible exception of very thin coal seams not generating explosive gas) but it can probably be used to the best advantage where the coal seam is not less than about four feet thick and not much broken by outcropping lines.

In the discussion which followed the reading of the paper Mr. Blick stated that the three entry system, aside from the question of safety to the miners, would enable the operators to mine about 55 feet of coal more than can be reached by the ordinary double entry system.

THE JUMBO AUGER.

An Improved Drill That Prevents Blown out Shots, and Reduces the Amount of Slack.

A bright and intelligent miner of Blue Rapids, Kansas, who appreciated the advantages that can be gained by increasing the diameter of a shot hole at the back, has invented a practical tool that will bore a large hole back of a small one as easily and with as much certainty, as a small hole can be bored in the bottom of a larger one.

This apparent mechanical impossibility is accomplished by the "Jumbo" Auger which is manufactured by the Hill-Fowler Manufacturing Company, of Blue Rapids, Kansas.

All miners will at once appreciate the advantage of being able to place their powder in a large compact mass in the bottom of a small, deep hole. The most effective blast is the one in which the tamping does not spring and which breaks from the very bottom. This result is made possible by the Jumbo auger. It bottles up the charge behind solid shoulders that never give way until the material in front is moved. It is the unequalled record of the "Jumbo" that out of the countless shots put in with the thousands of these up-to-date drills now in use throughout the West, not one blown out has yet been reported. When there are no "blow-outs" the powder is doing its work and all flame is stifled behind the mass of material that is moved, and the possibilities of dust and gas explosions are reduced to a minimum.

Another important improvement that the Jumbo auger effects is that it enables the miner to place the powder in a compact charge at the exact spot where it will do the most good and where it will move the most coal with the least breakage. From actual tests and experiments it has been found that by using the Jumbo, instead of a common drill, the percentage of slack is reduced more than one-half. It is strictly a lump coal maker.

When the Government recently chose the bottle-necked cartridge with a very large powder chamber back of a 30 calibre bullet, it adopted the same principle that makes the Jumbo shot so remarkably effective.

The "Jumbo" is a powder saver because it makes one pound of explosive do the work heretofore done by two, by concentrating it at the very bottom of the hole where the explosion should take place. It can be used in any mine where twist or rotating drills are used and it is guaranteed by its makers to do its work perfectly and without failure. It takes no longer to bore a hole with it than it does with an old-style bit. It is simple in construction, being made of a single piece of steel. It has neither springs, levers, nor loose parts, and it is practically unbreakable. It is self-cleaning, in up or down holes in either wet or dry coal. It is sharpened the same as other drills and will wear as long. It can be fitted to any rotating machine and operates equally well with air, electric or hand power. It is guaranteed to automatically bore a 4½" powder chamber back of a 2¼" hole, or in like proportion larger or smaller, to any depth, in coal, clay, salt, gypsum or any other material in which augers can be used. It is patented in the United States and foreign countries and all rights will be maintained.

The augers are made in the following common sizes: 6′ auger to bore a 3″ hole back of a 2″; 8′ auger to bore a 3″ hole back of a 2″; 8′ auger to bore a 4½″ hole back of a 2½″, and other sizes to order.

To sum up, the Jumbo auger drill possesses these points of superiority: Safety, effectiveness, simplicity, durability, cheapness, economy of labor, increase of lump coal, lessens the amount of slack, economy of explosives, halving the cost of mining.

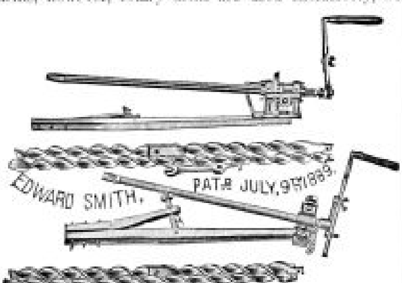
We do not hesitate to recommend all mine workers, operators and owners to investigate the merits of the Jumbo auger, which seems destined to work almost a complete revolution in the methods of drilling, charging and shooting coal and all other soft minerals. To the mine worker it will bring a larger income by increasing his output of coal for powder used and labor expended. To the mine owner it will save the loss entailed by disastrous explosions, besides lessening the amount of slack and increasing the amount of lump coal.

The Edw. Smith Coal Drills.

In no class of work is the difference in results between the older and newer patterns of tools more noticeable than in coal drills.

A case has recently come to our notice where an experienced miner with a knowledge of the ability of modern tools and methods of mining took charge of a mine abandoned some years ago as unprofitable and worthless, and has developed same into a handsomely paying proposition.

About 100 miners are regularly employed, and all are making good wages and prospering. Instead of hand drills, however, rotary drills are used exclusively, we



are informed, and the output per man is far above what it could be with jumper or churn drills. The seam worked is only 36 inches in height.

What has been done in one case can undoubtedly be done in others if proper attention be given the matter. In any case it is worth the while of every miner to get the best tools obtainable and make the greatest output possible. One rotary drill which has been well received in the anthracite districts where it has been used, is that illustrated herewith. It is made by Edw. Smith, Plymouth, Pa., and it will be advantageous to miners and operators to send to the maker for circulars, prices, etc. The advertisement of these drills will be found on page xxix of this issue.

COAL HANDLING.

A Description of the Hauling and Dumping Plant at Pikeville, Tenn.

BY J. J. ORMSBEE.

(Read at the meeting of the Engineers' Association of the South, March 9, 1895.)

In the early days of coal mining in this state the main idea seems to have been to get the output of the mines into the cars for shipment, regardless of everything else. It was all coal, whether lump or slack, so what matter if a car of lump contained a large percentage of slack, due to rough treatment after screening? If there were objections made to this fine stuff, the miner's profits were large enough for him to allow a rebate on it. Tipples then were considered the better, as their costs were lower. A bar screen and a steep chute constituted the typical structure, so built that the coal had a clear drop of several feet from the chute to the car. With increasing competition came demand for a better article. More especially was this true of such coals as those marketed from the Sewanee seam, soft and easily broken in handling and shipping. This, coupled with the poor demand for coke, generally made from slack in this district, determined the erection at the mines of the Sequachee Valley Coal and Coke Company, some two miles above Pikeville, of a plant that was designed to handle the coal tenderly at all points and to clean it thoroughly.

The average elevation of the Sewanee seam in this vicinity is 1,480 feet above tide; but the mouth of the entry is at 1,451, in order to win certain areas of low coal that were revealed by the preliminary drilling. The elevation of the railroad at the site for the chute is but 1,386 feet, and to attain this height required a grade of 4.05 per cent. The difference of sixty-five feet between mine track and railroad was too great for the coal to be conveyed by a simple chute extending from one level to the other. Such a plan would have resulted in serious damage to the product. As power would be required in any case for the proper screening, it was decided to make the lump at a point near the level of the railroad and to elevate the nut and the slack, separating them above their respective bins.

The cars from the mine are taken from the bank level to a trestle, twenty-five feet above the railroad, by an incline with a grade of thirty-four feet to the hundred. In place of a rope a creeper chain is used, carrying thirteen "dogs," that lower the loaded cars and push up the empties, the operating power being furnished by the excess in weight of the loads over the empties. Loaded cars average 2,200 pounds gross; empties, 585. A five-eighths inch Dodge chain with wearing blocks, six inch pitch, is used, working around two sprocket wheels at the top and bottom. To the shaft of one of the top wheels is attached a flange pulley with lever band-brake. At the bottom is a take up, with a play of twenty-four inches. The chain works in a trough. The great advantage of the chain over a rope lies in its automatic action. The cars detach themselves from the "dogs," the empties running to a position where the trips for the mine mules are made up, the loaded cars running some fifty feet out on the trestle to a switch-back, from whence they run to the tippler.

This is of the back tumbler variety, the advantages over the ordinary front tipping type being the reduction of the distance through which the coal falls and the fact that the coal is checked by its delivery against the slope of the short chute just above the screens, and hence is not shot upon the screens with damaging force. The car, when emptied, returns to its horizontal position, a foot lever releases the catches, and the car runs forward from the tippler to the foot of the chain, ready for the next "dog" to start it up.

The chute beneath the tippler is divided by a partition directing the coal to each of a pair of shaking screens, over which is made the lump coal. The screens are each 28 inches wide, 12 feet long, made of No. 8 steel, with circular perforations 1½ inches in diameter. Their slope is but 1¼ in 12, or about 7½ degrees. They are actuated by two eccentrics set at 180 degrees from each other on the same shaft. The throw is 6 inches, and the speed for full capacity, 130 strokes per minute. These screens were first hung by springs of 5-16x2½ inch flat steel, three on a side, the two screens being kept apart by buffer irons. The springs were used with the idea of reducing the shock at the end of the vibrations; but they soon broke and, as an experiment, were replaced by chains. The only alteration required was the placing of guides to prevent the "wobbling" of the screens, and the results have been so satisfactory that it is probable the chains will be used permanently. They have an advantage over the rigid connection in that the inclination of the screens can be changed easily and quickly at any time.

The lump coal passes from the screens to the lump coal chute, which is steel lined and has an inclination of 23½ degrees. On such a slope, with a good steel lining, this coal will just slide slowly. The nose of this sliding chute acts as a door to hold the coal. When the chute is full, the sliding chute is lowered by means of a hand wheel working a rack and pinion, the gate at the nose drawn up, and the coal delivered into the railroad car without having had anywhere a direct drop of more than a few inches. Counterweights render easy the return of the sliding chute to its place ready for another load. As a result of this careful handling and thorough screening, the lump coal loaded at this plant is remarkably free from slack, and has elicited favorable comment from those acquainted with the appearance of lump coal, as usually shipped from the Sewanee seam.

The coal passing through the apertures in the lump screens runs to the foot of a flight conveyor, whereby it is raised and delivered to a pair of shaking screens. This conveyor rises 7¼ inches to the foot, is made of sheets of No. 10 steel, 11 inches wide at the bottom, with flaring sides. Flights are 6x18 inches, fitting the trough, and set 18 inches apart on a ½ inch Dodge chain.

The upper screens are 14 feet in length, with ½ inch circular perforations. The sheets are corrugated. These corrugations run across the screen, are 1 inch high, and 6 inches apart from crown to crown. Their purpose is to check the coal and give every chance for the complete separation of the slack from the nut. The inclination was at first 15 degrees, afterwards reduced to about 12, the nut not being as clean as desired when using the steeper slope. These screens are in other respects similar to those already described. The nut and slack are stored in the bins over the railroad.

The power for operating the plant is furnished by a 15 horse-power 8″x10″ engine, supplied with steam from a slack-fired boiler of locomotive type rated at 30 horse-power.

The nut coal makes an excellent steam fuel, and the slack, on account of its uniform fineness, a strong, solid coke that will bear a heavy burden. This slack makes fully as good coke as disintegrated coal, except for the amount of ash, which is naturally somewhat higher in the screenings than it would be in disintegrated run of mines coal.

The perforated metal shaking screens not only make a clean article, but help the mine in another way—that of increasing the percentage of salable coal. Bar screens allow many large, but flat and thin, pieces of coal to go through the openings, while with the perforated screens, only pieces that will pass through a one and a half inch ring are lost from the lump coal. Nor does the consumer object to this in the least, since, although there are more small lumps, there is practically no slack at all.

The whole plant, so far as the work yet done may be taken as a guide, has fulfilled expectations. It is designed for a capacity of 1,000 tons per day of 10 hours, but has never been tried with anything like that quantity, as regular work in the mines has not begun. Judging from the trial runs it should have no difficulty in handling that amount.

The first cost, including ties, rails, and grading for incline, as well as grading for the bins and trestle, all timber, bolts, nails, machinery, and other supplies, and labor of erection, was $4,400. In regular running, five men and a boy should do the work from the mouth of the mine to the railroad car, at a daily cost, say, of $6. This would give a low cost per ton for handling, even with a moderate output.

FIRE-DAMP.

EXPERIENCES OF A MINE MANAGER

In Some of the Gaseous Mines in the Connellsville, Pennsylvania, Region, With Deductions Drawn From the Same.

BY F. C. KEIGHLEY, UNIONTOWN, PA.

(Read before Ohio Institute Mining Engineers.)

By the term "Mines which generate fire-damp" I mean those mines containing light carburetted hydrogen gas, no matter whether it may issue from the coal itself, the floor, the roof, from clay veins, from faults or by the reason of the presence of fissures in the strata. I do not wish to lead you to believe that mines containing fire-damp are more dangerous than other mines, for such is not necessarily the case. In fact I am going to try and demonstrate to you from my own experience and observations, that the known presence of fire-damp in a mine is not so much to be feared as the apparent and oftentimes presumed absence of it. It is not so much a question of fire-damp as it is a question of conditions, and it is the failure to properly weigh these conditions and the inability or in some cases, the neglect, to make timely and adequate provisions for them that brings disaster. Fire-damp of itself never caused an accident, but conditions neglected or conditions not foreseen, in conjunction with fire-damp do at times result in the destruction of either life or property and often both. Allow me to use an observation of every day life for an illustration of the point I now wish to make and impress upon you. A month ago I was away on a business trip and I went part of the way by boat. Whilst on that boat I saw the usual notice that the owners of the boat had complied with the law. The boat, its machinery, its various attachments and appliances were of the kind and to all appearances just in the condition the law called for. I further read a certificate of inspection from which I learned that the boilers of the boat were allowed to carry a pressure of 160 pounds to the square inch. My stateroom was right over these boilers. Right under me, whilst I slept, a terrible and deadly force was in existence, yet neither I nor any other person could with reason say that that boat was dangerous or unsafe; on the other hand I was perfectly satisfied it was safe. Why? Because the conditions were such that they made it safe. There was the guarantee of reasonable safety. Those boilers were of first-class workmanship. The material was the finest of steel, of sufficient thickness, rivet holes drilled, longitudinal seams double rivetted, flues properly spaced and designed, the diameter of the boilers in proper proportion and the boilers were furnished with safety valves of an area that was sufficient to carry off any excessive force or pressure and the whole was in charge of competent men. This is but one example of the numerous dangerous forces man makes his most powerful levers and best servants, that the traveling public come in contact with every day, and with all of them there is a reasonable, though perhaps not an absolute assurance of safety. Now again let me take a figure for an illustration (I am tempted to say a parallel case) a coal mine that I am perfectly familiar with. This is a shaft mine over four hundred feet in perpendicular depth. In that mine fire-damp made its appearance the second day after the coal was cut in turning off the first heading or entry, and from that day until this fire-damp has incessantly issued from the coal, the roof and the floor. At times the fire-damp was so strong that the men were kept out until it could be controlled; at other times blowers were struck that roared and hissed like escaping steam from a boiler, and at other times the fire-damp has silently filled up the headings in one hour's time a distance of 500 feet horizontally. This mine has been opened up two years and produced 415,000 tons of coal, and during those two years a terrific and deadly power has incessantly manifested itself, yet the first accident and first damage to life or property in that mine is yet to take place. With all this seeming evidence of safety and the non-appearance of disaster, can we justly say that mine is a dangerous one? I say no. Not any more so than we could condemn that steamboat as dangerous, and if I were to decide which was the best risk I would say that coal mine was a better risk than the boat. Now why has that coal mine been safe and why is it still safe? I say simply because the element of danger was known from the beginning, and the conditions being known, they were carefully weighed, understood and provided for. It is not the sandbar marked with a buoy or the rock lying under the gleam of the lighthouse and designated on the chart that brings disaster and death to the mariner, but it is the unknown, the hidden rock that sinks his vessel before he even has time to recognize danger and lift a hand to port his helm.

So it is in the mines, the recognized dangers do not necessarily bring disaster, for they are accepted as the conditions to which that mine is subject and a competent conscientious management endeavors to anticipate these, and when he or they once know them, they boldly and unhesitatingly grapple with them and strain every nerve to conquer and control them. Now I am not going to say that with proper care and skillful management accidents from fire-damp can be made impossible, for from the first breath we draw, we all know that death is ever ready to lay his clammy hand on us, and there is no such a thing as perfect safety in this world, but I will say that many accidents could have been prevented and possible ones may yet be prevented.

I am not going to spin before you to-day any of those beautiful, glittering and startling theories that throw around the science of mining a halo of romance and mystery. I am going to give you good plain horse sense, or in other words, instead of theorizing, it is my intention to reason—to endeavor to deduce from what has actually occurred (in my own experience and under my own observation) in the mines I am familiar with, what could have been done and what it is reasonable to expect or presumed can be done.

The first accident I will cite was the explosion at the Uniondale mine, Dunbar, Fayette county, Pa., some nine or ten years ago. Before I go any further let me say in this particular case my acquaintanceship did not begin until some four or five years after the accident, but that accident or explosion was the means of furnishing me with the biggest tussle I ever had with fire-damp in my life, and in that way I became quite familiar with that mine and the details and causes of the accident. I took out of the abandoned workings of that mine three and one-half million cubic feet of fire-damp, but as that proceeding would furnish abundant material for a paper of itself I must pass over it. The Uniondale mine was opened up on the crude system or methods in vogue in the Connellsville coke region twenty years ago. This mine was not an extensive one, neither was it what might be termed a fiery one. It was a slope mine. The slope being driven on the dip of the coal, the tendency would be for that slope to drain off, to a great extent, the little fire-damp in the coal, if there was any. Adjoining the Uniondale mine were the very extensive mines of a well known iron company and large areas of waste workings from these mines existed about the Uniondale mine boundaries. These waste workings were filled with fire-damp. It is said that one of the operators had trespassed, or in other words, had overrun the boundaries, which one, it is neither my purpose or desire to decide or even intimate; however, let it be either one, the consequence of that trespass was that one day a miner in the Uniondale mine suddenly struck through into those waste workings. The hole was a small one and the miner's naked lamp at that time gave no evidence of the presence of fire-damp. Without closing the hole thus made the miner left it to inform the mine boss of what had taken place, and I am informed that this man told the mine boss that there was no fire-damp there. The man and mine boss went down to the hole with naked lights and an explosion took place, burning them both severely but not fatally. This explosion put out the lights of other miners working in other parts of the mine. After some time one of the miners whose light had been thus extinguished became anxious to ascertain what had happened and he crawled in the dark out onto the slope and there struck a match, and a violent explosion took place, killing —— men and burning others. Now what was the cause of that accident? It is plain that fire-damp was the power that dealt the blow, but it was no more to blame for the accident than the pistol in the hands of an assassin. It was a clear case of conditions not anticipated, or if anticipated that were not provided for. Now what have we? The following facts, viz.: First, that one of the parties had trespassed. Second, that accurate surveys had not been made, or if made, either the matter had been kept secret or some one failed to notice that a trespass had been committed. This, then, was the real cause of the accident—unknown or neglected conditions. It is plain fire-damp was not guilty in this case. What could have been done? The party making the trespass could have had accurate surveys made and thus avoided a trespass, or if the trespass had been known to him or they, notice could and should have been given the other party of the danger. The party driving towards the abandoned workings could have kept bore holes in advance of him. He could have used safety lamps when he found that he was approaching waste workings. The miner should have immediately stopped up the hole he cut, with his hat, coat or shirt and not returned to the hole until notice had been given to the other miners. The mine boss should have scented danger when informed of the holing through and provided himself with a safety lamp before approaching the vicinity of the breach. Had any of these things been done the fire-damp would in all probability never have been ignited.

The second accident I take up for illustration is the Hill Farm mine disaster. This mine also was a slope opened up years ago (perhaps twenty years or more), when a hole in the ground and a pair of broken winded hoisting engines constituted a coal mine.

It, like other mines opened up in the Connellsville coke region ten, fifteen and twenty years ago, was headed into the coal (though occasionally t'other end went first) with nothing definite in view but the chopping out of coal in some way, cheap if possible, but coal in some way if not cheap. The only difference between headings and rooms was that one had an iron track in it sometimes and the other had a wooden one. This state of affairs existed for years, and though at times some fire-damp had been seen, yet for some time previous to the fire or so-called explosion, little if any had been detected in the workings—in short, it was not considered a fiery mine and both naked lamps and safety lamps were in use. After this mine had been worked many years and became an elephant on the hands of the owners a change was made in the management. The new manager was an able man and quick to see that radical changes were necessary—too many to make in a short time; however, to my own knowledge, he took the matter up in good earnest, and one of the first things done was to bore a hole to take care of the water with which the mine was greatly troubled and another hole was to have been bored (it has since been done) in order to get rid of the steam line on the slope. I will here state that I have known the temperature on that slope to reach 140° Fahrenheit whilst the steam line was in use, so you can readily understand why the new management commenced improvement in that direction first. When the first bore hole (or water hole) went down, it struck a point in the coal seam 11 feet from the slope. The hole was completed on Friday but not tapped until the following Monday.

At 11 o'clock of the morning of the fatal day, the miner's pick struck into the hole and the water contained in the hole rushed out with terrific force and a loud roar. The man working there escaped and his naked lamp did not fire the gas. A few minutes later a boy some distance up the slope, with a naked light on his head, heard the terrible uproar, and laboring under the impression that water had broken into the mine, rushed down the slope to warn the miners below. In passing the bore hole he ignited a blower of fire-damp that came out of the bore hole. This blower shot out a long finger of flame that reached out across the slope to the bratticing and that bratticing took fire. At this stage of the fire it might have easily been checked by the tearing down and trampling of the brattice cloth, but it was either not thought of or perhaps overlooked in the confusion and the flames at once began to play upon a trip of loaded cars standing on the slope. These cars were saturated with oil and, standing right on the main air return, they so constricted the air passage that a high velocity was reached and this fanned the flames with frightful vigor and in a very few minutes the whole of that part of the slope was a seething mass of flames and dense smoke. Twenty-nine men were cut off from retreat by that fiery barrier and two more brave fellows lost their lives by attempting to force their way through the smoke to their comrades and if possible save them.

Thirty-one persons lost their lives by that fire, not by explosion as commonly reported at the time, but through their inability to pass that fiery barrier. They were hemmed in there until suffocated by the fumes. Now what are the facts in the case? Did fire-damp kill those men? I say no. It was the conditions prevailing at the time that did the work. Fire-damp was the arrow and conditions the bow that drove it forward on its deadly errand. Need that arrow to have left the bow? I say no, if the conditions had been anticipated and provided for. Could these conditions have been foreseen? Could the deadly combination of circumstances have been prevented? It would seem upon reflection that they could have been. The hole could have been tapped Saturday evening or Sunday. Failing to tap it then the men could have been withdrawn on Monday and kept out until the tapping had been done. It might have been tapped in working hours with a reasonable degree of safety if nothing but safety lamps had been used for lights and a small bore hole kept a short distance in advance of the workmen. If the mine had been properly opened up and had a manway on each side of the slope or a brick overcast been built to connect both sides of the workings with the manway in existence at that time, the fire could have burned with the greatest violence and still not a man have been lost. It was not the fire of itself that killed the men, but the fact that the fire was in the only avenue of escape. It was a barrier with death on the one side and life on the other—those men were on the side of death. Years before that fire took place the death trap had been unconsciously set. It was the advance into the coal field with no route for retreat. The bridge to carry them back in and to safety was not destroyed. It was never built. Let every man today who is in the act of planning or opening up a new mine, long reflect and be sure that he is not setting a trap that will some day close its relentless jaws upon those who were not only not responsible for it, but who never suspected its existence. Opening up a new mine is a serious undertaking and the plans need to be skillfully drawn, deeply studied and carefully carried out if found to be drawn on safe and correct lines. The question will be asked, Why was that bore hole opened in the manner and at the time it was? To this I will say that I presume it was because the management anticipated no dangers, as bore holes had been tapped in a similar manner before without mishap. I am satisfied that if the management installed shortly before the time of the accident had had the planning and management five years prior to the date of accident, no such a deadly combination of conditions could have taken place, for Mr. Hill would never have tolerated such slipshod work as that which ruined that mine. Mr. Hill was not captain until the ship was a dismasted hulk, with a demoralized crew, and he had to run before the gale, not as he would, but as he could.

Now I cannot tell you all my experiences in the coke region unless I monopolize the whole of the various sessions, so I will take up only one more mine that I know. That mine will be the Mammoth mine. From what I experienced there I will conscientiously endeavor to point out the lessons to be learned from that terrible disaster. I say lesson because every accident reveals to all of us something we did not know and understand before, and the mining law of the state of Pennsylvania has reached its present efficiency by the means of accidents, each of which traced with its bloody finger the deficient clauses. The "Mammoth Mine Disaster" was in all probability the result of the ignition of fire-damp by a naked light. This fire-damp suddenly and unexpectedly gathered in the rib or pillar workings and in all probability it issued immediately after the fire boss made his examination from the strata underlying the coal and not from overlying strata. Previous to the explosion the Mammoth mines had always been remarkably free from fire-damp and open lights had always been used in all parts of the mines. I say mines because there were two openings—a slope and a shaft with hoisting engines at each opening. I had taken charge of the Mammoth mines a little over two months before the explosion and up to the day of the explosion I never carried anything but a naked light, as all others did, with the exception of the fire bosses, who in their daily morning examinations, of course, used the Davy safety lamp. I had traveled over the whole of that mine in company with the mine boss with nothing but naked lights, but of course never until after the fire bosses had had made their morning examination. During that time I never either saw or heard of fire-damp being found. When I went there first I asked the mine boss, assistant mine boss and the fire boss if they had seen any fire-damp in those mines. They said not, with the exception of a couple of small blowers that were struck when the shaft was first opened up years before and which were long ago exhausted. The mine I had last had charge of, before going to the Mammoth, was a very fiery one and it was worked with safety lamps. Being accustomed to the use of safety lamps I looked upon naked lights at first with some distrust, but learning that naked lights had always been used there and being assured by all and by my own observations that fire-damp did not exist in the workings and also knowing that the mine inspector had not said anything about exclusion of naked lamps, I saw no reason for comment on my part. My first intimation of danger was the explosion itself. On the morning of the disaster, not more than ten minutes before the blast came, I went into the engine house and examined the fire bosses report and found it signed as usual, with no remarks on its face beyond that the mine had been examined at such an hour that morning and found to be safe. After reading the report I put it back in the desk and was about to ask the engineer for a cage when I learned from him that there had been a wreck on the trestle leading to the coke ovens. I at once went to see what had caused the wreck and whilst standing within twenty feet from the shaft I was startled by a rumbling noise and looked up in surprise, to see a vast cloud of smoke hanging over the derrick like a huge balloon. I at once got down off the trestle and ran to the fire-pump and got it started and the water turned down the shaft, expecting to see flames next, but none came, so in about five minutes we stopped the pump for no flames showed up. We next started the cages to running and two men and a boy came up. They could tell us nothing, though all were uninjured, so I at once called for volunteers and together with two others (all that answered the call) I went down the shaft and found all the stoppings and doors blown down. Could not find a soul, so went to the top of the shaft for more help and boards, nails, etc. In a few minutes I went down again with the mine boss and some others to start bratticing and exploring, and a short distance from the bottom of the shaft we found six Hungarians from the slope workings alive and uninjured. These we sent out and proceeded with the bratticing and exploring and from that time forward we found nothing but destruction and dead bodies. One hundred and nine men had died in a few minutes time for the want of air. Of the forty-six bodies I personally helped to remove not one was mutilated and I understood from the other explorers that only two or three of the remaining sixty-three bodies were mutilated, so it would seem that all or nearly all died from the effects of after-damp. The cause for all this very great loss of life was undoubtedly the blowing away of the main door and stoppings. The air after the explosion simply went down one compartment of the shaft and up the other until the bratticing was replaced, which was of course the work of many hours' time, although we did manage to reach the first bodies in less than three hours' time. Had the mine been properly laid out without doors at the very base of the intake, and been ventilated by means of split air currents and overcasts, as it should have been, and as I planned but the day before the explosion, very few, if any, would have lost their lives. I had just completed a new ventilation plan for the mine the afternoon before the explosion. With the old system of ventilation the opening of one door near the foot of the shaft on the inclined plane where all our coal was hoisted to the foot of the shaft, cut off all air to the shaft mine workings. Of course that door was opened and shut for every trip of loaded cars hoisted and every trip of empties run down, and in case of a wreck that door would have to remain open.

Now what do we learn from this outline of that accident? First we find, as in the other cases cited, that there was a sudden and unexpected influx of gases. Could this sudden influx have been foreseen? I think it is doubtful in this case for the reason that only since the few days following the accident (it is now three years since it happened) has fire-damp been detected in that mine and then it was a sudden outburst lasting but a few hours. This time no naked lights were in use, so it was not ignited. Could the ignition of fire-damp have been prevented? It could in all probability if naked lights had been excluded; however, it is a difficult matter to determine just where safety lamps should be installed, and after my experience I would not wait for the appearance of fire-damp. I would favor the use of safety lamps from the beginning of the mine for it is an uphill business to introduce them and educate the miners after naked lights have once been used in a mine. This I know as I introduced or installed them at two mines and it was a bitter fight in each case. Even at Mammoth, after all the loss of life, it was no easy matter to get the men to look upon the safety lamp with favor.

A careful examination of the mine by many experts seemed to warrant the presumption that in this case the fire-damp came from the floor of the mine, which is a rather unusual circumstance in the Connellsville coke region, though I do know of another case where a sudden outburst of fire-damp came from the floor of one of the largest mines in the coke region, whilst the fire bosses were just completing their morning examination, preparatory to the lowering of the men into the mine. It was so sudden and of such violence that the fire bosses had to hasten to the top of the shaft by way of the cage and the fire-damp reached the surface as soon as they did. It took three days' work with a constant supply of 100,000 cubic feet of air per minute in circulation to control that outburst. I will here say that there was some disposition on the part of the public to charge neglect on the part of the fire boss making the examination at the Mammoth mines. Now I can hardly think that a fire boss would deliberately report the mine safe if he found it otherwise, go out to breakfast, then return to the mine without saying a word, to face a violent death, which he did. The fire boss died at his post and met it in one of the most remote headings of the mine, the lowest flat heading below water level. I knew the man intimately and I never met a more able man in his line or calling, in fact I had such a high opinion of him that I intended to make a mine boss of him at my first opportunity.

In the Mammoth mine disaster you again see the dreadful consequences of unforeseen conditions and the appalling results from the faulty planning and opening up of a mine. You will ask why did not the owners of the mine see that the mine was properly opened up? Let me say that the owners at the time of the accident were not responsible for its faulty development. They bought the mine years after it was opened and from the day they bought it until this very day it has been a continual succession of improvements. I was only there myself eleven months, yet during that time I used over 200,000 red brick for overcasts and stoppings alone. A mine spoiled in the beginning is a ticklish thing to handle,and it takes years of incessant study, labor and expense to right its wrongs, and in the case of some mines I know, the damage from poor planning and working is absolutely irreparable. Such mines as those wear out the very soul of the man in charge and an ordinary man can fight but one such battle in his lifetime, for by the time he gets a wrecked mine in shape he has become a wreck himself. Again let me say to those opening up or about to open up new mines, be careful and plan with skill, for as the twig is bent so the tree will grow.

Perhaps some of you would like to know what kind of a mine I would like to handle. I will tell you. I will take the gaseous mine every time. I want no more of your presumed absolutely non-gaseous mines. With the gaseous mine I know the danger and I know how to fight it. The miners know the danger and they are observant, careful and ever keenly alive to the existence and treachery of the enemy and it never catches them sleeping in fancied security. With the non-gaseous—that is the presumed non-gaseous mines—everything is happy go lucky; the naked light hob-nobs with the flaming petroleum torch, and the overflowing odoriferous petroleum can kicks up its heels and follows in the procession that revels in the very presence of death, and lights the ghastly horrifying pyre. The new mining law of Pennsylvania sits down heavily on the funeral torch that feeds on petroleum, and I am glad that it does, for of all the fights I ever had in my life, the fight against petroleum in the mines was the most bitter and hard.

I suppose that as I have expressed a desire for a fiery mine, you will next ask how I would open up my fiery pet. In answer I will say with three shafts, and with two, three, four and five headings, as the circumstances and conditions might demand or make justifiable. With heavy shaft and heading pillars, the division of the mine into sections—each section protected with heavy barrier pillars; no cut throughs in the barrier pillars excepting at section intersections; with split air currents; the exclusion of naked lights; fans in the duplicate; one shaft for return exclusively, shafts sunk as far apart as possible under the circumstances; concentration of working forces; drive the headings away ahead of immediate requirements; adopt rope haulage and aim for a large output.

MINE SURVEYING.

The Importance and Value of Accurate Mine Maps.

BY WILLIAM HIBBS.

(From Transactions of the Ohio Institute of Mining Engineers.)

This is a very common subject to many people, but the fact of its being common is like many other things that are conducted in old and narrow channels and for years and years make no change in their form or usefulness, until necessity or common sense, the mother of all invention, leads them out in a new way to improvement. Ninety-two years ago the surveyors laid out this part of our grand state into sections and quarter sections. They followed the magnetic needle through the dense forests from sun-rise to sun-set. Since that time the county surveyors have hunted for those lines and divided those quarters while the magnet varied from hour to hour, sometimes knowing they were right but frequently allowing a very wild guess.

With the mining engineer the case is different. He has long since departed from the guidance of the needle. He has a different *modus operandi* in a different place; a different work for a different purpose. And let me say just here, that it is not my desire to write of other states, but as to Ohio, a great amount of its mine surveys are not creditable to the profession. County surveyors and railroad engineers have no love for the miners and little affinity for the mines. This accounts for the fact that so much mine work is done in a careless and indifferent way, and when the work is platted upon the paper in map form, it is inelegant, inconvenient and of little practical benefit except to fulfill the law and to avoid lawsuits. Mine inspectors pay little attention to surveys, and of course many operators regard them as an unnecessary expense. And true, many are such.

The writer has seen a number of mine maps of this class. One in my recollection was drawn with a lead pencil upon manilla paper. All that could be seen was the entries, or rather the stations taken with straight lines drawn from one to the other. The work cost the operator $45, and he said it was not even correct. You need not go outside Jackson county to find this map and the man who made it. Another was platted upon vellum cloth. The work was correct, but several entry lines, which were the only ones shown, extended beyond the edges of the paper. These and a part of the boundary lines and buildings connected were the only things mapped. It cost the owner $230, and if viewed by a stranger it could not be told from a part of the jungles of Africa. This chart was the work of one of the profession in Guernsey county. Many others could be mentioned, but these are sufficient. They belong to the class which may be regarded as an expense; but that expense should yield a profit if the work were rightly done. The value of a good map can hardly be estimated.

A mine map should contain among many other features the following points of interest:

1. The property lines of the territory and parts of the adjoining lands.
2. The approximate crop lines of the property and that of the lands adjoining.
3. The location of all roads, railroads and buildings.
4. The meanderings of all water courses and ravines.
5. The forms of relief of the surface by contours and the elevation of important points inside the mine.
6. The correct form and size of the underground workings.

The surface lines are the first to demand the engineer's attention, and upon them depends not only the shape of the property, but in many cases a division of royalties must be made according to their position. The location of each corner must be made accurately according to the best evidence, the records of the public surveys and the rulings of the Commissioner of the General Land Office.

Each surveyor has his own particular way of doing things, and indeed the measure of an engineer's ability is in his being ready with a plan for anything at any time, and his having the stamina to carry it out. Probably the best way to locate the property lines is to first find one corner. Then from the records take the bearing to the next as nearly as can be calculated by known movements of the needle, being sure there is no magnetic disturbance, and if there is, to turn it off.

After deciding upon this approximate bearing, lift the needle from its pivot and range the line by use of the transit telescope, setting stakes, with tops flush with the ground, at important points and especially at places where a wide view of the surroundings can be taken in the future. No stake should be hid from view from the nearest two. Measure the horizontal distance from the beginning to each stake and also the full length of the required line, setting a stake at the end. From this the second corner can be located. Then take its bearing and distance to it. This new survey can be platted and the two corners located upon the map when a straight line can be drawn from one to the other, thus making the first true line of the survey. In a similar way other lines may be ranged out and the corners located, and when put upon the map, will constitute the property lines, while the different stakes upon them will serve in the future as references in obtaining the location of any point in the true lines.

The crop lines are of much importance, because when rightly traced they show the shape and size and the possible extent of the underground workings, besides they serve as a guide in laying out plans of mining. In surveying them it is well to use a combined transit and leveling instrument. (There are none better than those made by Heller & Brightly, of Philadelphia, Pa.) The start should be at a well known spot where the seam comes to the surface, or at the pit mouth of a drift mine at or above water level. After taking the height of the instrument upon the rod, let it be carried forward to a spot exactly on a level with the point of beginning, when the bearing can be taken from the needle and the distance read from the rod by the stadia wires. Thus will follow one course after another, checking up or down as the case may require at any and all points where the seam can be seen or found conveniently. After following out the croppings through the entire tract and as much more as would be of benefit, and after platting the survey, a number of points will be found on the paper by which the line may be drawn practically correct.

The location of roads, railroads, buildings and water courses may be generally made by taking notes by the use of the stadia wires as the other work proceeds, but when the streams and ravines lay above the underlying strata a careful survey of them must be made, which may be done by starting from a well known datum and by the needle, stadia rod and wires, reading the bearing, distance and elevation of every station along their courses, and at all points where the tops and bottoms of all strata occur, readings should be made, that the elevation and position of the overlying rocks, when platted upon the map, will show to the mine manager where to locate his works in the future. By this he can see at a glance where or in what direction to look for dips and rises, and by the position of the ravines to avoid deluging the mine by letting in some stream of water. Location of faults in some cases may be made when no knowledge of them otherwise exists.

Last but not least, the forms of relief may be considered. This part of the survey can be accomplished in the following manner: By stadia measurement starting upon the former datum and from this and the points whose elevations are known from the former work, take readings for distance, bearings and elevations to all points that may serve in getting the height at different places on the surface. Then extend this work to new points until a network extends over the entire territory. When this is platted, showing position and elevation of all the points, contours may be drawn among them, thus showing the thickness of the overlying strata and the shapes of the hills and valleys.

Much more could be said, but not in this short paper, and the author will cease by saying that the underground works should be traced correctly and extended at convenient periods and mapped in a separate color each time. The levels should also be taken for all inside points, with reference to the surface datum, and marked upon the map in a different color from surface figures.

Thus a mine map may be made that would be of some use to its owner. It would serve him in making his calculations, and if the chart be constructed before he commences his work, it may save him a great unnecessary outlay of capital and labor, for it is always best to know previous to any work, all that is possible to know.

Let an exact copy of this plan be made, divided into convenient sections and numbered and then cut apart. This sectional map can be carried, entire or in parts, into the mine or about the works, where reference to it can be had without the trouble of going to the office and unrolling the large one.

High Grade Coals.

The Berwind-White Coal Mining Co. has received from the officials of the World's Columbian Exposition, a bronze medal and diploma for an exhibit of three sections of typical coal seams, worked by the company. No. 1 section was from Horatio, Pa. It consisted of a section of a steam coal seam 7 ft. 7 in. thick. No. 2 section was from Anita, Pa. It consisted of a section of a steam coal seam 4 ft. 8 in. thick. No. 3 section was from Houtzdale, Pa. It consisted of a section of a steam coal seam 7 ft. thick.

The official analyses of the coal yielded the following results:

	No. 1 Section.	No. 2 Section.	No. 3 Section.
Water	0.954	1.090	0.844
Fixed Carbon	60.861	61.028	73.292
Volatile Matter	30.871	31.865	21.806
Sulphur	1.124	1.012	0.643
Ash	6.160	5.035	3.415
	100.000	100.000	100.000

Climax Boilers Adopted.

The Cloubrock Boiler Co. has contracted to erect 900 H. P. Climax boilers in units of 300 H. P. each for the new steam heat station of the Economy Light, Heat and Power Co., of Scranton. These boilers will be equipped with McClave grates, and will have three independent stacks. They are to be completed by September 1st.

Classification of Coals—Correction.

In the table showing the physical and chemical properties of Standard Connellsville Coke, on page 258 of the June issue, the terms Wet and Dry were transposed. The weights and measures therefore given for dry coke should be for the wet, and *vice versa*.

CORRELATION TABLE,

Coal Measures of Western Pennsylvania Compiled for The Colliery Engineer and Metal Miner by Baird Halberstadt, Mining Geologist, Pottsville, Pa.

Prof. J. D. Dana's Table of Formations.	Table of the Second Geological Survey of Pennsylvania.	Names Provisionally Adopted by Prof. Lesley.	Numbers.	Coal Beds and Their Thicknesses in Each Series.
Upper Coal Measures	Upper Barren Measure 1100 - 1200 ft.	Greene County Group 300 - 400 ft.	XVII	Windy Gap (1′ 0″ — 2′ 0″), Nineveh (1′ 0″), Dunkard (1′ 0″ — 1′ 3″).
		Washington County Group 700 - 800 ft.	XVI	Jollytown (2′ 0″ — 3′ 0″), Washington A (4′ 0″ — 5′ 0″), Washington (5′ 0″ — 8′ 0″). Little Washington (0′ 6″ — 0′ 10″), Waynesburg B (1′ 0″ — 2′ 0″), Waynesburg A (3′ 0″ — 4′ 0″).
	Upper Productive Coal Measure 350 - 450 ft.	Monongahela River Series 350 - 450 ft.	XV	Waynesburg (4′ 0″ — 10′ 0″), Uniontown (3′ 0″), Sewickley (5′ 0″ — 6′ 0″). Redstone (3′ 0″ — 5′ 0″), Pittsburg (4′ 8″ — 10′ 0″).

Easy Lessons on Mining.

This Department contains articles to assist ambitious Miners to educate themselves, and obtain Certificates of Competency as Mine Foremen, or to become Mine Superintendents.

The articles are written to be understood by the unlearned and the learned alike. Plain language is used, no obscure terms are employed, and each subject treated, is made as clear and easy to understand as possible.

Further: The Questions asked at the different Examinations for Mine Foremen and Mine Inspectors, are printed and answered.

☞ The Series of Articles "Chemistry of Mining," "Mining Methods" and "Mining Machinery" was commenced in the issue of March, 1894. Back numbers can be obtained at twenty-five cents per single copy, $1.00 for six copies, and $2.00 for twelve copies.

MINING ARITHMETIC.

Arabic Numerals—Numeration—How to Add Efficiently—Arithmetical Signs.

1. **The Arabic Numerals.**—In this course of lessons, only such instruction will be given in the simple rules as is necessary to draw attention to matters that are too often disregarded by beginners; therefore the student is expected to supplement the exercises that will be given in the four simple rules by examples of his own. Many persons live to regret their former carelessness in not having taken pains to master sufficiently at first the essential elements of the simple rules. We will therefore endeavor to present the facts that ought to be mastered and understood in such a simple way that the study of them will neither weary nor perplex the learner.

Notation or the mode of writing the figures, and *Numeration* or the mode of placing the figures to represent a number, will first have attention, and to clearly distinguish the meanings of the terms notation and numeration, we will reverse the course commonly taken, and begin first with numeration, for it preceded in human experience the practice of notation.

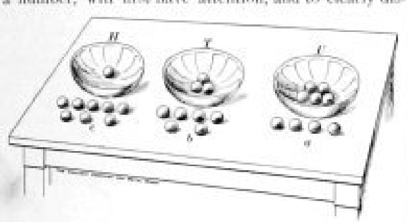

Fig. 1.

The figures in common use are supposed to have originated in Arabia or India, and they were at first only rude pictures of the bowl and pebble system of recording a number, or of numerating a host or multitude of things that could not otherwise be measured. Fig. 1 is an illustration of the ancient way of numerating a multitude of things that were all alike in character and value. The bowl and pebble system here shown was the forerunner of the Greek and Roman abacus and the present day Chinese counting frame, and therefore its use and history is in no sense mythical. Three bowls and three groups of pebbles are shown at *H T U* and *c b a*, and the process of numerating was as follows: *U* was the units bowl and *nine* pebbles were provided for it; for be it observed that a tenth pebble would never be required for it, as ten was represented by one pebble in the second bowl, and just in precisely the same way we now use *nine* figures only and the number *ten* is represented by 10 or 1 set before a cypher. Suppose a pile of apples have to be numerated; then one pebble will have to be put into the units bowl for every single apple up to nine and for the tenth apple the nine pebbles have to be taken out of the *U* bowl, and one put into the *T* bowl, and as ten tens are a hundred, when that number is reached instead of putting the tenth pebble into the *T* bowl nine tens are taken out of the *T* bowl, and one to represent ten tens, or a hundred, is put into the *H* bowl, and in the event of there being more than nine hundreds to numerate a fourth bowl is introduced, with the result that the numeration of the ancients, by the decimal system, was in every respect precisely the same as that practiced by us now. It will be seen that the number numerated by the bowls before us is 135.

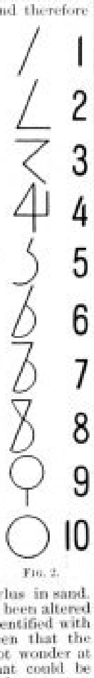

Fig. 2.

Nothing, perhaps, is more interesting than the pictorial system of notation, said to have been invented by an Arabian fisherman, and still practiced by us, and it is for that reason that we here give the figures in Fig. 2, as at first written by this Arabian with a piece of chalk, or with a stylus in sand. Indeed, so little has the form of the figures been altered that the original Arabic numerals can be identified with those we are writing now. It will be seen that the unit figure 1, is not altered, and we cannot wonder at this, because it was the best picture that could be taken to represent it. Two units were set down as two marks, and three as three, and four as four distinctly drawn lines; and by contrasting them with the figures one, two, three and four, as we now write them, they are still recognizable as the same pictures.

Five was a picture of *one*-half of a bowl, and, observe, it consists of half a bowl with a stroke above it, signifying *one*-half; six was half a bowl and one *over*; seven was half a bowl and two over, and eight was half a bowl and three over; nine is the picture of a bowl all but one, and the tail of the figure is the absent one; ten is a picture of the units bowl when empty, and the unit figure is shown at the left of the empty bowl as ready to put into the bowl of tens. The cipher is only a picture of an empty bowl, and therefore the figures our learned men employ for the solution of their grandest problems were at first only the childlike picture writings of a poor, ignorant Arabian fisherman, and, stranger still, the sketches made by this simple man have been copied and repeated again and again by millions of our race, and still the writing of these pictures is repeated. We now see that our notation is made up of nine figures and a cipher, and that by setting the figures in a certain order we can numerate values that otherwise would be incomprehensible.

2. **Numeration.**—To numerate a line of figures they are first divided into groups of threes, and these triplets as they advance to the left, are given different names, as follows:

B M T
123,123,123,123

That is to say this number reads, one hundred and twenty-three billions, one hundred and twenty-three millions, one hundred and twenty three thousands, one hundred and twenty-three.

All figures from and to the left of the unit's place represent concrete or whole things, and all figures at the right of the units place represent parts or fractions of things and being progressively less than one they are numerated as follows: hundreds tens (units), tenths hundredths; for example, numerate 236.543. Two hundred and thirty-six and five hundred and forty-three thousandths. When a point or period is set before a line of figures, the number is always less in value than one thing, because the point represents the end or unit's place of a whole number, and the decimal fraction before us in common with all others that ever can come before us, is easy to enumerate by observing the following simple rule. First, numerate the decimal number as if it was a whole number. Second, suppose the units place is one, and the other figures in the decimal number are ciphers, and then numerate as follows:

.543 five hundred and forty-three,
1000 one-thousandths,

or five hundred and forty-three one-thousandths. Again, .00005 reads five one hundred thousandths, and 27.15 reads twenty-seven and fifteen one-hundredths.

3. **How to Add Efficiently.**—No instruction is required to enable a student to perform the simple operations of addition and subtraction, and it is for this very reason that so many people are so slow and inaccurate in their additions and subtractions, for they believe that speed and accuracy will come with practice; but they do not, and then they conclude that they are not by nature gifted for rapidity in finding the sums and differences of numbers. In this conclusion they are wrong, for by proper training, most men can be made expert at addition and subtraction.

When a student is slow in these operations all his exercises with figures are tedious and fatiguing, and therefore he never becomes a good arithmetician, and for this reason we say to all our readers, if you are inefficient on this score, commence again with the first two simple rules, and follow our advice.

To be expert and reliable then you must first cultivate self reliance and courage; for timidity and hesitancy paralyze the mind and make you a stutterer in figures, and if ever you acquire the habit of inconfidence you can only cast it off by adopting a system of drill such as we are about to recommend.

First exercise in self reliance: Set down the following figures in the order in which we give them.

```
 5 7 9 3 4 7 2 6
 9 6 8 7 7 9 6 5
1 5 4 8 1 2 6 9 1
```

Here we have an exercise in addition in which the sum of the numbers is given, to prevent hesitancy: Drill one: Begin and say five and six are eleven, seven and two are nine, etc., and practice this very simple addition until you can do it with perfect self reliance in a second or two. Then take drill 2:

```
 8 5 9 3 6 8 4 2
 4 7 0 8 7 2 5 6
 5 4 6 7 8 1 8 9
1 8 7 7 0 2 2 8 7
```

and after you find that you can make the addition in about four seconds, make some examples for yourself in drill two; but take care while on this drill, never to make the columns more than three figures deep, and never increase the depth until you are very expert and quite able to trust yourself in attempting a greater effort. The senses of sight, hearing and feeling have all to be cultivated, and therefore it is imperative that at first you speak aloud the additions you are making, and above all you must not hesitate to consider whether the additions are right or wrong in any case, but tear away and remember that *faith* is the secret of success.

The same drill must be practiced with subtraction, and the exercises must be continued until you can trust your own self for accuracy, while your speed is so great that you have not time to *think* and hesitate. Slowness in the operation of multiplication is the result of hesitancy in adding, and slowness in division is the result of hesitancy in adding and subtracting, and therefore we ought to find an immediate cure by submitting ourselves to a proper system of drill.

4. **Arithmetical Signs.**—The use and correct meaning of the arithmetical signs should be understood; in this lesson three of them are introduced. The first is the addition sign, written thus +, and it is called *plus*. The

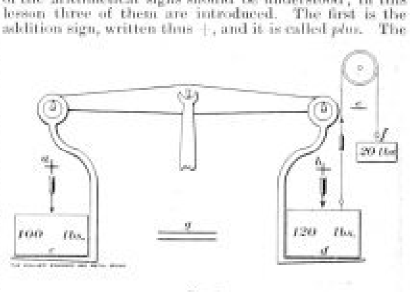

Fig. 3.

second is the sign of subtraction, and it is written thus —, and is known as *minus*. The third is the sign of equality, and is written thus =, and is called *equal to*. The uses of these three signs are exemplified in Fig. 3. Here we see a scale balance in a state of equipoise, and to indicate this condition with clearness, the equality sign *g* is set between the scale pans so as to render the use of the sign unmistakable; for with beginners the trouble is not so much to make them understand what you mean as to make them realize the application of a principle. Now, we have a 100 pounds weight on the *c* pan, and a 120 pounds weight on the *d* pan, and we are sure 100 pounds cannot balance 120 pounds; but a *negative* weight of 20 pounds is made to counteract at *f* the excess of weight on the *d* pan, and therefore the 100 pounds on the *c* pan, after all, only balances its equivalent of 100 pounds. Under these conditions we see the application and use of the signs, for 100 = 120 — 20, or, in words, a 100 pounds weight balances 120 pounds when the excess of 20 pounds is counteracted. If we consider the earth's attraction as a positive pull downwards, then any force acting upward is *negative*, or opposite, to the earth's attraction, or an upward force is negative to the earth's attraction. By introducing the pulley at *e*, 20 pounds at *f* are made to pull the left hand side of the cord upward, as shown by the arrow. Here, then, we see that forces acting downward are positive and those acting upward are negative, or, to be still more clear, if 100 pounds acting positively, or downwards are counteracted by 100 pounds acting negatively, or upward, then *nothing* is equal to one hundred minus one hundred, or 0 = 100 — 100. The plus, or positive sign, is seen at *a* + and *b* +, meaning to say that the weights in the pans *c* and *d* are pulled by the earth, but the negative sign is seen at *e* —, because the weight *d* is pulled upward with a force of 20 pounds.

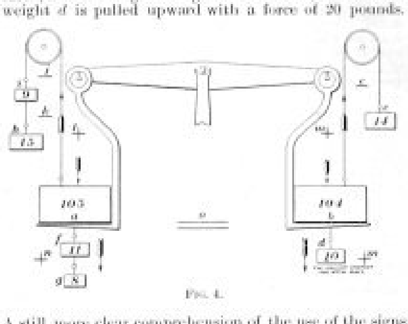

Fig. 4.

A still more clear comprehension of the use of the signs may be obtained by a study of Fig. 4. First, then, let us balance the forces by taking all the downward ones as plus, or positive, and all the upward ones as minus, or negative; then,

$$105 + 11 + 8 - (15 + 9) = 104 + 10 - 14$$

Here the mere downward force on each scale pan is 100 pounds; but before proving this, let us observe the weights *i* and *h*, when it will be noticed that although the force exerted by them is made by the cord and pulley to act negatively to the weights *a*, *f* and *g*, yet *i* and *h* are positive to each other, and it is for this reason that in algebraic equations, we change the positive and negative signs of all the letters within a bracket when the first letter is a negative one; for see, we have written $105 + 11 + 8 - (15 + 9)$, not $105 + 11 + 8 - 15 - 9$. By looking at the figure we see that *i* is positive to *h*, or *i* is acting in the same way as *h* to pull the pan *a* upward, then $15 + 9 = 24$ or $-(15 + 9) = -24$ and we now see that $105 + 11 + 8 - 24 = 100$; and that $104 + 10 - 14 = 100$, therefore the resulting positive force on each of the pans is the same, and $100 = 100$. The terms positive and negative are not confined to forces acting downward and upward but to forces acting in simply *opposite* directions.

In this case positive is downward and therefore *a*, *f*, *g*, *l*, and *d* are +, that is positive or plus, and the forces *i*, *h*, and *e* are −, that is minus or negative forces.

MINING MACHINERY.

The Principle of Action of the Lift Pump—The Pressures on the Valves of a Lift Pump—The Interruptions That Occur in Pump Action—Recapitulation of Facts.

123. **The Principle of Action of the Lift Pump.**—We need not insist upon the importance of miners having a complete knowledge of the mode of action of the common lift pump, for in some form or other it is an indispensable appliance in mine drainage. We never feel so much the value of knowledge as when we are confronted with a difficulty that requires its assistance, as for example, when a pump fails in its action through some disarrangement, and we are expected to diagnose the fault and correct it. Let us, then, in this lesson first notice the mode of action of a lift pump on the upstroke, and to make the subject clearly understandable, let us call to our aid Fig. 155. The pump piston *a* is advancing upward, as indicated by the arrow *g*, and the valve is down on its seat as the result of having the entire weight of the column resting on it. The statement just made is correct, but are we sure that we have the right understanding of what is meant by the words "entire weight of the column"?

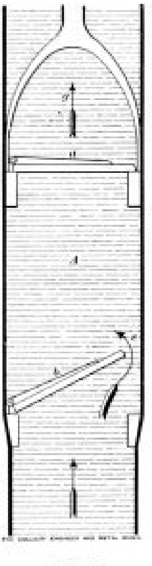

FIG. 155.

124. **The Pressures on the Valves of a Lift Pump.**—Then, let us suppose that in a mine shaft the column of water resting on the pump piston *a* is equal in length to a vertical height of 300 feet, then we may correctly conclude that the "entire weight of the column" will be equal to $300 \times 62.4 = 18{,}660$ pounds, or $\frac{18{,}660}{2{,}000} =$ 9.33 tons, assuming that the area of the pump piston is 1 square foot; or if it is not, then we may say that the *pressure* on the pump piston is in the *proportion* of 9.33 tons per square foot. All this seems to be right enough, but the column of water resting on the pump piston is partly above and partly below it, and this means to say that the vertical column extends in length from the surface of the standing water in the mine to the surface of the water column at the elevation at which it is discharged. We see, then, that if 20 feet of the vertical column is below the pump piston, the words we commonly use, "*resting* on," ought properly to be *depending* on, for if the mean height of the pump piston above the water in the sump is 20 feet, then 20 feet of column are *hanging* on the pump piston, and 280 feet of column are *resting* on the pump piston. Such a distinction may appear to be out of place, but if you desire to thoroughly understand the mode of action of a pump, the distinction is in place as illustrating the principles involved. Clear views are now within our reach, as, for example, we can investigate how it happens that the 20 feet of the vertical column are *hanging* on the pump piston. As the pump piston ascends it displaces a portion of the pressure of the atmosphere; for, suppose this pressure to be equal to the weight of a vertical column of water 34 feet long and also equal to a pressure of 14.7 pounds per square inch, then the 20 feet of column under the piston has to be lifted by the atmosphere into a partial vacuum made by the piston, and this partial vacuum will be equal to a pressure of $34 - 20 = 14$ feet of column, or $\frac{14 \times 14.7}{34} = 6.053$ pounds per square inch, but the under side of the pump piston makes a depression below the pressure of the atmosphere of $20 \times 62.4 = 1{,}248$ pounds per square foot, or $\frac{1{,}248}{2{,}000} = .624$ tons; therefore, we have

Weight *resting* on the piston	8.706 tons.
Weight hanging on the piston	.624 tons.
Total weight depending on the piston	9.330 tons.

In the values just given, the area of the piston is assumed, as before, to be equal to 1 square foot.

The piston valve *a* is closed by the weight of a column of 280 feet of water resting on it, and by a further addition of the weight of a column of 20 feet of water hanging upon it. The bottom or suction valve is seen to be open, and observe, the piston valve is always closed, and the suction valve is always open during the up stroke of the lift pump; but we should now know the reason why the suction valve is open, and only one answer can be given to the inquiry; and that is, the valve is open because the pressure under it is greater than the pressure above it; then let us now find how this occurs. Take the pressure of the atmosphere at 34 vertical feet of water column, and the height from the surface of the water pumped at 20 feet of water column, and let it require a 1 foot water column to lift the valve; then the pressure under the valve is equal to $34 - 20 = 14$ feet of vertical water column, and the pressure above the valve is equal to $34 - 21 = 13$ feet of water column, then the pressure at *A* is equal to 13 feet of vertical column, or the amount of depression below the pressure of the atmosphere is equal to a vertical column of 21 feet. The student should here realize the true meaning of the terms employed, and to do this consider that the

Total pressure of the atmosphere is	34 feet vertical
Depression below the atmosphere is	21 feet vertical
Total pressure below the pump piston is	13 feet vertical

Next let us proceed to investigate what takes place in the down stroke of the pump piston. By reference to Fig. 156 we see the suction valve is down and resting on its seat as *d*, while the pump piston valve *c* is up, and the pump piston is said to be *plunging* on the down stroke, and, therefore, it is plain, that the pressure due to the weight of the column, has been transferred from the piston valve to the suction valve. Now let us suppose that the suction valve is 20 vertical feet above the surface of the sump water in the pit bottom, and that the total vertical height the water is lifted is 300 feet, as before; then let us find the weight resting on, and hanging on, the suction valve *d*. If it requires a vertical column of 1 foot to lift the piston valve *c*, then let us reckon this 1 foot as weight; then the total vertical column becomes 301 feet, and therefore, the total weight of the column is $301 \times 62.4 = 18{,}782.4$ pounds or $\frac{18{,}782.4}{2{,}000} = 9.3912$ tons on a valve 1 square foot in area, and therefore,

The weight resting on the suction valve is	8.7672 tons
The weight hanging on the suction valve is	.6240 tons
Total weight depending on the suction valve is	9.3912 tons

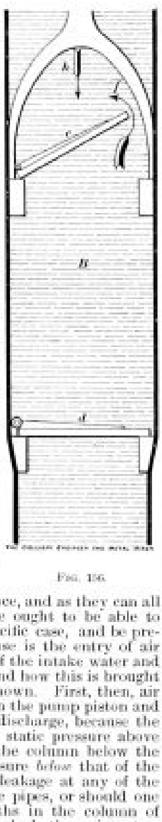

FIG. 156.

The pump piston is plunging into the water space *B*, as shown by the arrow *h*, and the water under the valves is seen by the arrow *f* to be escaping to the upper side of the piston. On the down stroke of a lifting pump, we see that the suction valve is closed and that the piston valve is open.

125. **The Interruptions That Occur in Pump Action.**—Interruptions in the efficient action of pumps are of frequent occurrence, and as they can all be classed under three heads, we ought to be able to determine the cause in each specific case, and be prepared to correct it. The first cause is the entry of air somewhere between the surface of the intake water and the pump piston; and to understand how this is brought about, a few facts require to be known. First, then, air does not enter the column between the pump piston and the upper surface at the head of discharge, because the whole of the upper column has a static pressure above that of the atmosphere; but all the column below the suction valve has a standing pressure *below* that of the atmosphere, and if there is any leakage at any of the joints of the pipes, or should one of the lengths in the column of pipes be cracked, then air enters freely, and in a peculiar way interferes with the pump's efficient action, and such a case as this is shown by Fig. 157. Here, from some cause, air is entering the tail column below the suction valve, and is seen bubbling up at *c*, while it is displacing the water and reducing the depression under the pump piston, as at *d*, and here we see the water head has fallen to *e*. Now this matter requires investigation to find how the air enters the lower, or tail column. This inquiry is capable of an easy answer, for, as has been shown, the *hanging* column is, at every point in its length, at a pressure below that of the atmosphere, and therefore every opening admits air in and presses the water in, for both are subject to a compression on the outside. The causes of the entry of air may be a bad or broken joint or cracked pipe, or the water in the pump may have fallen so low that air is entering the bottom end of the tail pipe with the water.

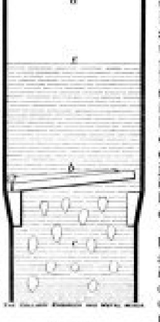

FIG. 157.

The entry of air, however, can be detected by three occurrences, and the first is a great reduction in the volume of the water discharged. The second is the rapid descent and sudden arrest of the piston at half stroke, for the pump rods descend through half of the stroke with the increased energy that is due to the entire weight of the column resting on the piston. The third is the sound of the shock produced by the piston striking the water. Second, the failure of the pump's action may arise from the lodgement of a piece of stick under the piston or the suction valve, and as the behavior of the pump is different in these two cases, let us notice each. When a stick is under the suction valve, the liability to a break up is considerable, because on the down stroke the entire column of water is resting on the pump piston, and therefore the piston's motion is dangerously accelerated, for the water between the piston valve and the suction valve freely escapes. When the stick is under the piston valve, the weight of the column does not rest on the piston, and the pump works as if it had lost all its hold of the water, and the snoring sound of the water rushing through the contracted opening of the piston valve can be heard by placing your ear beside the pump cylinder. Third, a broken pump rod removes all weight off the engine, for the wooden rods, after being disengaged from the piston, practically float, and therefore the engine loses all weight on both the up and down strokes. We now find that all the peculiarities in a pump's action, when it is subject to any disarrangement of its working parts, can be accounted for and corrected by the student who understands a pump's mode of action when all the parts harmonize in the execution of their functions. We have here taken, by way of example, the conduct of a large mine lift pump, but what applies to a large pump equally applies to a small one set up for pumping a local standage of water in the workings.

Recapitulation of Facts.—QUES. 1. What are the positions of the valves of a lift pump on the up stroke?

ANS. The piston valve is down on its seat because the entire weight of the column is depending on it; and the suction valve is up, because the pressure of the atmosphere is at that time forcing the tail pipe column into a partial vacuum.

QUES. 2. Explain the meaning of the terms resting on, hanging on, and depending on.

ANS. Resting on refers to the weight of the vertical column of water on the piston valve; hanging on refers to the tail pipe column that is supported by the pressure of the atmosphere that lifts it into the depression made by the pump piston; depending on refers to the total weight of the column, and is the sum of the weights resting on and hanging on the pump piston.

QUES. 3. How do you explain the fact that the pump piston valve is open and the suction valve is shut on the down stroke of a lift pump?

ANS. On the down stroke of a lift pump the whole weight of the vertical column depends on the suction valve and therefore it is shut, and the only pressure exerted on the piston valve is that due to lifting it by the water that is in course of being displaced by the plunging of the piston.

QUES. 4. Under how many heads may the interruptions of the efficient working of lift pumps be classed?

ANS. The failures in the efficient working of a lift pump may be classed under three heads, as follows:

First, the entry of air somewhere below the piston or suction valve.

Second, the lodgement of a stick under the bucket or suction valve, and especially the latter.

Third, a broken pump rod or the wearing out of the pump piston or suction valve.

CHEMISTRY OF MINING.

The Gauze Cylinder of a Safety Lamp—The Admission of Air to a Safety Lamp—The Ventilation of a Safety Lamp—The Flame of a Safety Lamp Affected by Ventilation—Restrict the Supply of Air to a Lamp—The Recapitulation of Facts.

111. **The Gauze Cylinder of a Safety Lamp.**—It is commonly believed, that the flame of a lamp can be completely isolated with a gauze cylinder, when it consists of wires reticulated with lines of 28 to the inch, to make 784 meshes to the square inch; but this belief cannot be maintained when it is subjected to the object lessons of practical experience, for then we find that the gauze is only one of the factors of security in the construction of a safety lamp. When testing safety lamps to ascertain the extent of their reliability, we learn

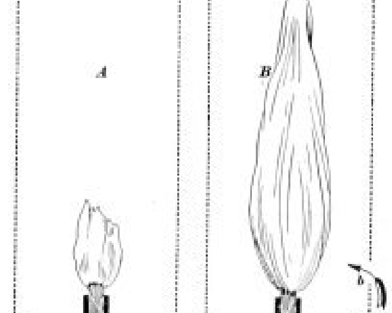

FIG. 150.

much that does not accord with popular ideas; as for example, if you were to propose to make a hole in the gauze cylinder of a lamp by puncturing it with a nail, the prevailing idea is, that the gauze would then be a useless adjunct of the lamp, that might be dispensed with; but testing it in a slightly explosive atmosphere, with a puncture made near the top and just under the cap as at *t* in that portion of Fig. 150 marked *A*, the flame does not elongate as the result of the puncture, but remains of the same size as before. For every effect, there is a cause and that statement is certainly true here, for after the exercise of a little thought we see that the hole *t* does not act as a port for the entry of an extra inflow of the explosive mixture, but as a port of discharge for the products of combustion. It is true that, if we had to select one from two lamps to carry in an explosive mixture, our feelings would make us partial to an unpunctured gauze, but yet the fact remains that a puncture at *t*, is not attended with the same risk as one at *b* in *B*, because an extra inflow at *b* fills the lamp with flame as at *B*; but worse than that, the sides of *b* are *too* far distended to chill a flame, and the result is, a gauze punctured at *b*, *fires at once* when set in an explosive mixture. We see then, that if a gauze cylinder is punctured near the top its efficiency is not impaired, but when punctured near the bottom, its use as a safety appliance at once ceases.

112. **The Admission of Air to a Safety Lamp.**—The facts of the punctures, furnish some instruction that is of great value in the construction of a safety lamp, for we now know that the admission of an excess of air, containing inflamable gas, into the bottom of the lamp, is attended with immediate danger, and that the free and unrestricted discharge of burnt air from the top of the gauze does not in any way imperil the safety furnished by the lamp. The question now before us then, is this: How can we restrict the admission of air into the bottom of the lamp, and yet make such provision as will furnish oxygen enough for the requirements of a good illuminating flame? Before deciding on this point, however, other matters of undoubted importance must be discussed, and the first one is that of a sufficient motive column to maintain a steady and almost invariable supply of air to the flame. In many of the lamps in use, the motive column is entirely disregarded, and the inventors appear to have been concerned about nothing but how best to avert an explosion within the lamp. In this endeavor they were right, and, therefore, the defects that now require a remedy are such as have not received *due* attention. Before the introduction of the bonnet, the ventilation of the safety lamp was like that shown in Fig. 151. The fountain of the lamp and the upper holes are purposely left out of the figure, to make the details of interest, and easier seen and understood.

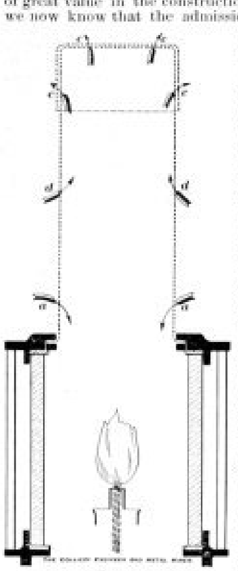

FIG. 151.

113. **The Ventilation of a Safety Lamp.**—The lamp before us is the type of the old Clanny without a bonnet, and the fresh air to feed the flame is seen to enter near the bottom of the gauze, as shown by the arrows *a* and *a*. The cold air will thus descend the glass cylinder as a shell, while the hot gases from the flame will ascend through the cylinder of cold air, but the hot air cannot rise through the cold air without some amount of mixing taking place, and the result is, a portion of the cold air mixes with the hot air and rises with it, and as a consequence of this occurrence, a larger volume of air must enter at *a a* than is necessary to feed the flame; while at the same time, the mixing of the cold air with the hot air reduces the motive column of the lamp's ventilation. Again, above the arrows *a a*, cold air enters and mixes with the ascending hot air, as at and below *d d*, and this entry still further reduces the motive column; therefore, the mechanical action of the ventilation of the lamp is such, that we are astonished when we find how little energy is necessary to blow down sufficient air to the flame to keep it alive. Should, however, the lamp be placed in an explosive mixture, the entry of fire-damp is so much assisted that we cannot but conclude that the lamp under such conditions is really as unsafe as experience has proved it to be. All the air discharged from this lamp escapes through the region of the cap, as *c*, *c*, *c*, *c*. It is pleasant, however, to discover that bad ventilation is a condition of unsafety, and, therefore, to make a safe lamp, the prime condition required to secure this, is good ventilation.

114 **The Flame of a Safety Lamp Affected by Ventilation.**—The flame of a lamp should have an ample supply of air to produce a good light, but the inflow of air should never be in excess, because every fraction of a cubic inch that is more than the flame requires, becomes a danger when the entering air contains inflammable gas. At first sight it appears to be no easy matter to regulate the ingoing supply of air to a lamp when the supply is a *limited* one, but we shall show, further on, how this can be done. A bonneted lamp is no doubt a marked improvement on the old Clanny, but still in many lamps of this type, the objectionable principle is retained of admitting the air at the bottom of the gauze cylinder as we see in Fig. 152; here the ascending hot interior column of air is shown at *d*, while the outer shell of cold air is seen to reach the flame at *c* and *c*, and to enter at *b* and *b*. In this lamp, as in the Clanny, a portion of the motive column is lost between *b b* and *c c*, but a distinct column is maintained between *b b* and *a a*, so that in this respect, the bonnet secures a true gain, but still nothing is done to restrict the supply of air to the net requirement of the flame.

115. **Restrict the Supply of Air to a Lamp.**—An excess of air not only reduces the motive column, but when it contains inflammable gas it supplies fuel for an explosion within the lamp; and to make this clear, let us suppose that the supply is ample, but restricted, and that the entering air is an explosive mixture; here then there is not oxygen sufficient to burn both gas and oil, and the result will be, the flame of the lamp, if it burns ever so feebly, will consume sufficient of the entering oxygen to make the entering fire-damp inexplosive. We here find that something more than a gauze or a bonnet requires close attention in the construction of a safety lamp, and that a lamp devised in harmony with the requirements of natural law must secure an amount of safety far beyond what is obtained when the principles of action are not correctly directed. When the motive column for the entry of air into a lamp is not sufficient, the supply cannot be restricted without, at the same time, affecting the steadiness of the light, for if the entering air contained even a small percentage of carbon dioxide the light would become dim, and the motive column would be reduced, and in some cases the flame would expire. To secure a steady light in a truly safe lamp, we see then, that it is imperatively necessary that two things should be done; first, we must restrict the supply of the entering air; and second, to restrict the supply, the minimum of the restriction must be maintained; and to do that, we must have a good motive column. Here it will be found that we have used a vague term, namely, "*good* motive column," but in future lessons the vagueness will be removed, for then we will be able to determine what is the numerical value of what is here called *good*. To secure a maximum length for the motive column the entering fresh air should not be made to take the form of a cylindrical shell, but should enter the lamp below the heated and burnt gases, for it is only in this way that the minimum supply of air can be provided; and to assist in establishing this conclusion Fig. 153 is introduced. The fresh cold air is here seen to enter the lamp beneath the flame at *c c*, and the products of combustion are seen to leave the lamp at *a*, *a*, *a*, *a*, and as the lamp is bonnetted the hot column extends from the flame to the top of the gauze.

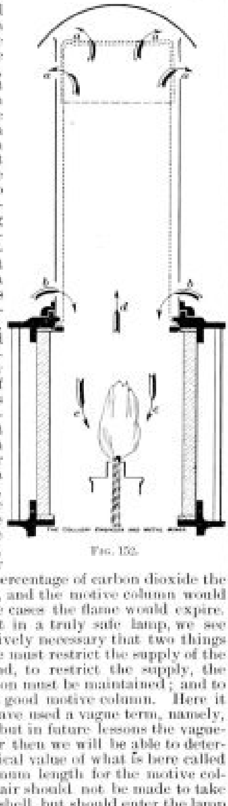

FIG. 152.

We do not doubt for one moment that something more than apertures are required to conduct the fresh air into the lamp and immediately under the flame; but the required provision for this will be one of the subjects of the future lessons, and therefore, for the present, let us decide that the air should by some means be introduced at *c c* with the intention of securing a long motive column and a steady flow.

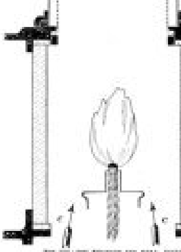

FIG. 153.

116. **The Recapitulation of Facts.**—QUES. 1.—If a puncture is made with a nail just under the cap of a Davy lamp gauze, will this hole reduce the efficiency of the gauze as an isolator of flame?

ANS.—A puncture made just under the cap of the gauze will not reduce the efficiency of the gauze as an isolator of flame, because such a hole is not a port for the entry of an explosive mixture, but for the discharge of the products of combustion.

QUES. 2.—If a Davy lamp gauze is punctured with a nail near the bottom, and just under the flame, will such a hole at all affect the efficiency of this gauze as an isolator of flame?

ANS.—Yes; a hole or nail puncture made near the bottom of a Davy lamp gauze will reduce the efficiency of the gauze as an isolator of flame, because the hole will be a port of entry for the admission of an explosive mixture, and, therefore, an explosion within the gauze will at once ensue.

QUES. 3.—What do you mean when you speak of the motive column of a lamp?

ANS.—I mean that length of a cold column of air that is equal in weight, to the difference in weight, of a cold and hot column, whose lengths are equal to the longest mean length of the hot air column; as for example, suppose the greatest length of the hot air column to be six inches, and the mean temperature of this column to be 600° F., and the temperature of the cold column to be 60° F., then the length of the motive column will be, if we take *d* to be equal to .5, that is, 6 inches or .5 of a foot, $\frac{(T - t) \times .5}{(460 + T)} = M\ C$, that is, $\frac{(600° - 60°) \times .5}{(460° + 600°)} = \frac{540 \times .5}{1{,}060} = .2547$ of a foot, or 3.0564 inches.

QUES. 4.—What occurs when the motive column of a safety lamp is too short?

ANS.—When the motive column of a safety lamp is too short, all resistance must be reduced, and an excessive supply of mine air is therefore admitted, with the result that danger instead of safety is promoted.

QUES. 5.—Where does the air enter and leave the gauze cylinder of a Clanny lamp?

ANS.—The air enters the gauze cylinder of a Clanny lamp from the bottom upward to the underside of the gauze cap, but only the air entering the lower portion of the gauze goes to feed the flame. The burnt air all leaves the gauze by passing through the meshes of the cap.

QUES. 6.—Should the supply of air to a lamp be restricted?

ANS.—The supply of fresh air to a lamp should be restricted, because every cubic inch admitted in excess of that required to maintain perfect combustion in the normal flame, reduces the protective or safety efficiency of the lamp.

QUES. 7.—What advantages does the bonnet secure in promoting the efficiency of a safety lamp?

ANS.—The bonnet acts in the first place as a shield or screen to prevent the air, in rapid currents, blowing through the gauze; and in the second place, it confines the entry of air to the lower portion of the gauze, and thereby increases the safety of the lamp.

QUES. 8.—On what principles should a safety lamp be constructed?

ANS.—A safety lamp should be constructed in harmony with the natural laws that secure the best light, with a minimum entry of air.

MINING METHODS.

Dust in Relation to Current Velocities—Wetting the Dusty Roads—Wetting the Suspended Dust with a Spray—Should the Intake or Return Air be Wetted?—Fine Dust is the Most Inflammable. The Agents that Supply Dust to the Air—Where Best to Apply a Water Spray—Recapitulation of Facts.

105. **Dust in Relation to Current Velocities.**—It was shown in the last lesson that the sizes of the dust particles in suspension in air were peculiar to the different velocities of the currents that supported them, and as such is the case, we ought to be just as able to determine the velocities of a current by the sizes of the largest particles it suspends, as we are able to find the sizes of the dust particles from the velocity of the current. Now the velocity of the current can actually be found in the way suggested and the truth of the statement can be fully established by an experiment with a simple apparatus, such as that illustrated by Fig. 142. First, then make a wire frame 10 inches square and having on the middle of one of its sides a socket to fit on the upper end of a stick, the bottom end of which is stuck into the ground, as shown by the figure. The wire frame carries a sheet of cotton cloth, and this is saturated with water when the arrangement is set up for a test. If at any time the air is highly charged with dust, the cloth quickly becomes blackened, and as we may expect the time of blackening varies with the charge of dust in the current, and, therefore, the time required for discoloration is the index of the state of the air. The speeds of the current are characterized by the presence on the sheet of different sized particles and these can be seen with a good magnifying glass. To distinguish the sizes, peculiar to the different current velocities, however, the observer requires practice in collecting different samples with his wet cloth. In the figure under consideration *w* is the wet cloth and it is seen to be supported by the stick *s*, whose lower end is firmly set in the ground, and in this position a *test* is supposed to be in course of being made. The water used to saturate the cloth ought to contain a deliquescent substance in solution, such as carbonate of potash, for this would prevent the evaporation of the water, or the drying of the cloth, and thereby add to the value of the test. Although this cloth is at the best, only a rough "rule of thumb" sort of a gauge of the dust in suspension in an air current, yet its simplicity of construction, and adaptability for ready application, make it at any rate a good index of whether the air in a room is in a safe condition or not, in so far as coal dust is concerned, for the firing of shots.

106. **Wetting the Dusty Roads.**—The dangers arising from the presence of coal dust in the air, immediately exposed to the flame given off by a shot during its explosion, have been suddenly brought into notice, and, therefore, even the best informed men are affected with the

confusion that always comes with a surprise. There are certain facts, however, that have come across the path of all practical men that bear directly along the line of our present investigation, such as, wetting the roads "to lay the dust," but this statement of what we do, and why we do it, suggests a question like this: In what way does the wetness of the roads lay the dust? and the answer we are likely to give is, When the dust of the road is watered it becomes adhesive and heavy, and therefore, cannot be raised by the scour of the wind sweeping over it. So far, this statement of the mode of action is right, but in what way does the wetness of the floor, roof, and sides of a road affect the dust that is suspended? This last question requires, certainly, a more comprehensive answer than the former one; and more than that, the answer can only be made satisfactory with the help of several riders to the answer to qualify it. The prime answer then is this: All the particles of the air that constitutes the current are, by the deflections from the roof, the floor and the sides of the airway, in their turn, made to sweep over these surfaces, and therefore, by this means the dust particles the air holds in suspension all become wetted and agglutinated, and by this means become too heavy to float, and therefore, sink and leave the air clean. But another question arises out of this, such as how far must the current travel for all the dust it contains to be wetted? and another question is, what weight or volume of water will be necessary to wet the road efficiently? and yet another question is, is it possible to do this extensive wetting in practice for the firing of a single shot? This last rider to the prime question, suggests another very pertinent one, and it is this: Can the dust in suspen-

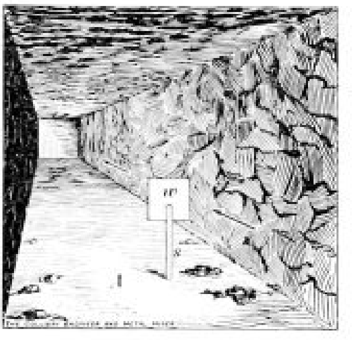

FIG. 112.

sion not be easier wetted and removed by a simpler and cheaper process, than that of watering the roads? and the answer, we are happy to say, is yes!

107. Wetting the Suspended Dust with a Spray.—Before showing, however, which is the best method of purging the air free of inflammable dust, let it be noticed that a large volume of water may be so misused as to effect very little good, while a small volume may be made to so wet the air as to remove all dust; for if the air is wetted with a water spray so fine that the particles of water are nearly as small as the particles of dust, then the air can be more perfectly cleaned with a gallon of water than it could be with one hundred gallons ejected in larger particles; or the one gallon of water ejected in particles so fine that they would float away in the air like smoke would more efficiently purge out the dust than a thousand gallons thrown on the roof, floor and sides of a road; for an air current saturated with dust must travel a long journey before the wet sides of the road can effect any good. Water ejected at a high pressure out of very fine perforations may be made as fine as the water dust of condensed steam, and where hose cannot be applied, a portable vessel may be made to run on a truck, and the necessary pressure may be obtained with compressed air pumped into the water tank, and if even this appliance can not be used, then small vessels can be carried by hand to eject a fine spray at a high pressure; this can be done by the injection of compressed air into the vessel with a forcing pump.

108. Should the Intake or Return Air be Wetted?—Another very important matter requires our attention in relation to dust in suspension, and it is this: Should the air be wetted before entering the locality of the shot, or should the air, and roof, and floor, and sides be wetted on the return side of the shot? Suppose the watering to be done on the side along which the air is leaving the locality of the shot, then it may be said that any flame produced by the shot will be cut short on entering the clean air that contains no fuel for further combustion, but during the time that elapses in the retreat of the fire boss from the shot to a place of safety, the ingoing air charged with dust has had time to displace the clean air and make the danger as great as ever. We see, then, that little good can be effected by wetting the return air, and therefore the flame from a shot ought to be so isolated with clean air, that, at the period when the shot is fired, not only the locality of the shot, but the air entering it, should be entirely free from dust. To secure this desirable result it is necessary that the ingoing air should be wetted and purged, for then, instead of the period of the retreat from the shot being one during which the danger increases, it would be one during which the danger decreases, and if this conclusion is a correct one, we see at once the importance of the matter.

109. Fine Dust is the Most Inflammable.—The finest dust will be much more inflammable than the grosser varieties, and this may be classed as danger number one. Again, air parts with its grosser dust the moment the velocity of the current is reduced, while the finest dust remains in suspension at very low velocities, and this fact may be classed as danger number two. But fine dust is easy wetted and purged out of air with a fine spray, and this constitutes safety number one, while a less volume of water is required for wetting air with a very fine spray than with a large volume of water improperly applied, and this furnishes safety number two. We now see the importance of knowing the true character of suspendable dust, for, while others think that the most dangerous dust is suspended in air currents of high velocities we now know that the most dangerous varieties of inflammable dust are contained in suspension in air currents of low velocity, and we now further know that to purge the air of its dust we must use a water dust in which the particles are nearly as small as those of the dust they are intended to remove.

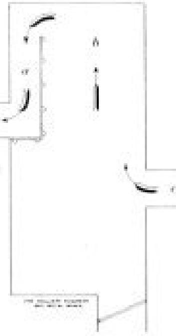

FIG. 143.

110. The Agents that Supply Dust to the Air.—We have given full attention to the study of the suspension of dust particles and now we are about to consider where and how the supply of dust is furnished, and we shall find the latter enquiry is only second in importance to the former one. The supply of dust is furnished by three agencies, and these are, the cutting of the coal, the filling of the coal, and the haulage. But for the dust given off by the shake of the cars during their haulage to the shaft, the ingoing current of the principal intake airway would be free from dust, and this state of purity would continue until the fresh air reached the first chamber or room to be ventilated. We can then see that the dust taken up in suspension by the air in the first chamber is borne forward into the second one, and then on from the second to the third, until the same distinct current has gathered dust accumulatively from the first to the last room in the series, when it enters the main return airway in a highly charged condition. The last fact that has engaged our attention suggests an important conclusion, namely, that the dangers arising from the ignition of coal dust are greater in the last room of a series ventilated than in the one that first receives the clean fresh air, unless the air is first purged with a water spray. We can see by an inspection of Fig. 143 that, if the air entering at *c* brings with it a charge of fine dust suspendable in a current of low velocity that comes from a former room, by the time this current arrives behind the brattice at *a* it will have taken up a second charge from *b*, unless the entering air is purged before emerging from *c*.

111. Where Best to Apply a Water Spray.—Again we are confronted with another question, which is this: Where should we apply the spray to effect the best result in purging the air? In answering this question, thought and caution must be exercised, because prudence is the best director in such important matters. If we apply the spray on the wide side of the brattice, we must either use more water or make the spray finer and use more time, and even then the air will never be efficiently purged, because the incoming air will enter at a higher velocity than that of the wide current in course of being operated on, and the result will be a continual mixing of the charged and purged air. We see, then, that the air should be wetted and purged before emerging from *c* to obtain the most efficient and economical results. Now, on the face of all this, the reader will see that if coal dust is attended with the dangers that are claimed for it, and perhaps none of us doubt the accuracy of the evidence, there is a right way of proceeding to purge the air and reduce the danger to a minimum.

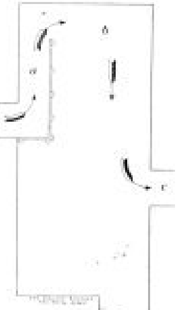

FIG. 144.

There are two things that require attention with regard to coal dust in air and the firing of shots. The first is, we require some ready and simple means of testing to find if the dust is present in dangerous proportions, for if it is not, then we may dispense with the use of the spray; and on the other hand, if the proportions of dust are found to be really dangerous, then we know that it would not be safe to fire a shot until the air is purged. The great thing to be done, however is to devise a testing apparatus that is simple in construction and in use, and until what we propose is done, the wet cotton cloth may be taken as better than no test, for it will at any rate indicate when the air is heavily charged. When the ventilation of a room or chamber is so carried on that the entering air comes up behind the brattice, as in Fig. 144, the conditions for purging the air with a spray are highly favorable, for if the shot has to be fired in the neighborhood of *b* the clean air from *a* will displace all the dust-charged air along the working face, and prevent even the possibility of the prolongation of the flame of a shot. Another matter associated with this figure requires attention, and it is this, if the air ought to be sprayed before entering a room when a shot has to be fired, the same rule should be applied throughout the mine, wherever the entering air is likely to be saturated with fine inflammable dust.

Recapitulation of Facts.—QUES. 1. Does watering the roads, or projecting a spray into the air current of a mine do the most good?

ANS. A fine water spray at once drenches the dust particles and causes them to agglutinate and gravitate out of the air, whereas when the roof, floor and sides of a road are watered the current has to travel over a great length before the dust is arrested.

QUES. 2. Should the ingoing or return air be wetted with the water spray?

ANS. The ingoing air, or the air entering a locality where a shot has to be fired, should be purged with a water spray, for then if the work is well done no explosion can occur by the ignition of the inflammable coal dust in the air.

(To be Continued.)

A Large Electric Mining Plant.

A few months ago we described the interesting power transmission plant installed by the General Electric Company at the Silver Lake Mines of Mr. E. G. Stoiber, at Silverton, Colo. The introduction of electricity into the operation of the mines has resulted in economy so noticeable that an increase in the plant is now being made to provide for an extension of the system in the mines and to reinforce the water power which is not sufficient to furnish all the power required throughout the year.

Two cross compound Corliss engines, with cylinders 24" x 46" x 48", each engine of 850 I. H. P., are now being set up, together with water tube boilers, mechanical stokers, coal and ash conveyors, feed water heaters, separators, water meter, coal weighers, the whole making what will be the most thoroughly modern steam plant in the state.

The difference between the cost of coal at the power house and its cost at the mine, which is at greater elevation by some 2500 feet, is such that the saving effected, even when steam power is used for generating purposes, will insure an ample return on the investment, while the economy induced by the use of the water power is considerably greater. Mr. Stoiber, therefore, feels that in adopting electricity for the operation of his mines he has more than considerably diminished the cost of working them.

The present plant now in operation consists of two 150 K. W. General Electric three phase water driven generators, supplying current to one 100 H. P. motor for the mill; one 100 H. P. motor for the air compressor; one 75 H. P. motor for the hoist; one 15 H. P. motor for the pump; one 1 H. P. motor for a blower and incandescent lights scattered throughout the station, mill and mine. The additional plant will consist of two 150 K. W. General Electric generators, one 100 H. P. motor for the mill; one 15 H. P. motor to drive a pump, and two 10 H. P. motors for blowers, forges and miscellaneous machinery, and to eventually utilize to the full the capacity of the steam and water power plants, additional and larger generators will be set up.

Not the least interesting feature of this installation, is that although the entire output of electrical energy is to be used in the operation of a single mining property, it will be, when completed, the largest electric power plant in the State of Colorado.

Cahall Boilers.

The Carnegie Steel Company, nearly two years ago, being favorably impressed with the design of the Cahall vertical water tube boiler, made an investigation as to its merits, the result of which induced them to put in a trial plant of these boilers of 2000 horse-power at their gas pumping plant at Bagdad, Pa. The performance of the boilers at Bagdad was such a marked improvement over the general boiler practice of to-day that they about a year later put four of these boilers at their Edgar Thomson Steel Works. They very carefully watched and tested the boilers at Edgar-Thomson under varying conditions, with the result that they have been so well satisfied with the work done by those four that they have made arrangements to tear out all the old style boilers at furnaces A, B and C at the Edgar-Thomson Steel Works, and have purchased 5250 horse-power of the Cahall vertical water tube boilers to be installed at these furnaces in place of the ones they will remove.

Water for Steam Purposes.

The dry season, with the accompanying scarcity of water for steam purposes at many coal mines, is again upon us, and any suggestions as to a remedy for the trouble we feel sure will be appreciated by our readers.

No company has had more trouble from this source than the Philadelphia and Reading Coal and Iron Co., and the officials of that company have spared neither time nor expense in endeavoring to utilize water more or less impregnated with mine water for steam purposes. The greatest success achieved was during the dry season of 1895, when they first tried and then adopted the Pittsburg Boiler Scale Resolvent, an economical and efficient preparation that prevents both scale and corrosion.

This preparation is made by the Pittsburg Boiler Scale Resolvent Co., Pittsburg, Pa., and it is guaranteed by the makers. It is now used by many of the leading mining companies of America.

English Wire Rope.

Messrs. George Cradock & Co., of Wakefield, England, extensive manufacturers of wire rope, whose advertisement has appeared in our columns for over a year past, request us to announce that Mr. T. A. Wigham is no longer connected with them in any way, and that, for the present, American customers are requested to communicate directly with them at Wakefield, England. Messrs. Cradock & Co. are desirous of securing live responsible agents in every American mining field.

MISCELLANEOUS.

SCENERY OF THE MOON.

Notwithstanding that the moon is 240,000 miles distant from the earth, it would in some respects be hardly an exaggeration to assert that we are better acquainted with the topography of our satellite that we are with that of the globe which forms our home. It is a peculiarity of our satellite that it manages its movements in such a manner as to withhold nearly half of its surface from ever being inspected. It follows that we have no means of learning what is on the other side of the moon. So far, however, as the neighboring globe is displayed for our observation, we can certainly assert that there is hardly a spot possessing the size of an ordinary parish which has not been studied and photographed, sketched by competent draughtsmen, duly laid down on elaborate charts of the lunar surface, and in many cases received the dignity of a special name.

For the purpose of the terrestial astronomer, it fortunately happens that the moon is almost entirely destitute of atmosphere. The features of its surface are consequently never obscured by any of those causes which would tend to hide the features of the earth from outside scrutiny. Whenever the clouds on our globe are out of the way, it is then possible to observe the moon with but little obstruction. If we also remember that many of the features of our satellite are within reach of a telescope of comparatively moderate power, it will not be surprising that the lunar scenery has attracted so much attention and that thousands of minute features on its surface have been carefully identified.

When we look up at the full moon, even without calling the telescope to our aid, we at once notice the presence of a number of large dark patches. The appearance of these dark spots, in days before telescopes were employed, suggested that those objects were basins of water, and accordingly they were anciently called "seas." In modern days, astronomers have somewhat awkwardly retained this name, or its Latin equivalent, to designate these peculiar dark tracts, notwithstanding the fact that there are sound physical reasons why it does not seem the least likely that there could be any water in the fluid form present in our satellite.

No doubt it seems the simplest supposition, so far as certain phenomena are concerned, to believe that they are the basins in which great seas did once roll, but that as the moon has gradually cooled down from a primeval state in which it was largely composed of molten matter, the water from the seas penetrated into the interior, and there entered into chemical union with the materials which were crystallizing. There are, however, many who believe that these dark regions are due to the pouring forth from the interior of vast volumes of molten lava which spreads over deep hollows, burying more or less completely the objects which had previously occupied them.

The most characteristic features of the scenery of our satellite are, however, the remarkable objects which are the results of volcanic phenomena. There are many classes into which these objects can be divided, but it will be sufficient if we attempt to give some brief account of what may be called the walled plains, and of the volcanic craters properly so termed. The most perfect example of a walled plain on the moon is the great object known as Ptolemæus. The remarkable district so designated covers an area on our satellite considerably larger than Wales. It is situated nearly centrally on that face of the moon directed toward us, so that it generally lies very conveniently placed for examination, and is the last of a chain of four magnificent objects of the same character, which lie along the coast of that darkest of lunar seas, known as the Mare Nubium. Ptolemæus may be described as almost circular in outline, though sometimes it might be regarded as a rudely six sided figure. Its appearance may be compared to that of an eyeglass, whereof the little handle is formed by a beautifully shaped crater bearing the name of Herschel. The floor of Ptolemæus is a plain, not much depressed below the general level of the lunar surface.

To my mind, however, the most interesting of these objects, as well as perhaps the most perfect representative of its class, is the beautiful walled plain named Plato. No other object of the same character happens to lie in its neighborhood, and, consequently there is but little difficulty in distinguishing it.

There is also another circumstance which is sometimes apt to puzzle the beginner, for, owing to what is called the moon's libration, the face which is directed toward us is not always exactly the same. The difficulties will, however, not prevent the student from readily identifying the superb object known as Plato. It lies in the northern region of the moon, and as our telescopes exhibit the object inverted, this means that Plato must be sought at the lower part of the field.

This walled plain is situated on the coast line of a magnificent lunar sea, namely, the Mare Imbrium, which may, perhaps, be described as a stupendous gulf branching off from the Oceanus Procellarum. The floor of Plato measures about sixty miles across. It may be said to be flat, with the exception of certain small irregularities; but the fact which chiefly strikes the attention of the observer, and which is specially noticeable in the photographs, is the unusual darkness of that floor as compared with other parts of the moon. The rampart of mountains which surrounds Plato is comparatively perfect, and no more pleasing lunar picture can be beheld than when the shadows of these mountain peaks lie stretched along the dark central floor, as they do when the sun is in such a position that it would just appear to be rising to the lunar inhabitant who was stationed in the neighborhood.

The shadows of lunar mountain peaks not only greatly enhance the beauty of our lunar picture from a spectacular point of view, but they have another importance. They present to the astronomer the only means which he possesses for measuring the altitudes of the lunar mountains. For, as a lunar mountain is more or less pointed toward the observer, its elevation above the surface cannot be attained by direct measurements.

The isthmus on which Plato is situated contains many other interesting objects. Beginning at the northern point, we first come to the very remarkable bay known as the Sinus Iridum. Then comes Plato, and then the gulf sweeps round by a noble range of mountains called the Caucasus, between which and the range of the Appenines there is a passage which leads into the Mare Serenitatis.

At this point the observer will notice three splendid rings lying out in the Mare Imbrium. The smallest of these is the Autolycus. Directly below that is the larger ring known as Aristillus, which is 34 miles in diameter. Its rampart rises upward of two miles above the surrounding plain, while the interior of it is depressed some 3,000 feet below the level of the general lunar surface. Aristillus may be regarded as a typical lunar crater, inasmuch as it is adorned by a lofty mountain peak ascending from the center. The third of the three craters which form this noteworthy group lies far out in the Mare Imbrium, and is the famous lunar object known as Archimedes. This crater is not quite so large as Plato, but its floor presents multitudes of points of interest to assiduous lunar observers.

Returning, however, to the neighboring coasts from our survey of these objects out in the Mare Imbrium, we perceive the splendid range of the lunar Appenines. The objects so called are by far the most magnificent range of mountains that can be seen on the moon, ascending, as some of its peaks do, to an altitude of about 18,000 feet above the surrounding plain. This superb range extends for a distance of no less than 400 miles along the shore of the Mare Imbrium, and the special summits which have been noticed upon it are to be numbered in hundreds. The Appenines project a mighty promontory into the Mare Imbrium, which terminates in the crater known as Eratosthenes. This object is of interest as being, perhaps, the volcanic vent for the mighty forces which were once concerned in the upheaval of this mountain range connected with it.

The promontory thus magnificently ended points to another lunar feature. This is the great crater Copernicus, which is regarded as the most noteworthy object of the moon. It stands isolated in the Oceanus Procellarum, and this peculiar situation gives to Copernicus a distinctness which makes it very easy to recognize. Among the features which makes Copernicus specially interesting as a telescopic object are the remarkable terraces which are to be seen in its interior. They are apparently due to successive floodings of the crater by lava. It seems probable that they were produced during some outbreak when the crater became filled with lava, then after a period of quiescence the surface of this would become congealed. If the molten lava beneath subsided it would leave a margin of solidified material, which would form the first or highest terrace. At a subsequent outbreak the basin might have been only partly filled, so that the lava did not ascend to so great an altitude. This would in due course become congealed on the surface, and again the lava would subside, thus forming a second terrace.

A remarkable characteristic of lunar scenery which is displayed on a grand scale by Copernicus, is the presence of bright radiating streaks which extend from the great crater for many hundreds of miles over the lunar surface. The explanation of these bright streaks offers one of the most difficult problems in lunar physics. They are sometimes thought to mark lava flow from the central spot at some earlier phase of eruption than the crater as it now stands would indicate. It does not, however seem apparent why these streaks should in this case possess the peculiar brightness which characterizes them.

Near the southern pole of the moon is the remarkable crater known as Tycho. This is situated in a region where the scenery indicates the wildest and most magnificent confusion. Tycho is specially noticeable for the number of bright streaks which radiate from it. Indeed, at the time of full moon, when these streaks are peculiarly visible, they have frequently been likened to meridians diverging from a pole.

One more striking feature in the scenery of our satellite should be referred to. I mean the deep but narrow clefts or chasms which extend for hundreds and often for thousands of miles across the lunar surface. These chasms seem in all probability to owe their origin to earthquake shocks, by which the moon was shaken in the days when its volcanoes were still active. Those days seem, however, to have long since passed. The volcanoes on the moon no longer give any manifestation of energy.—*Condensed from an article by Sir Robert Ball in The New York Sun.*

THE TOMBS OF ANCIENT KINGS.

Theorists have discovered, or think they have discovered, many wonderful properties about the Pyramids, but we should not lose sight of the main fact that they are merely vast heaps of stone, exquisitely built indeed, that mark the graves of monarchs who wished to keep their mummied bodies inviolate for all time.

The Egyptians built their houses for the living of perishable brick; they built their houses for the dead of immortal granite. There was a reason for this, founded upon the theory of human life and death. They regarded man as composed of several entities, each having its separate life and functions. First was the body; then the *ka*, or double, which was an etherial duplicate, feature for feature, of the corporeal form; then was the soul, which was popularly represented as a human-headed bird, and after the soul came the "luminous," a spark from the divine fire.

By process of embalmment they could suspend for ages the decomposition of the body, and by means of prayer and offerings the other component parts were saved from the second death, thus causing prolongation of existence. The "double" never left the body, but the soul and the "luminous" went forth to follow the gods, returning now and then to the resting place of the body. Thus, the tomb was called the "eternal house" of the dead, compared with which the houses of the living were but wayside inns, and, therefore, if possible, these eternal houses were built as durable as all time. The tomb must contain a private room for the soul, which was closed at the time of burial, not to be opened under any circumstances. It must also contain a wide passage or reception room, where priests and friends made offerings for the dead. Indeed, the tomb was looked upon as a permanent dwelling, and it was built to promote the well-being and insure the preservation of the dead.

The construction of the Pyramids and other imposing tombs illustrate this idea, and the success with which these ancient Egyptians preserved the mortal remains of their royal dead is seen in the mummies that retain their facial expressions after thousands of years.

The great Pyramid of Cheops, at Gizeh, the most prodigious of all human constructions, covers thirteen acres at the base and weighs about seven million tons. Originally it was 480 feet high, and it is estimated that the materials that were used for its construction would build over 20,000 eight-roomed cottages and house a population of 150,000.

Like most of its fellows, it stands exactly square to the four points of the compass. The great limestone blocks, some of them five feet broad and high and thirty feet long, were brought from distant quarries, propelled, doubtless on rollers from the river along a well-laid causeway to their present site. Mechanical appliances, as well as the art of cutting and polishing the hardest stone, were familiar to these Egyptians of 5,000 years ago.

Twenty years, Herodotus tells us, the great Pyramid was building, and, when it was completed, instead of presenting the rough series of steps it does now, the whole edifice was cased with shining red syenite, brought from the first cataract, 500 miles away, which caused it to glisten so brightly that it was known as the "Pyramid of Lights." Until the Arab conquest it preserved this stone casing, so wonderfully joined as to appear like one block from base to summit.

In the inside everything was arranged so as to hide the exact place of the sarcophagus and thus baffle all would-be spoilers of the royal tomb. The entrance was found to be nearly in the middle of the north face, at the level of the eighteenth course, about forty-five feet from the ground. When at last the casing was torn off and the block of stone was displaced which covered the entrance, an inclined passage 41.2 inches wide and 47.6 inches high was revealed, the lower part of which was cut in the stone. This descended for 317 feet, passed through an unfinished chamber, and ended sixty feet further in a blind passage. In from the door a block of granite was found which shut from view another passage. This obstacle being passed, there came an ascending passage which divided into two branches—one running into a limestone chamber in the center of the Pyramid; the other, continuing upward, became a gallery 148 feet long and 28 feet high, built of Mokattam stone, so polished and finely wrought that we are told it was difficult to put a needle or even a hair into the joints.

Another difficulty must now be surmounted. The final passage leading to the chamber of the sarcophagus was closed by a slab of granite, and further on was a small vestibule divided in equal spaces by four partitions of granite, which must be broken. When at last it was reached the royal sepulchre was found to be a granite chamber 19 feet high, 34 feet long, and 17 feet wide.

The second Pyramid of Gizeh, built by the brother of the builder of the first (according to Herodotus) retains some of its original casing at the top; and round the third, the Red Pyramid of Menkara, where it is supposed once lay the body of the beautiful Queen Nitocris, a Loreley legend has grown up. The queen's blushing face caused her to be confounded with the rosy-cheeked Rhodopis, the Greek favorite of King Amasis, and superstition imagines that a fair but treacherous woman haunts the Red Pyramid and bewitches travelers. —*From the Baltimore Sun.*

ONE OF NATURE'S PROVISIONS.

Man's inventions follow nature's lead, only they lag far behind. The cold storage of fruit is a modern device for the supplying of man with fruit long after the fruit-ripening season is over; but nature had done the same thing from time immemorial. Mr. Henry Seebohm, a famous English ornithologist, surprised from nature her secret, and discovered her great cold-storage system.

In the course of his researches he was led to visit Petchora River, which flows from the Ural Mountains into the Artic Ocean near Nova Zembla. Along the lower part of the river he found what seemed the most uninviting district—an uninhabited, treeless swamp, stretching on either side of the stream, and known as the tundra. Higher up the river was the great Siberian forest, but here in the tundra was nothing but hard, frozen snow. Yet this unattractive spot was found to be the summer home of half the bird population of the Old World.

Mr. Seebohm reached it in the beginning of April. Forest and tundra were as bare of life as the Desert of Sahara; but a change was coming. Suddenly summer broke over the scene, and with it came the birds. The ice in the river split and disappeared, the banks steamed in the sun, and innumerable birds of all sizes and colors appeared within forty-eight hours after the first warmth.

The once frozen tundra now showed itself to be a moor, with here and there a large bog and numerous lakes. It was covered with moss, lichens, heath-like plants, dwarf birch and millions of acres of cloudberries, cranberries, and crowberries. This was the storehouse of the feathered tribes.

The perpetual sun of the Arctic summer causes the plants to bear in wonderful profusion, so that fruit was abundant. But fruit-bearing does not come before blossoming, and blossom and fruit cannot be perfected in forty-eight hours. The little travellers were arriving by thousands. The fruit would not be ripe before the middle or end of the Arctic summer, and if the birds had to wait till then they must needs starve.

Not so, however, does nature provide for her pensioners. Long before the snow had melted, provision had been made for their maintenance. Beneath the snow lay the whole crop of last year's fruit, perfectly preserved by nature's system of cold storage.

Each year when the berries are ripe, and before the birds can gather them, the snow descends upon the tundra, effectually covering the crop, and preserving it in perfect condition until the spring sun melts the snow and discloses the bushes loaded with ripened fruit, or, in some cases, the ground beneath the plants, covered with the fallen treasure waiting for the hungry strangers. The berries never decay beneath the snow, but keep in perfect condition, and are accessible as soon as the snow melts. Nature's cold storage is never a failure.

Nor need the visitors depend on fruit alone for sustenance. The insect-eating birds are also provided for, and all may take their choice of fruit or flesh. The same heat which frees the fruit also brings into being the most prolific insect life in the world. No European can live there without a veil after the snow melts.—*From The Spectator.*

WHY SAND FLOATS ON WATER.

It is quite well known that small, dry particles of substances of greater specific gravity than water will float upon it, by reason of capillary action. The surface tension of the water enabling the water to form a depression somewhat larger than the particle, this has the same result as if the specific gravity of the particle had been decreased. The phenomenon observed by Mr. Simonds at Llano river is interesting, as the granite sand was larger and heavier than the dust which had usually been observed heretofore. He tried various kinds of sand and found that they all floated with one exception. Mr. Simonds says:

"The morning after my arrival, the river was found to be rising, and, as I stood on the bank, at the point where we secured our water supply, I noticed a considerable froth and what appeared to me at the time scum passing down the stream. I spoke of the condition of the river to my companion, Mr. Laurence D. Brooks, of Austin, who remarked that what seemed to be scum was really sand. I thereupon went down to the water's edge, and, dipping up some of the floating material, was astonished to find that the patches were composed of sand, mainly of quartz. At this time—half-past nine or ten—the water supported a large number of patches, which varied in area from less than a square inch up to several square inches, all swept along by the current. * * *

"A week later, when the river was well down and the sandy stretches of its bed had become quite dry on their surface, I gathered sand by handfuls, and sent it floating down the stream in such quantities that the sand rafts actually cast shadows on the bottom as they passed.

"When shaded, it will be seen that the floating sand grains cause a depression of the water's surface, which indeed is quite as apparent in the case of isolated grains as in that of patches. I recall one instance where the depression, of very short duration, possibly but a few seconds, was so great as to be positively startling. As I was sprinkling some sand upon the river, for experimental purposes, a pebble almost as large as the end of my little finger fell into the center of a floating patch, which, to my great astonishment and delight, was depressed like a funnel for say half an inch, before the cause of this unexpected phenomenon broke through the surface and sank to the bottom.

"It appears from these and other observations that the weight of the sand grains actually depresses the surface of the water; yet the elastic reaction of that surface is sufficiently great to prevent them from sinking, especially when the resistance offered by their angularity is taken into consideration. In the launching of grains the more rounded would tend to roll over in the water and thus become wet, in consequence of which they would sink, while those of an irregular shape would overcome the tendency to roll and remain partially dry, thus fulfilling a condition necessary for floating."—*From the American Geologist.*

A WORD WITH THE DOCTOR.

An invaluable aid for the preservation of one's health and spirits is to go out of the house, on some fixed errand, every day of one's life. This is not so easy as it seems, and all men and women know that it is not. But the practice, if carried on ever so short a time, will plead for itself. We get into very bad habits of staying within doors, and foregoing the change of air and scene and interest that is absolutely necessary not only to a broader mind, but also to a sane view of things in general.

⁂

The following are homely remedies for neuralgia: Boil a handful of lobelia in half a pint of water, strain and add a teaspoonful of fine salt. Wring cloths out of the liquid, very hot, and apply till the pain ceases, changing as fast as cold, then cover with dry cloths for a while, to prevent taking cold. Two large tablespoonfuls of eau de Cologne and two teaspoonfuls of fine salt mixed in a bottle make an excellent mixture to be inhaled for facial neuralgia. Horse radish, prepared the same as for the table, applied to the temple or wrist, is also recommended.

⁂

A good household remedy for burns can be made by mixing equal parts of raw linseed oil and lime water.

⁂

Wormwood boiled in vinegar and applied as hot as can be borne on a sprain or bruise, is an invaluable remedy. The affected member should afterward be rolled in flannels to retain the heat.

⁂

If castor oil is applied to a wart once a day for a month the wart will entirely disappear. In many cases it will not require so long a time.

⁂

Did you ever notice the way a physician prepares the court plaster for a wound? First, fold the piece lengthwise directly through the middle. The plaster should be considerably larger than the wound to keep well over the edges. Then slash the plaster lengthwise nearly to the edge. Straighten the court plaster out flat, and cut the slashed pieces at opposite ends. Place the straight edges of the court plaster to the flesh on either side of the wound, bringing the strips across the wound. Moisten them, and, taking a strip from each side, draw them together gently, closing the cut, and stick the plaster in place. Continue with all the strips, and the cut will be dressed in a manner to insure a perfect healing, and as well as any doctor could do it.

⁂

Defective hearing is a trouble that many children labor under, caused occasionally by disease, but oftentimes by lack of proper care of the ear passages. It is sometimes the case that the dullness and inattention of a scholar are due to impaired hearing, and the inability to hear distinctly gives the poor child the appearance of being heedless and inattentive.

The waxy secretion found in the ears is nature's own method of keeping the ears in a healthy condition. There is frequently, however, an excess of this wax, and occasionally it happens that, in cleaning the child's ears, the excess of wax is pushed further into the ear passages. Repetitions of this process cause the wax to become packed, causing gradual loss of the hearing power. Too much stress cannot be laid upon the fact that pins and such articles should not be used in the care of the ears, as serious injury is liable from the article entering too far.

Glycerine and warm water in equal parts is a mixture that will dissolve and remove the wax. Apply gently with a small syringe. Should there be at any time anything in the nature of discharges from either ear, a physician's advice should be sought without delay. In such cases there is almost certain to be some disease of the inner ear passage requiring medical attention. Prompt attention will probably save the child serious impairment of hearing, if not utter loss. It should be noted that teething may have close relationship to trouble in the ears, due to the swelling and inflammation of the gums. This inflammation is liable to extend through the eustachian canals to the ears; and any tenderness accompanied by redness around the ears, is a sufficient indication to warrant calling the physician's attention to the matter.—*From "The American."*

"HOW DO YOU DO?"

An American lady who spent some time in Paris says that she had a friend there, a French lady, who wished to learn a little English, and did so. Among her acquisitions in the language was the expression, "How do you do?" to which she was careful to learn the proper response.

One day the American lady met her French friend on the street. The American lady said, "How do you do?" with a smile, and passed on. She did not stop to notice that she had left the French lady standing on the street in astonishment.

Soon afterward she called on her friend, and was received very coldly by the French lady. As she did not know of any reason why the lady should be offended with her, she pressed her to tell her what was the matter. "Have I done anything to grieve you?" she asked.

"Anything to grieve me!" answered the French lady; "You meet me on the street, you ask me how I am, you do not wait to find out how I am, you pass on, and then you ask me whether you have done anything to grieve me?"

Then the American explained that it was not customary for Americans to wait for an answer to their inquiry, "How do you do?" that they commonly only utter the words and pass on, or if they stop to speak, at once begin to talk of other matters.

That this was the case she was able to prove by taking the French lady to a hotel where there were several Americans, and allowing her to hear their salutations, "How do you do?" "How do you do?" unaccompanied by any account of *how* they "did."

The French lady could hardly express her astonishment. "The Americans do many very, very strange things," she said, "but this is the strangest of all!"

The French when they are of the degree of acquaintance which justifies inquiry as to the health of another, stop and hear all about it, and all about the health of the respective families. When all this information has been exchanged the two persons part with many adieux and elaborate good wishes for each other's continued health and happiness.

The Italians frequently embrace one another in public places, and shake hands several times, and commit one another in parting to the care of God. The Americans and the English are the only people who question each other as to their health without stopping to find out anything about it.—*From The Youth's Companion.*

COLOR-BLINDNESS.

Persons may be born with color-blindness, or they may acquire it in after life. In the former case color-blindness is not, strictly speaking, a disease, but an imperfection of vision dependent upon some unknown cause. Its appearance in later life is significant of many diseases of the eye.

Color-blindness, especially that form of it which exists from birth, may be of any degree up to an inability to recognize any color whatever, so that the whole external world looks gray, like an engraving. Cases of this extreme kind are rare; but cases in which the blindness is limited to one or two or a group of colors are frequent enough.

The scientific explanation of color-blindness is easily understood and very interesting. It is based upon the theory that there are in the eye three sets of nerves, which correspond to the fundamental or primary colors. Perception of any one of these primary colors arises from the stimulation of the corresponding nerve by the light which is reflected from the color. Sensation to the remaining colors originates through a varying mixture of stimulation of two or all of the nerves.

Partial color-blindness, then, is simply the inability of any one of the nerves to correspond to proper stimulation; an inability which not only renders the afflicted person unable to distinguish a particular color,—red, green, or violet, as the case may be,—but makes him "blind" to all compound colors into which the primary color enters.

We are not to suppose, however, that the affected nerves are entirely insensible, for that would imply that the colored object would either be unapparent or seen as entirely colorless. Each of the groups of nerves of which we have spoken is set in action by all kinds of colored light, but to different degrees of intensity. Some nerves are affected most strongly by rays from red objects, less so by yellow, still less by green, and least of all by violet colors. These nerves are designated as the nerves for the perception of red. Other nerves respond more strongly to yellow, others to green, and so on.

Color-blindness may exist for years undiscovered, to be discovered at last by the committal of some gross mistake, like that of the tailor who wanted to mend a black coat with a patch of red.

The fault is one which can never be cured, although many persons, relying upon the brilliancy which certain colors present over others, appear to be able to correct their error of sight.—*From the Youth's Companion.*

THE FRONTIERSMAN'S RIFLE.

An old-time plainsman, writing about the good points of the old-style rifle, says: The modern riflemen do not appreciate the possibilities of the old-fashioned arms of the kind Daniel Boone thought perfect. There was no such phrase for the frontiersman as "accurate enough for hunting," which is common these days. A rifle which a frontiersman owned had to be one he could bet his life on and win. It must be, above all, accurate. If it was aimed at a candle wick, it must must not hit the candle. If aimed at a man's heart, it had to hit it, and not an arm or ear. Up to 200 yards the accuracy of the old weapon, the pea rifle, has not been excelled, and few modern rifles equal it.

In these days of pump guns, which throw bar lead out of the muzzle and brass pipe out of the breech, accuracy is thrown to the winds. If the first shot misses, why, a second later another is ready. Not so with the muzzle loader. The game was in sight for just one shot, and no more. If that shot was not fatal, more game must be searched for. Knowing this, the old-time hunters drew down and shot for meat. They did not pull when the sights were in line with a leg or the paunch. When they pulled the set trigger, the sights were in line with the heart, head, throat or back, and the whip-crack of the weapon oftener meant death to the game than the rip-roar slam of a modern repeating rifle.

A man who would use a shotgun for game in those days was a contemptible freak, and even to-day the shotgun users respect the man who uses a rifle for shooting birds' heads off, instead of using a scatter gun. The frontiersman trusted his rifle. It was "Bess," or "Chain Lightning," or "Kills 'em Quick," to him, not just "my rifle." He said, "Me an' Bess got a deer yisterday," and when "Bess" got ill, she was sadly out of order, and had to have the doctor right away.—*From "Shooting and Fishing."*

USES OF A PIECE OF STRING.

A piece of string is often of great value to a hunter or fisherman. Stout string, such as is used to tie up heavy bundles, is most valuable. Some sportsmen put a piece of string at a higher value than any other single part of the camp outfit, apart, of course, from the implements of sport.

If the fishing rod breaks, the string mends it again. If the suspenders break, the string ties the ends together. Should the gun stock break, the string is invaluable. If a pack basket strap fails, a string takes its place. A tear in a tent is sewed up with string. Game is hung up out of reach of animals with string. A lost man makes snares out of string and catches birds and rabbits enough to keep him from going hungry; likewise a stout string will serve as a fish line in the absence of regular tackle. If the chain is lost, the dog may be led with a string. A boat can be anchored with a rock and cord.

In the absence of a string a substitute is made by cutting a strip as long as needed from a deer hide off which the hair has been taken. The woodsmen prefer a rawhide string to all others, because it is much stronger, if properly cut, and the woodsman is very expert in cutting the string of even strength. Where the hide is thin he cuts a broad strip; where it is thick he cuts a narrow one. He prefers horsehide to buckskin, and a buck's skin is better than a doe's.

A raft is easily made with a string and three or six logs, according to the size, and many a skin boat is sewed with rawhide strings. With a piece of string in his pocket no man need starve, or lack for sport, though lost and forty miles from anybody. He can break off a hemlock branch, make a bow, use a slender sapling for an arrow, and shoot his game as the Indians did. If he has a jackknife, so much the better, but the string alone will do. Fire may be started in an unravelled string by striking sparks into it from two hard rocks. A very important use of a string is stopping the flow of blood from a wound. A strip of bark, with a round stone to press into the artery, and a string to tie tight over the bark, has often been the means of saving a woodsman from bleeding to death.—*From The New York Sun.*

HOW TREATIES ARE MADE.

"The treaty-making power is given to the President, in connection with the Senate, by the Constitution. The initiative—the negotiations with foreign Governments leading up to an agreement, and the framing of the articles of the treaty—is with the executive. The Senate has no part in the matter until the President communicates the treaty to it, and asks its concurrence. It may then, however, either concur or reject, or concur with amendments. * * When the Executive has agreed with any foreign power upon a treaty, and it has been duly signed by the plenipotentiaries for their respective Governments, it is sent to the Senate for its concurrence, and is considered there in secret session. Whatever may be said as to the wisdom or necessity of secret sessions for other purposes it is manifestly necessary that the terms of treaties, and the discussion of them, should in many cases be kept in the confidence of those charged with concluding them, until they are concluded.

"Though all the attempts in the Constitutional convention to give the House of Representatives a part in the making of treaties failed, it is still true that many important treaty stipulations depend for their execution upon the action of the House. If a treaty stipulates for the payment of money by the United States the money cannot be taken from the treasury without an appropriation. It may be said that as a treaty is a part of the 'supreme law of the land,' it is the duty of Congress to appropriate the money necessary to carry it into effect; and that in the making of the appropriation the House has no right to consider the question of the value or propriety of the treaty. But, all the same, if the appropriation is not made the treaty fails. * * Usually appropriations to carry out a treaty have been given freely by the House; but there is a power to withhold them, and so to defeat the treaty. As to treaties involving our revenue laws, the House—having by the Constitution the sole power to originate revenue bills—has claimed the right to act upon the wisdom or unwisdom of the treaty."—*Ex-President Harrison in his "This Country of Ours" article in May Ladies' Home Journal.*

REALITY IS THE GREAT EDUCATOR.

Dr. Parkhurst asserts that "there is a certain keenness and vigor of discipline that can come to a man only as he lives out in the midst of things and becomes himself a part of the world and of the events with which the world is so solidly packed. Those to whom my words are particularly addressed are young men who are anxious to make themselves felt in the world, and to such it needs to be said that we best learn how to do by doing. A sense of opportunity, a feeling of being a part, even a minute part, of the machinery by which the threads of current event are being woven in, works upon us with the power of a fine discipline and a strong inspiration. The solidity of the burden that is carried helps to solidify the man who carries it. Problems tumble easily apart in the field that refuse to give up their secret in the study or even in the closet. Reality is what educates us, and reality never comes so close to us with all its powers of discipline as when we encounter it in action. In books we find truth in black and white, but in the onrush of event we see truth at work; and it is only when truth is busy, and when we are ourselves personally mixed up in its activities, that we learn to know of how much we are capable, or win the power by which those capabilities can be made over into effect. Let no young man, then, of spirit and purpose be dismayed by his inability to attend either college or university. Life is itself the oldest and best endowed university in the world, and will guarantee to its pupils all in the way of vigor, keenness and grasp that they have in them the grace and persistency to acquire."—*Rev. Charles H. Parkhurst, D. D., on "Substitutes for a College Training" in Ladies' Home Journal.*

INTERESTING FACTS REGARDING DIVERS.

The dress of a fully equipped diver weighs 120½ lbs., and costs about £100. First of all comes 8½ lbs. of thick under-clothing; then follows the dress itself, weighing 14 lbs., boots, 32 lbs., monstrous things with leaden soles; breast and back weights, 80 lbs.; and lastly, the helmet, which weighs 35 lbs. When the hull of the Great Eastern was cleaned by divers as she was being loaded with the cable for the Indian submarine telegraph the contract price for the work was £1,800, and it was completed in six weeks by twelve divers. The incrustation on her bottom was more that a foot thick and after it was removed she lifted fully two inches. The greatest depth at which a driver may safely work is 150 feet. There have been however rare instances of diving to 204 feet, and sustaining a pressure of 88½ lbs. on every square inch on the body of the diver. Diving was first incepted by the action of the elephant in crossing a deep river, when he swims beneath the water elevating his trunk by which method he breathes. The work of a diver consists in recovering lost articles, and slinging them in such a manner that they can be easily hauled up, cleaning and coppering ships' bottoms, cleaning propellers, and communicating by slate and voice. When able to work at a depth of 120 feet a diver is considered fully qualified. The flag ships in the British navy carry eight divers, and the cruisers four each, fully equipped.—*From the Strand Magazine.*

HISTORY IN A TREE.

In the British Museum of Natural History there is a section of the trunk of a large fir-tree from British Columbia, the growth rings of which indicate that it was more than 500 years old when it was cut down in 1885. The fact that about twenty of the annual rings of growth, marking the latter part of the first hundred years of the tree's existence, are crowded together in a remarkable manner, indicates that during these twenty years some cause was in operation greatly retarding the growth of the tree. On looking into history the correspondent found that, nearly at the time when the tree in question was evidently suffering from very adverse conditions, Asia and Europe were undergoing extraordinary disturbances from earthquakes, atmospheric convulsions, the failure of crops, pestilential diseases, etc. China, in particular, suffered even more than Europe. He therefore suggests that possibly the crowded rings in the trunk of the tree may be a record of the existence of the same unusual conditions affecting animal and vegetable life at that time in North America also; and he shows that if the tree had reached its full growth, and ceased to form new rings a few years before it was felled in 1885, the correspondence in time would be complete.—*From Nature.*

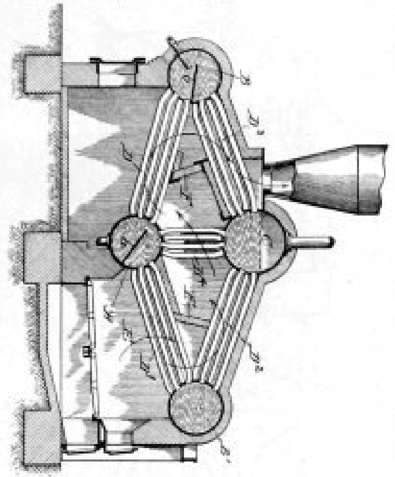
THE COLOR OF WATER.

The fact is generally known that pure water appears blue when light is transmitted through a sufficient thickness of it, and that when opaque particles are suspended in it the hue of the water is greenish. But while pure water looks blue when light passes freely through it, yet when it is contained in a deep, opaque receptacle, like the basin of a lake or the ocean, it ought to absorb all light and look black. Experience shows, however, that the deepest parts of the Mediterranean, for instance, appear not black, but intensely blue. This has been supposed to be caused by minute particles held in suspension, but the recent experiments of Professor Spring at Liege suggest a different explanation. He has found that warmer currents passing through pure water interrupt its transparency, even when the difference of temperature is very slight. Such currents may cause deep water to appear blue by reflecting light back from its depths through the transparent layers above. This, it is suggested, explains the fact that fresh water lakes are more transparent in winter than in summer, because in winter currents of heated water are not traversing them. Even the shadow of a mountain falling on a lake may increase the transparency of the water by cooling the surface.—*From The Youth's Companion.*

NEW INVENTIONS.

STEAM BOILER.

No. 556,697. JOHN E. SCHLIEPER, PITTSBURG, PA. *Patented March 17th, 1896.* This boiler consists of four transverse drums, connected by five sets of water tubes. The feed water is delivered into the "feed drum" *B*, under the plate *b*, which deflects it into the tubes *D*. The circulation currents move from *B* to the mud drum *A*, thence through the tubes D^1 to the front drum B', then through the tubes D^2 to the steam

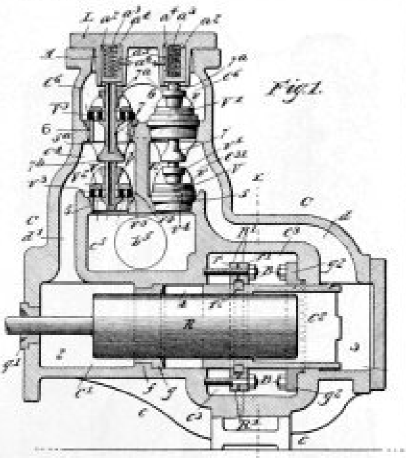


drum C. Here the steam and water separate, and the water continues down through the tubes D^3 to the feed drum. A part of the flow from the mud drum goes directly upward to the steam drum through the tubes D^4. The burning gases are compelled to travel crossways of all the tubes, by means of partitions *F* of fire brick. The course of the gases is shown by the arrows. A very effective application of the heat is thus secured.

PUMP.

No. 557,285. FRANK PEARN, MANCHESTER, ENGLAND. *Patented March 31st, 1896.* The view shown is a vertical section through one cylinder of a twin or duplex pump. The plunger *R* is double acting, being packed in the middle at 4. The gland is prolonged by a sleeve C^2, which projects into the back end 3 of the water cylinder, and is made water-tight by a gland g^2. The packing bolts *B* are accessible from the outside at all times. The main gland or sleeve may be removed at any time by pushing the plunger to the forward end of the stroke, and opening the joint between *c* and c^1, when either piece will come out sideways. The valves are

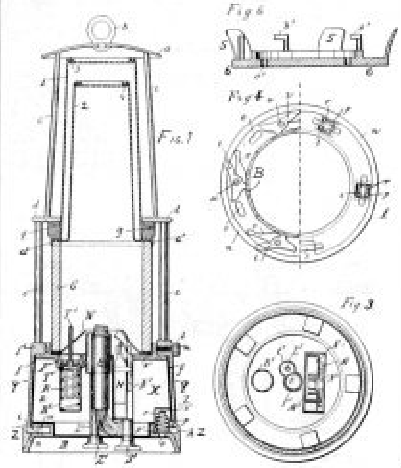
No. 557,285.



so arranged that all of them may be removed by taking off one cover *L*. There is no joint through which water can leak from the delivery side to the suction. The suction valves 5 will pass upward through the seat holes of the delivery valves 6, and collars on the lower end of the stems 7 serve as stops to limit the lift of the suction valves. The valve seats are fitted into taper holes and are pressed home water-tight by the water pressure.

SAFETY LAMP.

No. 557,548. KAREL BROUCEK, M. OSTRAVA, AUSTRIA. *Patented April 7th, 1896.* Fig. 1 is a vertical section of the lamp; Fig. 3 is a cross section on the line *Y Y* of Fig. 1; Fig. 4 is a section on the line *Z Z* of the same; and Fig. 6 is a section across the unlocking tool. This lamp is constructed to burn benzine, but can be easily adapted to burn kerosene if desired. The wick may be round, flat or tubular. The upper part of the lamp is provided with two gauze cylinders *1* and *2*. These are flanged outwardly at *a'*, and are held tightly against the end of the glass cylinder by means of a coiled spring *g*, which is held in place by the middle ring *d*. The lower end of the glass cylinder rests upon the flange of the cone *W*, which surrounds the burner. The wick is secured to a short sliding tube *t* which can be moved up or down by the screw *Z'*. The wick is ignited by means of an exploder *N*, which is loaded with a coil of detonating material. The igniter is operated by pulling down the knob *S'*. The lamp front *X* is removable from the lamp base *f*, and is secured in place by a lock



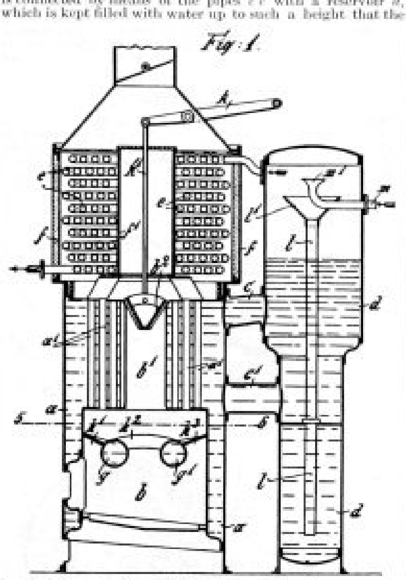
ring *R*. This ring is provided with a number of spring latches *i*, which catch into notches in the lamp base. The lamp front cannot be removed except with the aid of the tool shown in Fig. 6. This consists of a ring having several lugs 5, by which it may be turned, and also a number of pins *U*, which are adapted to enter the holes *o*, in the lock ring *R*. By turning the ring 6, the pins operate to open all the latches *i* simultaneously, and thus unfastens the ring and releases the lamp front. *T* is a filling tube, provided with a spring-closed valve, by means of which the fount may be filled, when detached, without permitting the vapor of the benzine to escape into the air.

SUPERHEATING STEAM BOILER.

No. 558,210. WILHELM SCHMIDT AND GUSTAV HENKEL, WILHELMSHOHE, GERMANY. *Patented April 14th, 1896.* This boiler is designed for the rapid and economical production of highly superheated steam.

Referring to Fig. 1, *a* is the boiler, and *a'* the heating-tubes of the same. Said tubes are arranged around a large central flue *b'* extending upward from the furnace *b*. Said flue may partly or wholly be closed by a lid or cover b^2. The boiler *a* is connected by means of the pipes *c c'* with a reservoir *d*, which is kept filled with water up to such a height that the

Fig. 1.

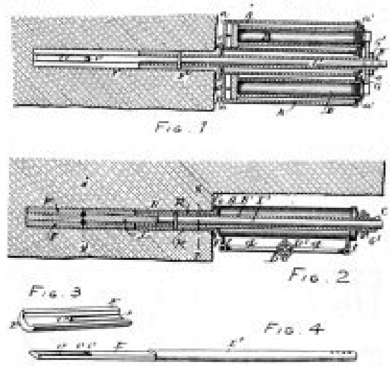


level of the water is constantly higher than the upper ends of the heating-tubes *a'*. The latter are therefore constantly surrounded by water throughout their whole length, and are secured against burning.

The superheater *e* consists of a series of horizontal coils arranged above the boiler *a* and between an outer casing *f* and an inner casing *f'*. One end of said superheater is connected with the dome of the reservoir *d*. The steam escaping from the latter and flowing through the coils of the superheater *e* is superheated by the furnace-gases passing either through the heating-tubes *a'* only or through the flue *b'*. If the latter is closed by the lid or cover b^2, the fire-gases will be comparatively much exhausted by the large area of surface offered by the heating-tubes, and the degree of superheating will thus be less than if a smaller or greater portion of said gases is allowed to escape through the flue *b'*. There is thus afforded a means of regulating the degree of superheating of the steam.

MINING WEDGE.

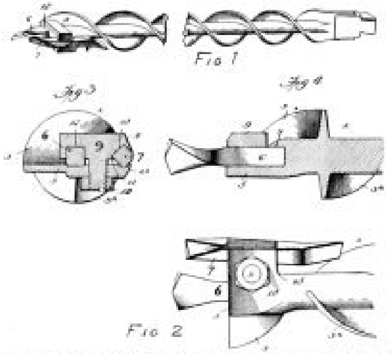
No. 557,143. WILLIAM A. MCKINLAY, DENVER, COLO. *Patented March 31st, 1896.* Fig. 1 is a top view, in section of the machine in place; Fig. 2 is a sectional side view of the same; Fig. 3 is a perspective view of one of the shells; and Fig. 4 shows the central wedge and rod. A section through the wedge *I*, and the shells *F*, is shown in Fig. 2. Small rollers are interposed between them, and when the rod *I'* is pulled outwards, they roll forward between the inclined surfaces of *I* and *F*, and spread the shells apart with great force. The



necessary power to operate the wedge is applied by means of two cylinders *A*, and pistons *B*, which are coupled to a cross-head *G*, to which the rod *I'* is also attached. The rear ends of the cylinders rest against tubular blocks or distance pieces *R*, which extend to the shells *F*. To use the machine it is inserted in the drill hole, with all the parts in the position shown in Fig. 2; water is then pumped into the cylinders *A*, forcing the pistons *B* outward, thus pulling the bar *I* forward and forcing the shells apart. The machine is very compact, and in practice it supports itself without any additional post or bar.

COAL AUGER.

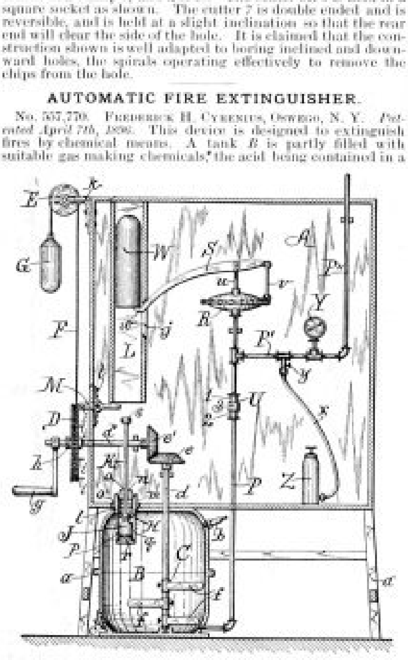
No. 558,204. JOHN T. SNYDER, LUZERNE, PENNA. *Patented April 28th, 1896.* Fig. 1 shows the auger complete; Fig. 2 is an enlarged view of the end of auger; Fig. 3 is a cross section through the bit clamps; and Fig. 4 is a section along the center line. The body of the auger is made with a double twist and a central core. The cutting end is provided with



two removable cutters, 6 and 7, which are held in place by means of a clamp 9, and nut 10. The center bit 6 is held in a square socket as shown. The cutter 7 is double ended and is reversible, and is held at a slight inclination so that the rear end will clear the side of the hole. It is claimed that the construction shown is well adapted to boring inclined and downward holes, the spirals operating effectively to remove the chips from the hole.

AUTOMATIC FIRE EXTINGUISHER.

No. 557,770. FREDERICK H. CYRENIUS, OSWEGO, N. Y. *Patented April 7th, 1896.* This device is designed to extinguish fires by chemical means. A tank *B* is partly filled with suitable gas making chemicals, the acid being contained in a

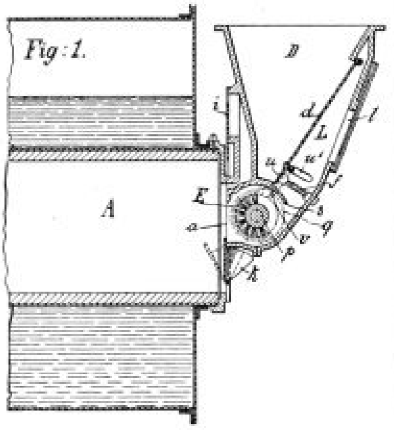


glass bottle *J*. The premises to be protected are provided with a series of pipes and "fusion valves" similar to the automatic sprinklers now in common use for fire protection.

The pipes are filled with compressed air. At *U* there is a washer of thin sheet lead which cuts off the compressed air from the tank *R*. When the temperature rises above 100° at any of the fusion valves, the valve opens and allows the air to escape. The diaphragm in the case *R* falls and lowers the lever *S*, thus liberating the weight *W*. When the weight falls it strikes the pin *K*, and smashes the acid bottle *J*, thus mingling the acid with the other chemicals, and starting the formation of gas. The weight also trips the latch *M* and frees the wheel *D*; the weight *G* runs down, and the cord *F* turns the wheel *D*, and the agitator *C* stirs up the materials in *B*. As soon as the gas pressure rises to the proper degree it bursts the lead washer in *U*, and the contents of *B*, both liquid and gaseous pass into the pipe system and are ejected from the valve which was unseated by the heat.

APPARATUS FOR BURNING COAL DUST.

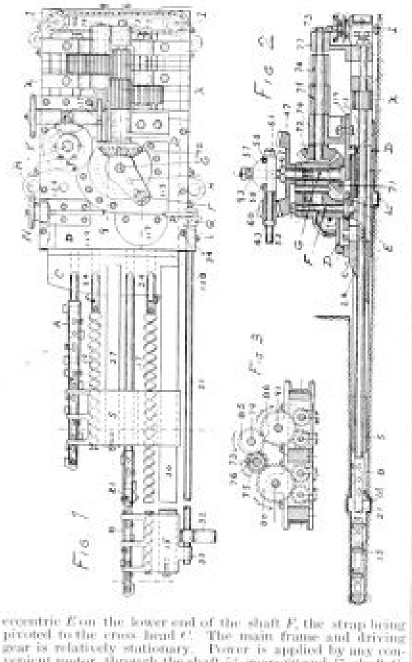
No. 558,875. George Hillinger, Berlin, Germany. *Patented April 21st, 1896.* The drawing shows the apparatus attached to the furnace *A*, of an internally fired boiler. The ground coal is fed into a hopper *D*. No particular pains need be taken to have the fuel very dry, because all lumps are broken up by means of a vibrating shutter *d*, which is opened



by a cam tooth on the shaft *p*, and closed with a shock by the spring *f*. The material which passes by the shutter falls to the under side of the revolving brush *E*, and is projected by it through the opening *a* into the furnace. No grates are used. The necessary air for combustion is admitted through the damper *h*. The brush is made of steel wires, which are so elastic that they throw the fine fuel a sufficient distance into the furnace to ensure its proper combustion.

MINING MACHINE.

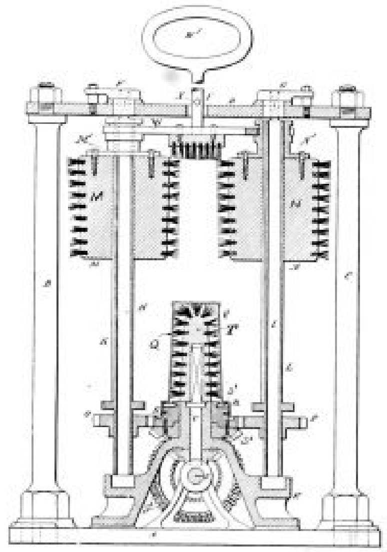
No. 557,340. Charles O. Palmer, Cleveland, Ohio. *Patented March 31st, 1896.* Fig. 1 is a top view of the machine; Fig. 2 is a longitudinal section of the same, and Fig. 3 is a cross-section on the line *x x*. This machine employs two revolving cutter bars *A* and *B*, which are forced sideways against the coal. They revolve in opposite directions, so that the tendency to deviate from a straight line in cutting is obviated. Spiral conveyors 17 and 19 are placed behind the cutter bars to remove the chips out of the kerf. The outer ends of the cutter bars are supported in bearings 3 and 15. The whole frame which supports the cutter bars and conveyors is vibrated in and out while at work, by means of an



eccentric *E* on the lower end of the shaft *F*, the strap being pivoted to the cross head *C*. The main frame and driving gear is relatively stationary. Power is applied by any convenient motor, through the shaft 53, gears 69 and 47, shaft 61, gears 71 and 72, and the train of spur gearing shown in Figs. 1 and 3. The machine is fed forward by means of a rope and the windlass *J*, which is operated by means of a ratchet wheel 135 and a worm *K*. The ratchet is turned slowly by means of a pawl, which is mounted on the reciprocating frame. The machine is guided by means of blocks which are fastened in the eyes *H*, and which engage the groove *L* in the floor. The cutter bar *B* is provided with an extra long tooth 27, which serves to cut a guide groove *M* similar to *L*, for the next cut. The point of the cutter bars may be forced up or down by means of the arm 52 on the rock shaft 51. The position of the arm is controlled by the hand wheel *N*, through the rod *P* and arm *Q*.

SAFETY LAMP CLEANER.

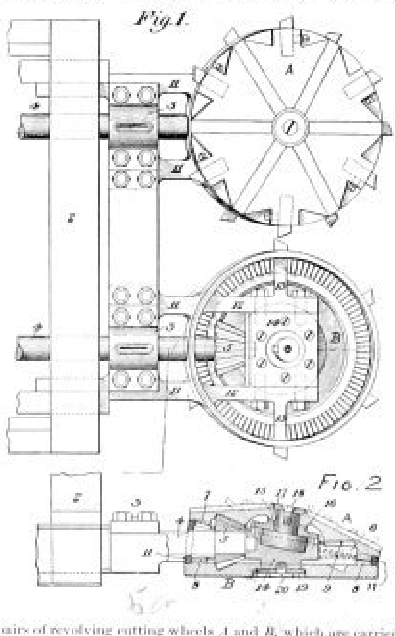
No. 559,171. Gottfried Grossman, Dortmund, Germany. *Patented April 28th, 1896.* The object of this invention is to clean the wire gauze cylinders of safety lamps thoroughly and quickly, without injuring or deforming them. The machine contains three rotary brushes *T*, *M* and *N*, all of which may be rotated simultaneously, by means of a crank on the end of the shaft *V*. The gauze cylinder *Q* is cleaned internally by the brush *T*, and is then secured to the hub of



the wheel *S*, by means of a clamp ring *S'* and a rubber washer *R*. The two brushes *M* and *N* are then moved downward by means of the yoke plate *W* and handles *W'*. Motion is communicated from the central wheel *S* to the shafts *H* and *I*, by the pinions *P* and *O*. As the gauze is turned by the wheel *S*, the brushes *M* and *N* operate on all parts of its circumference. The shafts *H* and *I* can be adjusted to compensate for the wear of the brushes, and to suit the shape of the gauze cylinder.

MINING MACHINE.

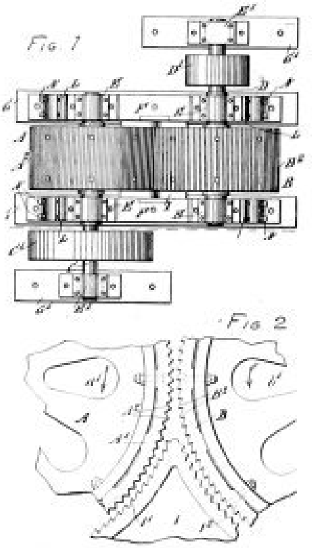
No. 557,745. C. E. Wolfendale and G. W. Fritz, Pittsburg, Pa. *Patented April 7th, 1896.* This is an improvement on the machine shown in Patent No. 536,912, which was described in The Colliery Engineer and Metal Miner of June, 1895. Fig. 1 is a top view, one of the top cutter wheels being removed, and Fig. 2 is a vertical section through a pair of cutter wheels. The under cutting is done by means of two



pairs of revolving cutting wheels *A* and *B*, which are carried on the front end of the machine, and are forced against the coal by suitable feeding apparatus. Each pair of wheels are geared together by means of teeth 7 and 8, and the upper wheel is driven by the shaft 4, pinion 5 and gear teeth 9. The gearing is protected from the entrance of dirt by the shield 17 which encloses them. The cutters, which are inserted in the edge of the wheels, cut a kerf extending across the entire front of the machine, and provide ample clearance for the sliding frame and driving mechanism. Both pairs of wheels deliver their chips well to the rear.

COAL GRINDER.

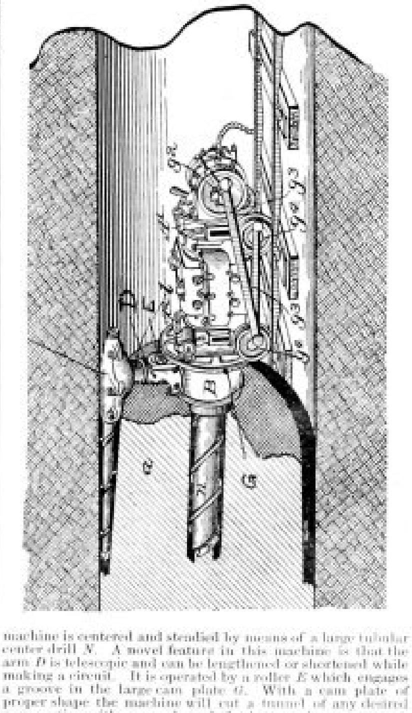
No. 559,272. Samuel Evans and F. J. Morgan, Elkhorn, W. Va. *Patented April 28th, 1896.* This machine is designed to disintegrate bituminous coal and prepare it for coking. Fig. 1 is a top view of a pair of grinding rolls; and Fig. 2 is a sectional view of a part of the grinding surfaces. The rolls *A* and *B* turn at different speeds, *A* being the slow roll. The grinding surfaces on both rolls are grooved, the grooves being



inclined at a small angle to the axis. The grooves on *A* are V shaped, while those on *B* are ratchet shaped. The coal which passes between the rolls is further ground against the stationary block *I*, which also is provided on its working faces with grooves of a similar kind. The grinding surfaces are made in segments, which are attached to the roll bodies by bolts, so as to be easily removed when worn or broken.

TUNNELING MACHINE.

No. 556,985. Frederick Hurd, London, England. *Patented March 24th, 1896.* The drawing shows the machine at work cutting a tunnel. The working parts of the machine are similar to those described in patent No. 556,986 shown in The Colliery Engineer and Metal Miner for June, 1896. In this machine the cutter bar is mounted at the outer end of an arm *D*, which, together with the head *E*, can be swung in a complete circle, thus cutting around a core piece *A*. The



machine is centered and steadied by means of a large tubular center drill *N*. A novel feature in this machine is that the arm *D* is telescopic and can be lengthened or shortened while making a circuit. It is operated by a roller *E* which engages a groove in the large cam plate *G*. With a cam plate of proper shape the machine will cut a tunnel of any desired cross-section, either round, oval, flat-bottomed or square. A machine of the same general construction is made for boring vertical shafts, etc.
